Examine such interfaces and the documentation associated with them for testable assertions. For example, the statement "A user should be able to change his own password" is an assertion that might be found in design documentation; a test can be built around this assertion.

Distinguish between Different Types of Tests. Security test procedures will be needed for several types of tests:

- Prototype testing to validate the security capability
- Component testing to validate package, reuse, and custom security component tests
- Integration testing to validate security functionality in integration testing and product testing
- Volume testing to ensure that the system will process data across physical and logical boundaries
- Stress testing to ensure effective transaction processing immediately after system downtime, after network downtime, or during peak periods (denial-of-service conditions)
- Data recovery testing to investigate both data recovery capabilities and system restart capabilities for fail-over and redundancy
- Database security testing to ensure that access is not provided outside the system environment

Step 3.5: Security Design Deliverable

The security design deliverable should be a subset of the overall system design deliverable produced in the SDLC process. The format and subheadings of the security design deliverable should follow that of the overall system design deliverable.

Exhibit 103.5 provides a recommended listing of security subheadings for this document.

Step 3.6: Security Test Plan

The security test plan should be a subset of the overall test plan deliverable produced in the SDLC process. The format and subheadings of the security test plan should follow that of the overall test plan deliverable, as summarized in Exhibit 103.6.

Stage 4: Build and Test

The high-level objectives of the Build and Test stage are to:

- Build secure environments to foster system development integrity and protect preexisting infrastructure
- Promote secure coding practices to ensure the security quality of the finished product
- Enforce formal code review procedures to inculcate checks and balances into the code-development process
- Thoroughly test all security components to validate the design; build a pilot capability
- Resolve issues within the certification process and pass the vulnerability assessment (discussed later).

Step 4.1: Build Secure Environments

Due to the laxness that typically exists in nonproduction environments, preexisting and future production environments should be appropriately demarcated from development, testing, and training segments. The project team should also configure (or arrange for the configuration with the network support team) network control points (such as firewalls, routers, etc.) to meet development, administrative, and operational objectives. Furthermore, the development environment should mirror the production environment as closely as possible for system build because the system will ultimately have to function properly in the more rigorously controlled production environment.

EXHIBIT 103.5 Recommended Subheadings for the Security Design Deliverable, and Their Suggested Content

Subheadings	Content
Introduction	Purpose
	Context
	Scope
	References
Security requirements to design mapping	List security requirements
	List matching security components to meet each requirement
High-level description	Describe each security component design at a high level
	Describe interaction among security components, system architecture, and network infrastructure
	Describe information flow
	Describe environments
	Include diagrams and flow charts
Detailed design	Describe each security component in detail
	Describe software, hardware, service specifications
Environment design	Describe details of development, testing, staging, and production environments
	Describe code maintenance process
	Describe secure code migration strategy
	Describe media protection and licensing protocols
	Describe change control and risk mitigation processes
	Describe physical security of development servers and workstations

EXHIBIT 103.6 Recommended Subheadings for the Security Test Plan Deliverable, and Their Suggested Content

Subheadings	Content
Introduction	Purpose
	Context
	Scope
	References
Security design to test mapping	List security design
	List matching testing components to validate each design
High-level description	Describe test approach or process and documentation procedures (should be similar to SDLC)
	Describe each testing stage: component, integration, product
	Characterize test environments
	Specify entry/exit criteria
	Describe dependencies
Detailed design	Develop list of assertions
	Specify test input requirements
	Describe test cases
	Define each testing phase; provide entry/exit criteria for each phase
	Describe test procedures; specify "testware" to use
	Describe regression test approach and criteria
	Describe code fix criteria
	Describe testing deliverables

A key activity in the SDSM's Build stage is server hardening. Hardening is the process of removing or disabling unneeded services, reconfiguring insecure default settings, and updating systems to secure patch levels. A common fallacy in the SDLC process is that systems are developed on unhardened servers and server hardening takes place in the production build-out phase. This predicament makes deploying applications on hardened servers a crapshoot, often resulting in system anomalies, finger-pointing, delayed timelines, and worst of all, a permissive hardening stance to accommodate the application. A better approach is to ensure that development is done on hardened servers and that documentation of necessary services, protocols, system settings, and OS dependencies is captured through the development process.

Finally, to ensure availability, the project team should build or make arrangements for appropriate backup and availability capabilities.

Step 4.2: Enforce Secure Coding Practices and Build Security Components

Software developers must be educated in secure coding practices to ensure that the end product has the required security functionality. This is a challenge in most organizations because, historically, security techniques have not been taught in programming classes. Where possible, the organization should arrange for formal secure coding training for its developers.

The following paragraphs describe some high-impact recommendations for improving information security within an organization's application(s).

Encryption and Random Number Generators. The developer should use well-established cryptographic algorithms as opposed to implementing proprietary or obscure cryptographic algorithms. An example of published encryption standards and mechanisms recognized by the cryptographic community are those listed in the Federal Information Processing Standards (FIPS) publication.

Another fallacy related to cryptographic functions is the use of pseudorandom number generators (PSNG). Developers should evaluate their PSNG against the criteria set by RSA:*

- Random enough to hide patterns and correlations (i.e., distribution of 1s and 0s will have no noticeable pattern)
- Have a large period (i.e., it will repeat itself only after a large number of bits)
- Generate on average as many 1s as 0s
- Not produce preferred strings such as "01010101"
- Is a simple algorithm with good performance
- Knowledge of some outputs will not help predict past or future outputs
- The internal state of the PRNG will be sufficiently large and unpredictable to avoid exhaustive searches

Input Validation and Exception Checking. Always validate (user and application) input. Most of the exploits seen in recent years were a direct result of poor or incorrect input validation and mishandled exceptions. Independent of the platform, applications have been regularly broken by using attacks such as buffer overflows, format string vulnerabilities, utilization of shell escape codes, etc. Never trust input when designing an application and always perform proper exception checking in the code.

Authentication. Authentication strength is paramount to the security of the application or system, because other security controls, such as authorization, encryption, and auditing, are predicated on the authenticity of the user's identity. However, authentication strength must always be weighed against usability. Enforcing a 10-character password will only lead users to write passwords on Post-It notes and stick them next to the terminal.

Do not hardcode credentials into applications and do not store them in clear-text. Hardcoded passwords are difficult to change and sometimes even result in a clearly visible password in compiled application executables. A simple "string application_name" command on a UNIX host can reveal a password that is not encrypted. A good practice is always to encrypt authentication credentials. This is especially important in a Web application that uses cookies to store session and authentication information.

Favor centralized authentication where possible. Centralized authentication repositories allow for a standardized authentication policy across the enterprise, consistency in authentication data, and a single point of administration.

Authorization. The authorization control is only as strong as its link to the identity it is authorizing (this link is the main target of impersonation attacks). In building out the authorization model, it is critical to form a strong link to the identity through the life cycle of the authenticated session. This is of particular importance in Web applications or multi-layered systems where the identity is often propagated to other contexts.

Logging and Auditing. Logging and auditing can provide evidence of illegal or unauthorized access to an application and its data. It can become legal material if law enforcement authorities get involved. For this reason, logging and auditing should be designed to offer configurable logging and auditing capabilities, which allow the capturing of detailed information if necessary.

Code Dependencies. Code development, especially object-oriented programming, often depends on the use of third-party libraries. Only acquire and use libraries from established vendors to minimize the risk of

*http://www.rsasecurity.com/solutions/developers/whitepapers/Article4-PRNG.pdf

unknown vulnerabilities. Also, validate return code or values from libraries where possible. Similar precautions should be taken when relying on external subsystems for processing and input.

Error Messages and Code Comments. Error messages should not divulge system information. Attackers usually gather information before they try to break into an application or a network. For this reason, information given out to a user always should be evaluated under the aspect of what a user needs to know. For example, an error message telling the user that a database table is not available already contains too much information. Exception handling should log such an error and provide the user with a standard message, saying that the database is not available.

In the same vein, do not include comments in public viewable code that could reveal valuable information about the inner workings of the system. This is strictly targeted at Web applications where code (and its associated comments) resides on the browser.

Online Coding Resources. The following Web pages provide detailed practical assistance for programmers:

- C/C++: http://www.cultdeadcow.com/cDc_files/cDc-351/; http://www.securityfocus.com/data/library/P49-14.txt
- Perl: http://www.perl.com/CPAN-local/doc/manual/html/pod/perlsec.html
- Java: http://java.sun.com/products/jaas; http://java.sun.com/security/seccodeguide.html; http://dwheeler.com/javasec/
- UNIX: http://dwheeler.com/secure-programs; http://www.sans.org/
- ASP: http://msdn.microsoft.com/library/default.asp?url = /library/en-us/iisref/html/psdk/asp/aspguide.asp

Step 4.3: Conduct Code Review

Code review from the SDSM perspective has the objectives of checking for good security coding practices as well as auditing for possible backdoors in the code. It is a well-known fact that insiders conduct the majority of security exploits. Code developers are no exception to that rule.

Step 4.4: Conduct Security Testing

Security testing provides assurance that security was implemented to meet the security requirements and to mitigate the risks identified in the security design plan. Security testing ascertains that the proposed components actually perform as expected and that security requirements are met throughout the integrated solution.

The key aim of security testing is to search for exposures that might result in unauthorized access to the underlying operating system, application resources, audit or authentication data, network resources, or that could lead to denial-of-service attacks. Security testing also aims to identify and address the risk of noncompliant components. The risk and proposed mitigation plans should be captured in the project's risk mitigation document (which was created in the Analyze stage).

There are as many different breakdowns for testing phases as there are SDLCs. In the interest of simplicity, the SDSM has three broad test phases: component testing, integration testing, and product testing, as described in the following paragraphs.

Perform Component Testing. Many components combine to form a security infrastructure. In general this includes firewalls, authentication servers, encryption products, certificate servers, access control mechanisms, and routers. Configuration management is often the weak link that creates new exposures. Perform testing for these components individually to test the functionality and to identify any weaknesses in the configuration. The component testing should cover security functionality, performance, failure-proof or fail-safe ability (in case the individual component is compromised), logging and monitoring capability, and manageability.

Security testing should include stress testing. Stress testing and worst-case-scenario testing will help in exposing how well the component behaves under overloaded conditions. These types of testing will also indicate the capability's exposure to denial-of-service attacks.

Perform Integration Testing. The next phase of the testing should focus on integration testing. This phase focuses on how well each component integrates with the other components in the architecture. The objective is to ensure that security requirements are met throughout the environment. Migrations to new environments and integration of custom and packaged components should be thoroughly tested.

Perform Product Testing. Product test execution will occur only after all package, custom, and reuse components have completed integration testing. The product test execution may not end until the entire product test model has been executed completely and without discrepancies.

All pieces of the security solution are to be installed and configured in a test environment to mimic a production environment as closely as possible. For the best results, product testing should occur in a

production-readiness (staging) environment. This environment should include all packaged software and all hardware chosen for production.

When a new capability is introduced into an existing networked environment, the new capability inherits all the risks associated with that environment. Therefore it is extremely important to test how well the capability meets its security requirements within the production environment.

General Tips on Security Testing. The following list provides some general tips on testing for security:

- Discourage the use of production data in the test environment
- Do not use production passwords in the test environment
- Use strong passwords (minimum seven characters, alphanumeric, with mixed case and special characters) in the development environment to emulate production
- Educate the testing team on specific security concerns, such as buffer overruns in C, TCP/IP vulnerabilities, operating system bugs, and ActiveX, Java, and CGI code problems
- Purge test data appropriately so that residual data is not available in the operating environment after it is used
- Disable test accounts when they are no longer necessary
- Document, evaluate, and address security risks of a noncompliant component at each testing phase

Step 4.5: The Prepilot Environment

The prepilot environment should have full system functionality and have gone through and passed all testing stages. This environment should be part of the SDLC process. The additional security requirement here is getting the environment through the security certification process. This involves coordinating with the certification team to conduct a vulnerability assessment on the prepilot environment.

Stage 5: Deploy

The high-level objectives of the Deploy stage are to migrate systems safely from development through to production; systematically cleanse obsolete environments of security-sensitive information; ensure and preserve the confidentiality, integrity, and availability of the production environment(s); implement secure deployment of systems, user information and credentials, post-configuration information, etc.; employ secure code enhancement, software updates, and bug-fixes procedures; secure deliverables produced during the SDLC; and complete the risk mitigation document and obtain certification sign-off.

Step 5.1: Secure System Migration

A secure system migration process contributes to the goal of keeping the production environment as pristine as possible. To ensure that security is maintained throughout the migration process, the project team should assign migration owners and appropriate approval processes to ensure accountability and control during migration. Furthermore, least privilege should be used when granting access to personnel involved in the migration process.

The migration should be conducted using secure protocols and mechanisms across environments. Once the system has been migrated, integrity verifiers (e.g., checksums, message digests) should be used to verify the system's integrity. The project team should also identify and enforce security maintenance as part of regularly scheduled maintenance windows to ensure the continued integrity of the new system in production. Security regression testing should be incorporated in the maintenance cycle to validate the integrity of the system after scheduled changes.

Step 5.2: Sanitize Obsolete Environments and Secure Production Environment(s)

The project team should implement a process to identify and sanitize development, test, and staging computing resources or environments that are no longer needed. Passwords (root, system, administrative, default, etc.) used in predeployment activities should be changed in all environments, especially production. The project team should also conduct a formalized transition of relevant credentials, system information, processes, documentation, licenses, etc., to the permanent operations or production team.

During the SDLC process, a number of deliverables were produced that contain sensitive information, such as architecture specifics and risk analyses. Such deliverables must be kept for auditing and historical purposes, but they must be controlled to avoid improper disclosure of the information they contain.

Finally, the project team should ensure that the new system has adequate physical security when placed in production.

Step 5.3: Secure Deployment

In the rush of making production deadlines, it is not uncommon for user password lists and other sensitive material to be mass distributed. These types of information could be used at a later time to gain unauthorized access into the system. The SDSM seeks to raise awareness of this issue. During deployment, the collection, setup, and distribution of credentials (passwords, tokens, etc.), and post-configuration information (gateway, required ports, environment variables, etc.) should be appropriately controlled, monitored, and accounted for. When granting access to personnel involved in deployment activities, and to permanent system users, least privilege should be used. All user access should be documented.

Step 5.4: User Awareness and Training

It is difficult to maintain the security of a system without properly educating the users of that system. It is important that the project team raise user awareness on how to create good passwords, protect credentials, and promote understanding of other security-specific features, such as timeout mechanisms, account lockout, etc.

The project team should identify user support activities and set up caller authentication procedures to verify the identities of users calling the help desk for assistance, and users should be made aware of help desk authentication practices to avoid social engineering attacks.

Step 5.5: Completed Risk Mitigation Document

The risk mitigation document is a living document that was created in the Analyze stage and updated throughout the SDLC process to track information security risk. The project team should confirm that all open risk items have been adequately mitigated or have appropriate exception approvals. The completed risk mitigation document should be signed-off as part of the certification issuance process.

Certification Framework

Throughout this chapter the concept of certification has been alluded to. A certification framework is critical to ensuring the sustenance and improvement of the organization's information security baseline. The objectives of certification are to:

- Ensure correct interpretation of security policies and standards
- Assess and manage risk throughout the capability development life cycle
- Formalize the confirmation of compliance to security policies and standards
- Formalize the acknowledgment and acceptance of information security risks
- Facilitate resolutions, suggest alternatives, and authorize waivers to achieve compliance
- Authorize and track waivers and postponements

It is highly recommended that the organization develop an internal certification process in conjunction with the internal audit and compliance group. An internal certification process can be implemented instead of or in preparation for a formal, external certification such as SAS 70 or ISO 17799, or for a government certification and accreditation. The following paragraphs describe the certification components that have been referenced throughout this chapter.

Initial Certification Review

The initial certification review takes place after the Requirements and Analyze stages and before the Design stage. The objectives of this review can be seen from two sides — the certification team and the project team. For the certification team, this review is an introduction to the project and allows the team to get acquainted with the project's key players as well as the overall capability that is being proposed. For the project team, the objectives of the review are to familiarize them with the certification process, raise exceptions issues, and glean security subject matter expertise from the certification team. The benefits of the initial certification review are early identification of noncompliant issues, facilitation of exceptions requests, and knowledge sharing.

In the initial certification review, the certification team will conduct requirements review and interview sessions with relevant individuals, collect and document the project's alignment with security policies and standards, and provide project teams with resources (e.g., templates, information from similar projects) to facilitate the certification process. The certification team will also review any exception requests that have already been documented, and facilitate the approval or denial of those requests. It should be noted that although the certification team is comprised of security professionals, the individual that certifies the system or approves an exception is a functional owner, who is in a position to accept the risk for the organization.

Prior to entering the initial certification review, the project team must have obtained and reviewed all pertinent information security policies and standards, business requirements, and external regulatory requirements, and produced a detailed security requirements document, a security project plan, an initial risk mitigation document, and any initial exception requests.

Upon completion of the initial certification review, the project team will be provided with approvals or denials of all initial exception requests, and they will have all the information necessary to create the risk analysis document for the Requirements and Analyze stages, which capture risk issues, policies, standards, and regulations that are violated, business impact, likelihood of risk, the discovery timeframe, and the cost to fix. The document also contains a listing of risks that are ranked, an outline of mitigations, and timeframes for compliance.

Certification Checkpoint

The certification checkpoint takes place after the Design stage and before the Build and Test stage. The purpose of this checkpoint is to keep the channels of communication and feedback open between the certification team and the project during the Design stage.

At this time the certification team validates the project team's security design against stated security requirements. The certification team also reviews the security designs to identify noncompliant issues and potential security implications with the enterprisewide security posture. Handling exceptions should also be a common activity during the certification checkpoint. Finally, the certification team should also provide cross-enterprise resources to the project team. For example, the certification team would know of previously certified projects that have a secure file transfer design similar to the needs of the current project.

Prior to entering the certification checkpoint, the project team must have a completed security design document. After the checkpoint, the project team will receive approvals and denials on any new exception requests, based upon which they will need to update the risk analysis document.

Vulnerability Assessment

The goal of the certification team during the vulnerability assessment is to test and identify noncompliant areas prior to deployment. In so doing, the certification team should exercise best effort to minimize disruption to project productivity. As a result of the vulnerability assessment, the certification team will provide empirical data to the project team, so they can update the risk mitigation document. The certification team also facilitates discussions with project teams to establish detailed activities for certification issuance at this point.

The certification team's activities during a vulnerability assessment are to:

- Understand and analyze the environment by conducting interview sessions with relevant parties
- Obtain and review environment documentation
- Assess threat factors and identify application, system, infrastructure, and process vulner-abilities
- Perform a vulnerability assessment with automated scanning tools and selected manual exploits
- Present security analysis findings to the project team
- Discuss security implications and project mitigation activities
- Establish and gain consensus for the completion of the risk mitigation document
- Establish a timeline and checkpoints for certification issuance

Prior to entering the vulnerability assessment, the project team must have an updated risk mitigation document, as well as completed build and test deliverables.

Once the vulnerability assessment has been completed, the certification team provides the project team with a security assessment report, which contains the findings from the assessment. At this time, the project team can update the risk analysis document for the Build and Test stage, as well as the risk mitigation document.

Certification Issuance

The purpose of certification issuance is to formalize the confirmation of compliance to security policies and standards, as well as the acknowledgment and acceptance of information security risks.

Prior to certification issuance, the certification team must validate the completion of the risk mitigation document; ensure that all design, build, and test deliverables have been finalized; and that all exceptions have been approved or that risks for denied exceptions have been mitigated. At this time, the certification team makes a recommendation to the certification issuer about whether or not the system should be certified.

Upon completion of this phase, the project team has completed risk mitigation and risk analysis documents, and a certification issuance decision.

Summary

To those unfamiliar with the SDLC and SDSM processes, the information presented in this chapter may seem daunting and unrealistic. Implementing such a methodology is in fact mostly a cultural issue, because it requires that project and development teams be more disciplined. It can also extend the project timeline a bit longer than management would like. However, the additional time and due diligence exercised prior to implementation has proven time and again to pay dividends in the long run, by producing systems that are robust, secure, and that do not require costly redesign. Those organizations that have undergone the growing pains have found that it was well worth the effort.

For the implementation of an SDSM or the larger SDLC to be successful, full management support and attention are needed. Also, a complete methodology must be developed by each organization with much more detail than was provided here, in terms that are specific to the needs of the individual organization. Furthermore, such a methodology must be maintained over time to ensure relevance. The technology focus at the writing of this chapter includes things like application servers and CGI scripts, but by the time this text is published, the hot technology will be Web services. Although the base methodology of Requirements–Analyze–Design–Build and Test–Deploy and certification will stand the test of time, the technical details will change frequently, and project teams and developers must keep up.

104

A Security-Oriented Extension of the Object Model for the Development of an Information System

Sureerut Inmor, Vatcharaporn Esichaikul, and Dencho N. Batanov

The meaning of computer system security varies, depending on the assets that the security mechanism is designed to protect. The main objective of all security mechanisms is that a system's assets perform their tasks according to authorized user expectations, while maintaining the confidentiality, integrity, and availability of information (CIA). The security aspects can be categorized, based on related assets, into four types: hardware security, software security, network security, and information system security.

Hardware security relates to the security of computer-related equipment, and requires physical access control mechanisms. Software security relates to the security of application programs, the database management system, and the operating system. The security mechanism might require both physical access control and access control via an authentication process. Network security is required when the computer system performs its tasks through some network connection. The security mechanism should emphasize data communication, such as transmission protocol security and data encryption. The information system security relates to how to analyze and design the organizational information system in such a way that this valuable data is protected against improper disclosure or modification.

From a security perspective, system analysts and developers should be most concerned with information system security. By contrast, providing security for hardware, software, and a network requires specific technical knowledge, and several vendors offer efficient security mechanisms and tools. These mechanisms are called infrastructure security and are already available through middleware products such as WebSphere and WebLogic. WebSphere is infrastructure software for dynamic E-business, developed by IBM business partners.[1] WebLogic Server is application infrastructure software, which was developed by BEA Systems, Inc. The security framework in BEA's WebLogic Server 7.0 has enabled the developer to unify security infrastructure to secure interactions among objects in an application system.[2] The analysts and developers cannot do much about these security infrastructures because commercial software is tested prior to acquisition and accepted as is. For their part, system analysts and developers should concentrate on what directly affects their tasks — that is, information system security.

Because information system security is the most manageable security requirement and the most important for system analysts, this chapter deals with how to analyze and design a security-oriented information system. Use of the information system will vary, depending on the type of organization and the kind of information or valuable data that each organization maintains. Information system security requirements are unique to

each organization, varying with business needs and types, as well as kinds of users — who may differ in terms of trustworthiness.

It is no longer sufficient to provide information system security in the traditional way, that is, providing an access control mechanism at the user interface level after developing and implementing the application system. Now there are mechanisms that concentrate on the object, mainly supporting the control of all direct access to objects. Several studies show how to provide suitable security to the system in this manner.[3-5] None of them, however, concentrates on how to design an object model to support the security requirements.

The need for information security is common to all organizations. In addition, the National Academy of Sciences (United States) has noted that poor analysis and design methods of developing information systems are major factors causing security problems in computer-based information systems.[6] Therefore, we propose an Object-Oriented Security Model (OOSM) with a "security-oriented extension of the object model" that can be used and implemented in the system analysis and design phase of system development. To design an object model that satisfies most of the security requirements is very important because it is the foundation of the overall security of an information system. There should be a useful guideline for the system developer on how each method (part of the object model) can be designed, in order to fulfill the system's need for security. Integrating security into an information system should start as early as possible. Our security model suggests integrating minimum-security requirements when each method is created. That is, developers should carefully control each method that is designed in order to provide an application system with satisfactory security requirements.

Most often, however, security requirements are left to the security administrator. As a result, access control mechanisms are put into the system after system development is done, in order to control how the end user gains access to the system's user interface. The system designer has little or no guidance in designing the system to keep the participating objects secure.

Security-Oriented Analysis of the Domain's Object Model Elements

In an object-oriented information system, the typical object model has three parts: the object name, the attributes and structural properties, and the operation that is required to access and maintain the object attributes, as shown in Exhibit 104.1.

All the operations in an object class comprise the object interface because they are the only way that other objects can "collaborate" with this object. There are three forms of object interface, according to Fayad et al.:[7]

1. The *attribute interface* provides access to the attributes of an object. The attribute interface can be used in three different categories:
   a. To return the value of an attribute
   b. To initiate the value of an attribute
   c. To notify other related attributes when the value of one attribute changes
2. The *action interface* provides access to other objects. The action consists of a task, such as displaying an object's attributes or adding one object to another set of objects. These actions can be implemented as a *public member* function;
3. The *event interface* provides notification to other objects when one object changes its state.

EXHIBIT 104.1 A Typical Object Model

Object name (class)	
Structural properties (attributes)	
• XXXXXXX	• XXXXXXX
• XXXXXXX	• XXXXXXX
Operation required to access and maintain object	
• V1:XXXXXXX	• V2:XXXXXXX
• V3:XXXXXXX	• Vn:XXXXXXX

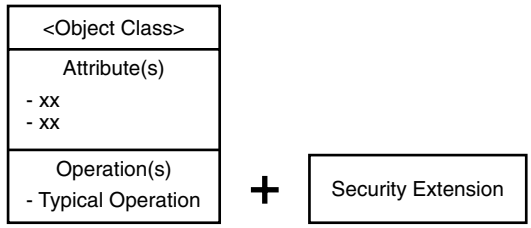

EXHIBIT 104.2 An object model with security extension.

The typical object model in Exhibit 104.1 is the starting point of an object model designed with security considerations. For each operation in an object model, we suggest that the analyst or developer consider security requirements of an application system and finally integrate them with the typical function. The information on security requirements comes from the security specifications through the software prototype technique.

From the security specifications, which were captured by the software prototype, the analyst or developer will understand the object relationship of an application system and also realize which operations have significant meaning from a security aspect. Those operations require a carefully designed object, which results in security extension to each typical operation, as shown in Exhibit 104.2.

The key difference between the traditional operation of the object model development and the proposed method is that our model adds an extra mechanism to each operation to ensure the security requirements. The model includes guidelines for designing each type of operation to satisfy the system's confidentiality, integrity, and availability needs.

The model extension, which performs on system domain objects, aims at helping the designer solve difficult information system design problems while satisfying security requirements. If each operation category is designed with security in mind from the beginning, the overall information system security should be significantly improved.

In each object model, operations are classified according to their purpose when interacting with an object instance. In general, there are four operation types:

1. *Query operation.* This type of operation displays the attribute value of the destination object instance.
2. *Update operation.* This operation makes some modifications to the attribute value of the selected instance.
3. *Terminate operation.* This operation terminates the object instance from any object class. After termination, the object is no longer an instance of any object type.
4. *Create operation.* This operation adds a new object instance into an existing object class.

Each operation category maintains extra information, listing conditions for invoking the operation to satisfy security requirements. Each operation also has an extra function: to perform secure operation invocation handling. The result of operation invocation depends on whether or not access control is currently accepted according to security requirements. Any possible operation invocation that will make the system vulnerable will not be allowed. The security function may be applied to any operation that is considered important for security, by specifying the pre- and post-conditions for every protected operation, as shown in Exhibit 104.3:

- A *pre-condition* is a set of security functions invoked prior to the invocation of the specified operation.
- A *post-condition* is a set of security functions performed after the operation finishes executing its task.

The pre- and post-conditions to normal operation will expend some execution time overhead, but this is the trade-off for security. It is the designer who decides how and in which operation security is applied.

We propose a classification of security functions for use with our model extensions. These security functions, which are in addition to the typical operation, can be categorized as follows:

- *Set membership test*. In some application systems, there exists a specific rule if the new object instance is to be added to an existing object class. This security function will check the condition to ascertain that the new object instance can be added properly.

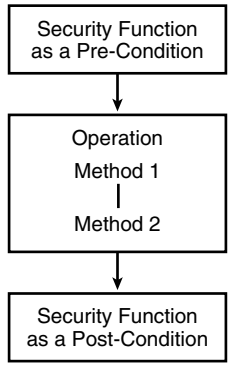

EXHIBIT 104.3 Normal operation integrated with security functions.

- *Terminate membership test*. The condition to remove an object instance from an existing object class must be checked. This function must guarantee that the object instance's termination will not cause any problem to other related domain objects.
- *Relationship cardinality test*. If the relationship cardinality between objects in a system is significant for security, one of the object attributes should maintain the value of cardinality. This kind of attribute can be used for checking the relationship cardinality.
- *State change permission test*. The state of the object depends on the different states that object of that class may have, as well as the event that will make it change its state. This security function can be implemented by defining conditions for restricting the possible state change in both pre- and post-conditions.
- *Correctness of input data test*. This function can be implemented as the pre-condition to limit the scope of the input parameters. The tasks of this function include:
  - — Character checks
  - — Range checks
  - — Relationship checks
  - — Reasonableness checks
  - — Transaction limits
- *Correctness of output data test*. This function is implemented in the form of post-condition to limit the range of the output parameters. The suggested tasks are as follows:
  - — Character checks
  - — Range checks
  - — Relationship checks
  - — Reasonableness checks
  - — Transaction limits
- *Notification*. According to the dependency relationship among objects, when one object changes its state, all its dependents should be notified and updated, to maintain consistency between related objects. For example, if a librarian decides to remove an out-of-date magazine from the library, what the system should do is:
  - — Remove magazine title in Title Object
  - Notify dependent objects, which are Item Object, Magazine Title Object, and Reservation Object, to update their instances.
- The notification function is also mentioned in an observer pattern in Gamma et al.[8]
- *Control condition for synchronizing series of operations.* To perform a specific operation, it is sometimes necessary to control the concurrent execution of transactions. In applying this kind of condition, we classify a series of operations into pre- and post-functions:

— A pre-function lists all the functions that must be executed before the system can invoke this operation.
— A post-function lists all the functions that the system should invoke in the next operation, after executing this operation.

- *Organizational policy.* The policy of each organization in the application system should be explicitly stated. For example, a university library system should have a policy on how to accept membership, the period for borrowing items, and the condition for specifying items as damaged or lost, among others. The user role, which can perform important operations, is also an organizational policy that must be specified in the operational design.
- *Audit trail.* This function will perform the following tasks:
  — Record all necessary information for future investigation.
  — Record the date, time, and user who invoked the protected operation.
  — The information comes from the authentication process.
- *Permission test for operation invocation.* This function is to assign a group of users/operations that have the right to invoke a protected operation.

Embedding security functions into a normal operation requires applying the pre- and post-conditions to an existing operation. To illustrate our concept, we employ a well-known object-oriented system analysis and design example from a university library system discussed by Eriksson and Penker.[9]

The use of software prototypes in the software development community is widespread, the main purpose being to present the user with the first version of software. A use case diagram can capture user functional requirements at the early phase of system analysis. But to ascertain that the analyst understands the user requirement correctly, the software prototype could be an essential tool for this task. The use of a software prototype from the OOSM viewpoint is to capture the users' and applications' security requirements. The design of a software prototype for this purpose should be a multilevel menu with a necessary access control mechanism. The feedback from users will help the analyst better understand the security requirements of an application system. The suggestions on how to develop a software prototype with the OOSM are as follows:

- *Prototyping language.* The designer should use the same programming language in both prototyping and the final software product. As in the OOSM, Visual C++ has been used both in prototype and software development;
- *Prototyping tools.* The application generator is a faster way to produce a prototype. If the language used does not have this tool, simple program construction could be used instead.

The software prototype in the OOSM is intended for the sole purpose of capturing security requirements. A description on how to translate this prototype into an object model can be found in Krief.[10] In the OOSM, the prototype is created using Visual C++, which uses the application generator plus additional programming language as necessary. The multilevel menu interface is applied with the interface of this prototype. The resulting software prototype, after discussion with the user, will provide the analyst with the security requirements of an application system. The analyst then considers which operation has significance in the security perspective and continues working with a carefully designed prototype of that operation.

Methodology for Applying the OOSM to Information System Development

The objective of the OOSM is to provide guidelines and procedures for an application system designer to use as a part of the analysis model. As a result, when the design is derived from the model, security will be well integrated into the application system. Before the application of the OOSM is explained, it is necessary to define the term "security" in this model. The model aims to meet three aspects of security:

1. *Confidentiality.* Information is not revealed to an unauthorized object in the system. This can be implemented by restricting access, that is, determining a set of objects that are allowed to request the execution of operation v from object x. In this model, a set of objects refers to an operation group name. An operation group and an operation differ as follows:

a. An operation group refers to the name of the task that the user needs to perform, such as borrowing a book or returning a rented tape.
b. An operation refers to each method in an object class that must be performed to accomplish one operation group or user task (e.g., checking for borrower identification, or retrieving information from the borrower record).

2. *Integrity.* The system's information maintains integrity with respect to overall information. Integrity is the ability of software systems to protect their various components (programs, data, and documents) against unauthorized access and modification.
3. *Availability.* The system provides necessary information to other objects on request, given the authorization to do so.

The OOSM is designed to be used side by side with the traditional Object-Oriented System Analysis and Design (OOSAD). The objective of OOSM is to be used with the information system development, which has a special need in security requirements. A use-case approach to system analysis and design as described in the UML standard is to be used as the main diagram to capture the system's functional requirements at the beginning. The additional diagrams are role diagram, operation structure diagram, sensitivity level diagram, and use-case diagram for security purpose.

Another tool in the analysis phase is the software prototype. The use-case diagram and the role diagram will be used together, mainly as resources to create the software prototype. An overview of OOSM with the traditional OOSAD is illustrated in Exhibit 104.4.

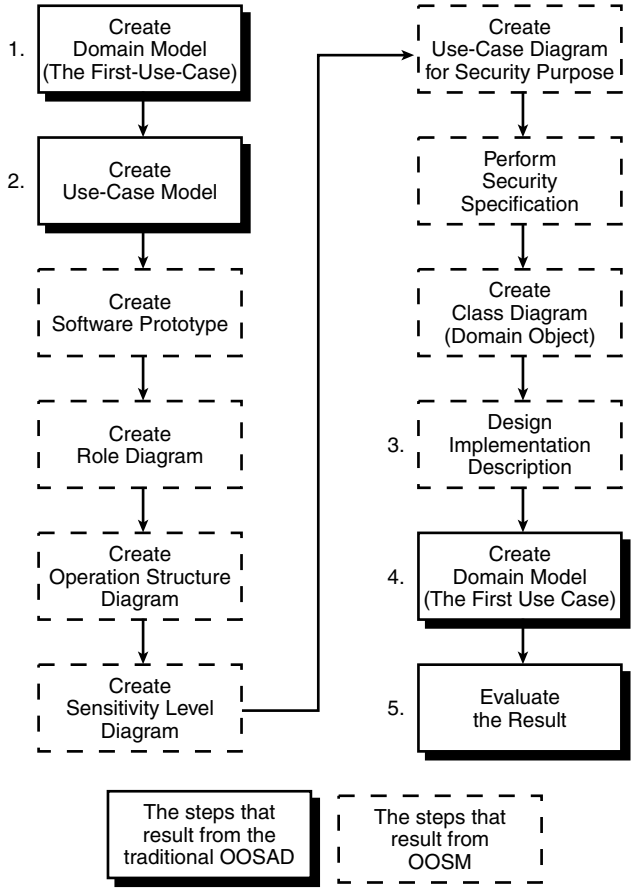

EXHIBIT 104.4 Overview of OOSM with the traditional OOSAD.

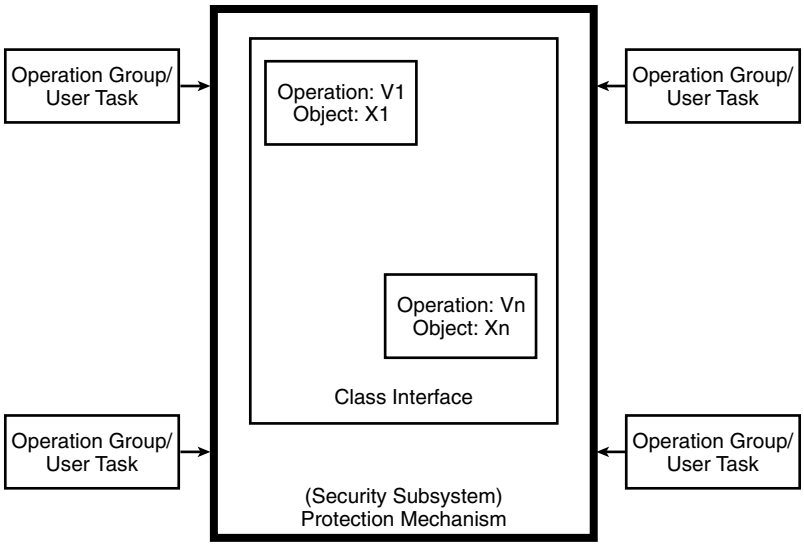

EXHIBIT 104.5 Protection mechanism for operation invocation using the model extension.

From the use-case diagram for security purposes, the analyst also provides new information for the security subsystem, which comprises all the operation groups or user tasks. Instead of directly invoking each operation group with the operation in the class interface, the model extension will provide a protection mechanism for operation invocation, as shown in Exhibit 104.5.

Every request for an operation must go through the process of access checking in the security subsystem. Therefore, the security subsystem must maintain all necessary information needed to accomplish the task of access checking. This model extension has a role in providing safeguards for the application system during the development process.

As shown in Exhibit 104.6, the system analyst or the system designer will use this model extension as a part of his or her design. After implementation, the model extension will be the part of the operation in which the application programmer or the client programmer will be directly involved.

Illustrative Example

We use a university library system as our sample application system. This example (taken from a CD-ROM[9]) is a typical object-oriented application system, and widely used to describe the object-oriented analysis and design process. The analyst meets with the domain experts and users of the application system to create a use-case diagram to capture the application's main functional requirements, as shown in Exhibit 104.7.

A use-case diagram is employed to capture the main functional requirements of the application system. It is the tool for communication between the user and the analyst or developer. In Exhibit 104.7, the library system use case is shown as two primary actors of the system, which are librarian and borrower. The librarian is referred to as the internal actor and the borrower as the external actor. These two actors will need to be classified in more specific categories at the next stage of the analysis process.

The use-case diagram in Exhibit 104.7 will be used as the main source to create the software prototype. The multilevel menu interaction for the library system is to be constructed as shown in the diagram in Exhibit 104.8.

This operation structure diagram is very similar to the menu for the most-privileged user of an application system. The way that groups of operation are separated here is a suggestion, and not recommended to be used as a standard. Each application can have its own security policy and requirements that would also affect the grouping of operations. Therefore, analysts and developers should carefully analyze the specific application they are working on.

After the creation of the use-case diagram in Exhibit 104.7, the analysts and developers will make a decision to create another use case based on system security requirements. This use case is the new diagram created

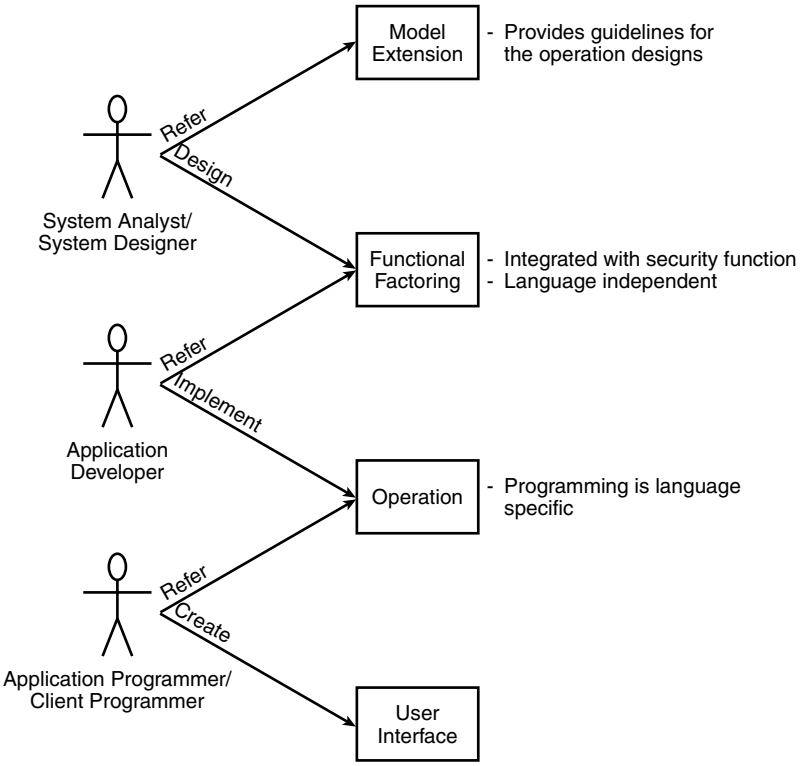

EXHIBIT 104.6 How the security model fits in the application system life cycle.

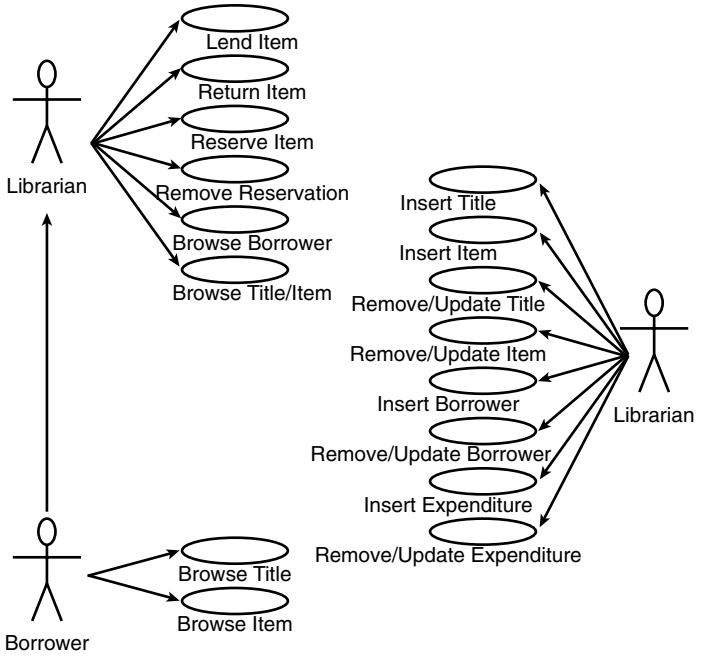

EXHIBIT 104.7 A use-case diagram for the library system, representing all operation group names.

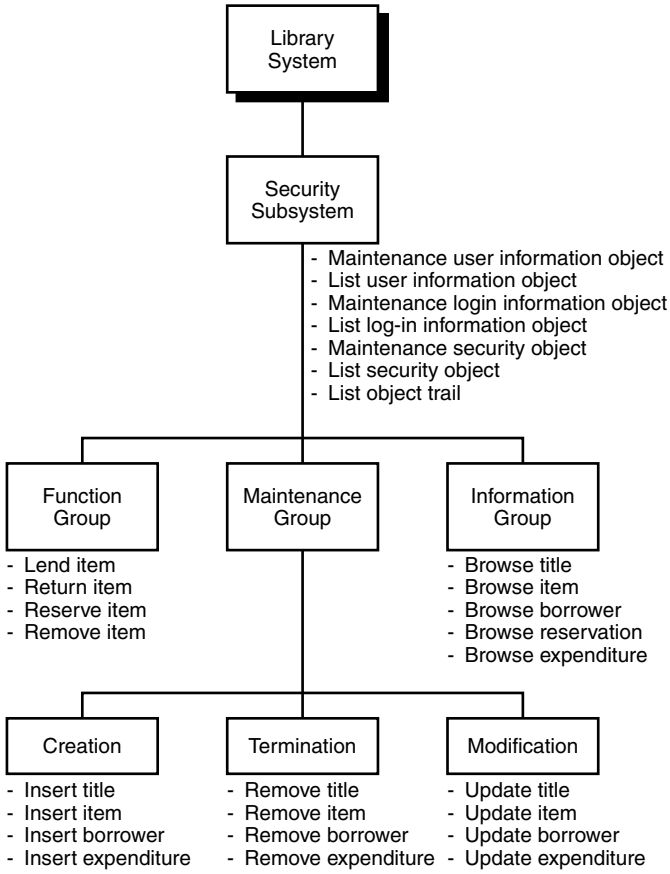

EXHIBIT 104.8 The multilevel menu for the software prototype.

with the main purpose of capturing the security function requirements. The relevant data come from several tools and diagrams:

- *Software prototype* is the starting point in the design of a security mechanism in an application system. The accurate security specification depends on the shared work between system user and analyst.
- *Role diagram* gives data concerning each user role that is significant in the security aspect.
- *Operation structure diagram* groups the operations by similarity in access privileges.
- *Sensitivity level diagram* presents data about each group of users' access privilege to the group of operations.

The use-case diagram for security purposes presents each role of the users and how each of them has a privilege to access the group of functions. With the help of this use- case, the analyst and developer will understand the role of each user more clearly toward security requirements and specifications. Exhibit 104.9 presents a use-case diagram for security purposes as mentioned above.

The separation of groups of functions in Exhibit 104.9 is only a suggestion. It is not meant to set an example for other applications. The diagram only shows the result of security specification through the software prototype. This diagram is created with the objective to help system analysts and developers clearly understand the role of each actor (user) in the operation group in an application system. The information from this diagram could give analysts and developers a basic understanding of how to design an information system that meets the security requirements.

Examples of how to integrate the security function with normal operations are shown in Exhibit 104.10 through Exhibit 104.13.

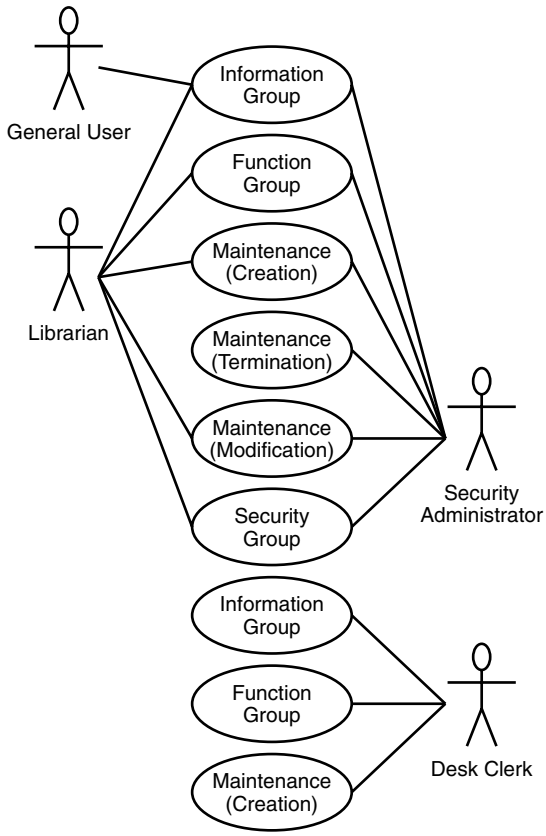

EXHIBIT 104.9 A use-case diagram for security purpose.

Query Operation

This displays the attribute value, for example, lists overdue books and borrowed books for a specific member (see Exhibit 104.10). The query operation will follow the encapsulation mechanism in an object-oriented paradigm. The suggestion is that all attributes of an object model should have access specifiers as "private" or can be accessed only by the function in the same class.

One of the security functions of the query operation that can be used as an extension of the model is "the permission test for operation invocation." This function is an important part if the analysis shows that this attribute is crucial for security purposes. Along with the permission test, another security function that can be implemented with it is the audit trail function. This function will record all necessary information for future reference.

Update Operation

This makes some modification to the attribute value, for example, changes the status of a member from a master to a doctoral student and changes the member's address (see Exhibit 104.11). This operation is also called an object state change.

The security requirement for an update operation is to ascertain that the object's attributes can be changed in a way that does not violate the relationship's rule among domain objects model. The general requirement is that the invocation of this function will be given only to an authorized user or operation group.

EXHIBIT 104.10 The Query Operation with Security Functions

Pre-Condition	
Type:	Permission test for operation invocation
Content:	Give permission only to an authorized user
Type:	Correctness of input data test
Content:	Test for query condition
Operation	
Type:	Query
Content:	List book's price
Post-Condition	
Type:	Correctness of output data test
Content:	Test for the result
Type:	Audit trail
Content:	Record all necessary information about transaction

EXHIBIT 104.11 The Update Operation with Security Functions

Pre-Condition	
Type:	Permission test for operation invocation
Content:	Give permission only to an authorized user
Type:	Correctness of input data test
Content:	Checking for the value of all attributes
Type:	State change permission test
Content:	The set of data values that the object can change its state to at a certain time
Operation	
Type:	Modify
Content:	Changing membership's status in Borrower Information object
Post-Condition	
Type:	Audit trail
Content:	Record all necessary information such as the authorized person who is permitted to invoke this operation
Type:	Notification
Content:	Notify the related objects, such as Loan, Reservation
Type:	State change permission test
Content:	Check for the object state and the output values after the method invocation

Terminate Operation

This operation terminates the object instance, for example, removes a damaged or lost book from circulation (see Exhibit 104.12). In an application system, while in an operation process, some events or transactions might result in the deletion of any object instances from the class. To do so, the terminate operation should have security functions as the pre- and post-conditions presented in Exhibit 104.12.

The terminator and destructor are not the same function. The destructor function cleans up the memory allocation for an object when the application system has finished its execution. The terminator's main objective is to terminate an object's instance from a specific object class according to some predefined rules. Because this is a very important function, and considering how this can relate to other objects in the same application system, the permission to use this function should be carefully checked.

EXHIBIT 104.12 The Terminate Function with Security Functions

Pre-Condition	
Type:	Permission test for operation invocation
Content:	Give permission only to an authorized user
Type:	Terminate membership test
Content:	Test that current state of book is not on Loan
Type:	Notification
Content:	Notify dependent object and update — Book Title — Item — Expenditure — Reservation
Operation	
Type:	Terminate
Content:	Remove damaged book
Post-Condition	
Type:	Audit trail
Content:	Record date/time of remove transaction, including reason

EXHIBIT 104.13 The Create Operation with Security Functions

Pre-Condition	
Type:	Correctness of input data test
Content:	Test for all attributes
Type:	Relationship cardinality test
Content:	Set relationship of book and title
Type:	Set membership test
Content:	Test for the population of object
Operation	
Type:	Create
Content:	Add new library book
Post-Condition	
Type:	Correctness of output data test
Content:	Test for all attributes

Create Operation

The create operation adds a new object instance, for example, buys a new book, receives a new dissertation, or receives a new CD-ROM (see Exhibit 104.13).

An application system with maximum-security requirements trades off usability against system performance. The security functions, such as an audit trail, provide higher security for each function but also consume much of the system execution time. Therefore, it is the system designer or security analyst who makes the final decision on whether to put minimal security requirements in the application system.

The update operation demonstrates how this model extension could be used, employing the Visual C++ syntax to illustrate the concept. Exhibit 104.14 shows a typical update operation without a security function.

In the university library system example, the group name of the user is very important from a security standpoint. The user interface menu differs, depending on the group to which each user belongs. Therefore, the function that changes this attribute's content should be carefully designed, using a security-oriented methodology. Exhibit 104.15 presents a way to design and implement the same update operation, using a security-oriented model extension.

Additional security functions that are added to the original update operation are `CheckGroupname()` and `CheckUserRight()`, and they are updated in the audit trail attribute. The audit trail attribute in this

EXHIBIT 104.14 A Typical Update Operation

```
void ChangeGroupnameNOSecurity(CString ChangeGroupname)
{
  m_Groupname = ChangeGroupname;
}
```

EXHIBIT 104.15 The Update Operation with Security Functions

```
ChangeGroupnameWSecurity(CString Groupname,
                         CString UserName,
                         CString UserGroup)
{
  CString Username, Message;
  CTime present_time = CTime::GetCurrentTime();
  CString newtime = present_time.Format("Data has been changed at
                    %H:%M:%S");
  CSecurityObj::CheckGroupname(Groupname);
  //Searching to compare "groupname" in
  //the security object which has list of
  //user group name that can access the system
  //This security function is called
  //"Correctness of input data test"
  CSecurityObj::CheckUserRight(UserGroup);
  //Checking for the right of user
  //who invokes this operation
  Message = "\n" + newtime;
  Message += "\nBy Username " + UserName+ " of " + " Group " +
             UserGroup;
  Message += "\nfrom " +m_Groupname+" to "+Groupname;
  m_Groupname = Groupname;
  m_BorrowerAudit = Message;
}
```

sample application is called `m_BorrowerAudit`. This attribute tracks all changes that are made to all of the attributes. Only the changes that have significant meaning from a security standpoint are recorded for future reference.

Exhibit 104.16 illustrates the output of these two update operations, showing how an extension object model can increase the security of each important function. The security of each function also contributes to the security of the overall system.

This example aims at keeping the program as simple as possible. By omitting unnecessary features such as a graphical user interface and persistent utilities, the program is easy to understand but still clearly illustrates the model extension. Implementation of the model extension may vary with the operation, and the security function details will differ somewhat.

Conclusions and Future Work

The objective of this article is to propose a security model, OOSM, that can be used as a model to analyze and design a security-oriented information system. The process starts with the design of a domain object model. As a result, each domain object will have the additional security functions as a model extension. These security functions will be implemented as the pre- and post-conditions to the typical function in an object model. The guidelines for how each type of security function can be used with the typical function are described in the article. The analyst or developer can utilize the model throughout the process of system analysis and design. The application system resulting from this model should satisfy most organizational security requirements.

The implementation process described in this article uses the Visual C++ programming language. No special language features were used, to keep the program as simple as possible, while providing enough detail to show

how to implement the model extension. The evaluation process of this model, however, could not be measured on an empirical basis. But when compared with different software process models such as the Spiral model and the Waterfall model, the OOSM has the benefit of giving the analyst or developer a better understanding of how to integrate the system's security requirements in the early phase of system development. The OOSM also solves the problem of retrofitting the security mechanism into an application system that is already developed.

The use of OOSM along with the traditional process model, OOSAD, could enhance the security of the overall application system. What we thought of as a problem at first, the success of the security mechanism depending on an individual analyst or developer, could not be solved entirely. The model provides some design guidelines and also additional tools and techniques to help solve the design problem. There are still some difficulties when mapping the design into the implementation process. The problems vary according to the experience of developer, the programming language used, the nature of the problem domain, and the specific security requirements.

Solving the design problem requires more than providing the design guidelines and tools. We planned to move the OOSM from guidelines to the Design Pattern. Gamma et al.[8] explained the meaning of the design pattern as "*descriptions of communicating objects and classes that are customized to solve a general design problem in a particular context.*" By creating the design pattern for security-oriented systems, the analyst or developer can get the pattern and implement it in a more efficient way. The design pattern also helps prevent the developer from inaccurate interpretation of any guidelines. The programming language source code should accompany each pattern in order to give the developer a better understanding of the pattern.

Methods of Auditing Applications

David C. Rice, CISSP and Graham Bucholz

Introduction: Ubiquitous Insecurity

The microprocessor — the computer — is the seventh simple machine. Like its predecessors, the wheel, the incline plane, and the lever, the microprocessor performs simple tasks, and therefore makes it easier to accomplish more. Moreover, as production costs and the size of the processors shrink, the silicon chip is becoming inexpensive and tiny enough to slip into every object we manufacture.

As the number of devices containing microprocessors increases, so too will the impact on daily life. Personal computers, the most popular and well known of devices containing a microprocessor, are only one example, but there are many, many others as well. Microprocessors are embedded in everything: cell phones, watches, microwave ovens, automobiles, stereos, and even rice cookers. These "noncomputer" chips already number in the billions. Devices are getting smarter and smaller, but there is more to the story: a single microprocessor can only do so much. Sure it may be fast, and the microprocessor may be smart, but the technological revolution occurs when microprocessors start talking to one another. In other words, the microprocessor by itself is an impressive invention, but interconnected microprocessors, well, that is momentous. Whether personal computer, BlackBerry, PalmPilot, AutoPC, or refrigerator, we are attempting to connect everything to everything else through copper, radio, infrared, and fiber.

Of course, distributed and decentralized computing is nothing new, but it is the scope and scale of microprocessor technology and communication protocols over the last three decades that has allowed decentralized computing to attain new heights. Microprocessors are talking on more devices than ever before, but more importantly these microprocessors are *listening* on more devices than ever before. This grand network of protoconsciousnesses is creating an environment of ubiquitous computing and pervasive connectivity that surrounds and infuses the everyday life of humanity. Underlying this marvelous development of universal computing, however, is something completely transparent to the everyday user: software.

"Connecting all to all" becomes possible only because software, or code, *makes* it possible. Paralleling the rapid expansion of microprocessors into virtually all areas of our business and private lives is the expansion — and dependency — on code. Wherever microprocessors can be found, so must software.

Most computer users probably have not heard of languages like C, C++, Java, and COBOL. If they have, they most likely shun the very mention of them, warily avoiding such cryptic lexicons. Yet these languages and many, many others shape the function — and ultimately the devices — that serve humanity.

If microprocessors are finding their way into our traffic lights, medical devices, airplanes, homes, business supply chains, enterprise management systems, transportation systems, and household appliances, then so too is software. Ubiquitous computing *means* ubiquitous software. Code therefore is quickly becoming the foundation of civilization.

As reliance on software grows, so do the consequences of software failure. If code is becoming the foundation of civilization, then civilization is only as durable as the code.

A majority of consumers would never settle — let alone pay for — homes, automobiles, or buildings constructed as poorly as many software applications are today. Software bugs seem to be an accepted part of the computing environment. However, if the software is buggy, what does that say about the software's security? Bugs are indicative of a greater problem, yet they are often eschewed as "the cost of doing business."

The heavier the reliance on software in our everyday existence, the higher the exposure to risk if that software should fail or be leveraged for malicious intent. Couple this risk to a highly networked, distributed environment — an environment that almost insists on pervasive communications — and the potential for havoc becomes highly feasible. If ubiquitous computing means ubiquitous software, then ubiquitous software means ubiquitous insecurity.

Perhaps the reader's first inclination is to state the effectiveness of firewalls, intrusion detection systems, and virus detectors against insecurity. Ironically, many of these security applications are no better designed or implemented than the applications they are attempting to protect. If the software on security systems is flawed, so is the security the device provides. However, too much faith in security systems or encryption masks the real problem. Firewalls and intrusion detection systems are really just a network response to a software-engineering problem, and for the most part, do not and cannot protect from ZeroDay[1] events. This is not to say security systems are entirely useless. Security systems can be a valuable addition to a network's defense, but do nothing to solve the problem of insecurity, only delay it.

Ubiquitous insecurity stems from our unwillingness and inability to unravel the software-engineering predicament at its root: code. The pronoun "our" in the previous sentence is left purposely nebulous because the software-engineering problem belongs to everyone — government, industry, consumer, and developer. As long as insecure code is developed and purchased, whether by private consumer, corporate entity, or government institution, ubiquitous insecurity will imperil the foundations of the civilization being built today. This is not to say that the future is unequivocally doomed; every civilization has faced a foreboding, dark shadow threatening its very survival, but few civilizations have willingly created and installed a nemesis within their fledgling critical infrastructure.

Although the seventh simple machine can be a great servant to humanity, it can also be an appalling master if not supervised appropriately. The inventor of the wheel could never imagine to what ends the wheel would be used, no more than the future utilization of the microprocessor can be foreseen at this moment in time. We must create software worthy of the title "foundation."

Scope of Discussion

This chapter is intended to inform technical managers and developers about the mistakes and bad coding practices that make ubiquitous insecurity a reality. What follows in this chapter is a description of vulnerability discovery methods or attack techniques used to audit and evaluate applications for insecurities. These same techniques can also be used to subvert applications for gain, curiosity, or otherwise. In no way do the authors encourage illegal behavior.

The methods discussed in this chapter apply mainly to binary applications, and do not address Web applications or Web services directly, though some techniques may be leveraged to do so. Web applications are avoided as a topic of discussion mainly because they are site-specific and techniques are not easily generalized.

Every section deserves to be its own book, but by necessity only a subset of relevant topics can be discussed within the limits of a single chapter. Therefore, exhaustive technical depth must give way to brevity in a majority of this discussion; the reader will not be able to put down this book and immediately begin subverting applications. However, the authors have made every attempt to keep this chapter meaningful and informative.

Setting the Stage

Meaningful vulnerability discovery requires a nontrivial skill set, one that requires an extraordinary amount of patience, time, resources, and exhaustive technical knowledge to acquire. The world of vulnerability discovery is not for the indolent or the faint of heart, nor is that world abundantly populated. To some extent, the difficulty in acquiring the necessary skills to discover unique and original vulnerabilities should comfort those who use the digital world on a daily basis. In laymen's terms, vulnerability discovery is not an amateur endeavor. However, these skills are not impossible to learn, and even a rank amateur can attain some modicum of success.

As code infiltrates and delineates our critical infrastructure, more individuals will be enticed to acquire these skills.

In this section, we summarize the required knowledge base for a software/application auditor to understand binary applications, the tools required, and the crucial mindset for executing successful vulnerability discovery. There always will be exceptions to this list, and also unfortunate omissions, but what follows is a good starting point.

Mindset: "There Is No Box"

> The world is seamless, with no boundaries or dividing walls…
>
> **— Ikkyu, Abbot, Buddhist Daitokuji Monastery, Kyoto, Japan**

The foundation for continued, successful vulnerability discovery is the right mindset. Although it seems most of corporate culture, political leadership, and mid-level managers spend time striving to "think-outside-the-box," great hackers[2] — truly great hackers — know *there is no box*.

This apparently esoteric point is absolutely necessary to understand why great hackers are so good at discovering vulnerabilities or subverting applications, networks, and just about anything else they get their hands on. It is also absolutely necessary to understand the concept of "no box" to comprehend why corporate leadership feels hoodwinked when their intranet gets compromised despite liberal firewall placement.

"No Box"

The "box" is simply the identification of "what is possible or acceptable," based on a given body of knowledge or assumptions. What is considered possible articulates the boundaries of the box. The paradox of "thinking outside the box" is the box immediately expands to include that which escapes it; that is, original thought is quickly burdened with the onus of formulization and imitation.

Boundaries, or boxes, are created by the human mind for the benefit of perception; the mind *must* classify, it must distinguish between good and bad strategies, between "this" and "that" for a matter of survival, but reality is by no means ruled by the mind's perceptions.

Great hackers comprehend the digital world, like the real world, as "seamless, with no boundaries or dividing walls." The digital world is not cordoned off by firewalls nor defined by applications. The digital world is not illuminated by intrusion detection systems nor bounded by user interfaces. The digital world is influenced by these abstractions, no doubt; but the digital world is not beholden to any authority save one — code. Code determines how bits, the 1s and 0s, are created, stored, and transformed into usable information humans can digest. Code is law in the digital world, but it is not absolute. In other words, boxes are a manifestation of code, but code transcends the nature of boxes. Unlike in the real world, where the gravitational constant in one part of the universe is the same as in another, code determines which rules are applied in the digital world and to what extent.[3] Changing the code changes the rules. In a sense, there are those individuals who are impressed with their ability to "think outside the box," and then there are those who create the boxes in the first place.

Often, in the authors' evaluation of software applications, the comments "that's not what the application was designed to do" or "you shouldn't be able to do that," have been heard regularly. From the client's perspective, this is certainly true, but only from that singular perspective. A developer looks at an application as a collection of well-behaved components. A user sees applications as a collection of desktops, windows, and icons. A network administrator sees the network as an amalgam of switches, routers, and proxies.

However, the digital world is by no means ruled by these perceptions. Great hackers see the digital world without the assumptions placed on it by developers, users, and marketing divisions; great hackers see through convenient distinctions as the illusory boxes they are. Hackers see bits only[4] as perhaps scientists see only matter or energy.

Great hackers, however, are not all-powerful deities roaming the digital landscape, changing the rules at whim. For the most part, such a description is inappropriate, but not wholly inaccurate. Code can be a great servant of mankind, but it can also be an appalling master, even to those who know its nuances. Acknowledging "no box" is an important realization, but one that does not confer magical powers upon the enlightened. What is essential after this relatively inexpensive epiphany is a strong, practical foundation in the skills software developers possess.

Knowledge Set

Knowledge of the intended target is vital. In large part, the required knowledge set is target dependent, and increases in importance the deeper into the technical architecture one travels. While the "no box" mindset may permit the application attacker to view the digital world in an entirely different way, the current rules (i.e., code) in place must first be understood before they can be altered.

The first requirement is to identify the target's platform. A platform is defined by a combination of a microprocessor architecture (Intel, Motorola, AMD, etc.) and an operating system (Windows, Linux, MacOS, etc.). It is not necessary to understand the target platform in its entirety — a task that is almost impossible for any single person — but it is essential to understand a majority of the platform's functional aspects, including input/output, security implementation (if any), file access, memory management, and process creation.

The second requirement is knowledge of a programming language. Languages such as C/C++ are most common, but knowledge of other languages such as Java, COBOL, and Ada may be required; which language is necessary will depend on the target application. Also, knowledge of the assembly language the microprocessor architecture executes can be extremely helpful.

Programming languages are the prime vehicles for exploring a target in-depth. Knowledge of how applications are designed and written assists in analysis. The public interface conceals much of the underlying operations an application performs. The more adept an auditor is at programming, the more portions of an application unexposed by the public interface may be examined. Additionally, programming skills may accelerate the vulnerability discovery processes by automating many common testing procedures and, if a flaw is discovered, to verify the flaw's potential as a vulnerability. Without a doubt, programming skills will augment the auditor's tool set.

The third requirement is knowledge of communication protocols, both network and host-based. TCP/IP is the most common network communication protocol and any application capable of internetworking will usually employ it, but knowledge of other network protocols, such as NetBIOS and IPX/SPX, may be required. The requisite network protocol will depend on the target application.

Host-based communication protocols are those that involve intra-computer communication such as interprocess communication (IPC) or serial/parallel ports. This is one area where developers often devise their own proprietary protocols; however, understanding standard protocol implementations, such as TCP/IP, along with their respective strengths and weaknesses, will help in deciphering and analyzing these proprietary protocols.

The fourth and final requirement is a willingness to learn. It takes time and effort to acquire this body of knowledge and apply it accordingly. Although a computer science degree would be helpful in learning the above-mentioned requirements, it is not mandatory. Knowledge can be acquired by anyone. Every individual has the potential to become a proficient vulnerability researcher with work and practice; a degree is not necessary, it just lowers the learning curve.

Tools of the Trade

Possessing the basic knowledge described previously is often not enough; having the proper tools is also important. Tools of the trade not only include specialized software applications, but also the people you know and the books you read.

There is a number of specialized software applications available free from the Internet or for purchase on the open market. These tools allow auditors to increase their understanding of a particular system. A number of the tools application developers utilize to debug their applications are similarly useful for the auditor in analyzing the same application. Two such tools for software auditing come to the forefront: Numega's SoftICE and DataRescue's IDAPro.

SoftICE is a dynamic debugger for Intel's x86 architecture, capable of interrupting an application while it is executing, permitting the examination of the application's current internal state. This is especially useful for examining current operations that the application is performing that are not observable through the public interface.

IDAPro is an interactive static disassembler capable of displaying the operations for more than 30 different microprocessor architectures on which an application may execute. Much like SoftICE, IDAPro allows the auditor to view operations not observable through the public interface; however, unlike SoftICE, IDAPro examines the entire application without execution. By loading an executable into IDAPro, the auditor may view all possible instructions an application may perform in an easily readable document-like format. However,

IDAPro does not support run-time evaluation so the auditor cannot view which instructions are actually executed.

Other tools frequently needed are binary editors, network protocol analyzers, and various forensic programs and devices to display the current state of the system. Binary editors are frequently used to modify programs or files that reside on disk. Forensic programs provide a window into the system's current state without altering data or interrupting program execution. Network protocol analyzers allow an auditor to capture and view inter-application network traffic. Whichever tools the auditor selects is usually dependent on the target environment, economic factors (some tools are more expensive than others, and usually a similar freeware program can be found), and personal preferences.

The expertise of others is one tool most often overlooked. As stated earlier, most modern applications and operating systems are too complicated for any one person to know everything in detail. However, there are experts on facets of every platform, willing to share their insight. This sharing usually manifests in newsgroups, mailing lists, lectures, application documentation, and books, books, books. Usually a good starting point to answer any question may be found in one of the aforementioned forums.

Attack Methodology

An Art Built on a Science

Currently, auditing programs is still more of an art than a science. There is no "right way" to go about probing an application for security vulnerabilities. Although the methodology for attacking applications mirrors the scientific method, it also has a lot to do with intuition, viewpoint (i.e., "no box"), previous experience, and innovation. These four traits make successful auditors. However, without the patience of a scientist and the critical mindset, most auditors would simply yield to frustration.

Information Gathering

The first step in any process in auditing an application is gathering as much information as possible. Without defining and describing the target, it is difficult to see the full picture, and obvious flaws might be missed. The first place to look is product documentation. Documentation is a great way to see how developers presume their product is supposed to work, and is usually available for applications in varying forms and degrees. Usually, documentation regarding the internal structure of an application is unavailable, but information on a majority of the public interfaces and functionality is included for the benefit of the average user.

After the basics of the application are understood, other information should be gathered to flesh out the picture and focus the search. Most modern applications for personal computers are so large that trying to examine the entire package at once is not feasible, especially if there is a deadline. Good places to look for more information are newsgroups and mailing lists for any mention of the product. Reading other users' experiences can lead to insight into how the product is actually being used (or misused) in the real world. Also, any mention of difficulties or problems using the application should be noted, as this might be indicative of a flaw in the application.

As well as looking for information on the specific product, looking for information on similar products and on different products by the same vendor/developer also can lead to insights. Certain types of applications have specific concerns, regardless of the vendor who created the application, so difficulties in a different application might lead to ideas as to what to explore in the evaluated application. The same concept can be used with different programs from the same vendor. Often applications from a vendor are created by the same developers, or by developers that program with the same corporate mindset. So flaws found in other, unrelated products by the same vendor might also lead to thoughts as to where to focus attention in the targeted application.

Mainly, the purpose of this step is to gain a thorough understanding of the application, and uncover as many potential problems as possible. All this information is then fed into the next step: analysis.

Analysis

Once the raw information is gathered from the preceding step, it must be collated and whittled down into a number of specific areas that might be vulnerable to attack. How this narrowing of possibilities is done is most

often based on the past experiences of the person performing the application audit. There really is no right or wrong way to complete this step. Often, the information from previously discovered vulnerabilities is reused against the current application, such as testing user inputs for buffer overflows. Truly unique vulnerabilities are discovered most often by understanding the application as specified in the documentation and then observing the application acting in an inconsistent way. By definition, these types of vulnerabilities are the hardest to find because there is no historical precedent for them. They must be discovered by understanding how the system works, how the application is actually working (as opposed to how the documentation says it works), and often by a good dose of luck.

Once the list of possible vulnerable areas is sorted based on probability of success and resources available, the list is then used in the next step: hypothesis.

Hypothesis

From the last step, a list of possible vulnerabilities was produced. For each of these, a hypothesis should be generated. A hypothesis allows the parameters for each vulnerability to be specified, making it easier to both develop a test for the vulnerability and to more easily see what assumptions may have caused the test to fail. Also, having a semiformal statement of what is being considered is good for documenting the actual testing. Nothing is worse than coming back a few months after an audit, or being handed someone else's work, and not knowing what was done. Usually a hypothesis takes the form, "If we do X, then Y will (or will not) occur." In the application-testing arena, an example may be, "if a large string is entered into a specific field, then an access violation will occur." A true hypothesis would be more specific than that example, but that is the idea. These hypotheses can then be developed into actual tests to be run against the application.

There are a number of common classes of vulnerabilities that should be looked for. Following is our list of them. It is by no means a complete list.

Input Validation

Previously highlighted as an example, input validation tests whether an application properly handles input from an external source. In this context, an external source could be the user, another program, operating system, or anything outside the application destined for internal processing. The most common types of input validation errors result in buffer overflow, format string, or denial-of-service exploits. Because developers can accidentally overlook input validation, this type of error occurs frequently.

Most often this form of testing is accomplished by sending varying amounts of data — both properly and improperly formatted — into an application and viewing the results. Application response will help determine if this application is potentially vulnerable to the aforementioned exploits.

Angry Monkey

In this method, an automated program randomly performs input validation against the target. Angry Monkey, as any other input validation test, focuses on the application's ability to handle input; however, no criteria are established for external interfaces of the application. Any component of the application may be tested with randomly generated data, in no particular order or for any particular reason.

Session Management Validation

Network applications need to manage multiple conversions with numerous communication partners often at the same time. State variables such as session IDs, cookies, and secret keys uniquely identify these sessions. These variables are often randomly generated values that are assigned to a particular communications channel for a limited period of time.

Testing an application for session management vulnerabilities consists of attempting to guess, capture, and modify any of these state variables to elicit undesirable results from the application. By altering these variables, access may be gained to other communication channels that could lead to privilege escalation, loss of privacy or data confidentiality, or unauthorized access to resources.

Race Condition Analysis

Applications perform numerous operations in the course of completing any function, including security-related functions. In general, a race condition exists when there is a window of time between a security operation and the general function it applies to. This window of opportunity can allow security measures to be circumvented. An example of this is an application first creating a new file and then applying security to that file. Racing the

application attempts to access the file between the time the application creates it and when it actually applies the security. Identifying and testing for race conditions can be difficult due to very short windows of opportunity.

Cryptographic Analysis

Applications may handle sensitive data, such as passwords, credit card information, company trade secrets or intellectual property, or private personal information. This data is frequently protected by cryptographic methods. There are a lot of different cryptographic algorithms available for applications to use, both public and private. Experts have created and extensively examined some of them, and the vendors themselves have developed others. Those subjected to public scrutiny by experts are believed to be much stronger and more resilient to attack than private algorithms created by vendors. Determining what algorithm an application uses may lead to knowledge of its strengths and weaknesses. However, regardless of the strength of the algorithm used by the application, if the vendor uses it incorrectly, the data may not be protected as advertised. Errors could include improper creation, handling, or storage of the cryptographic keys. Examination, then, needs to include both the algorithm itself and the key management mechanism.

Code Coverage Analysis

Applications need to make numerous decisions in the course of performing their tasks. Each end result of these decisions should be secure. Code coverage analysis usually employs source code (or disassembled code) to ensure that proper security measures are taken on all possible paths of execution. There may exist execution paths through the application that allow for security to be bypassed, leaving the system in a vulnerable state. This analysis can take an extremely large amount of resources, both in people and time, depending on the size and complexity of the application. If at all possible, this type of analysis should be done in stages during the development of an application before it is ever considered ready for production.

Testing

The final step is taking the first hypothesis and actually testing it. How this is exactly accomplished all depends on both the application and the hypothesis. Sometimes it can be as simple as changing a setting and observing the effect. Other times a complex set of interactions between the application, the system, and possibly some custom-designed code must be choreographed.

Additionally, because applications today are such complex pieces of code, the results of testing a hypothesis can as varied as all the possible tests. However, if the hypothesis was sufficiently developed before testing, success or failure should be fairly easy to determine.

The most difficult part of testing is not finding vulnerability, though. It is proving (at least to whatever level of satisfaction required) that the application is not vulnerable to a specific test. If the test failed to prove the hypothesis, then the next step is to decide whether it failed because the parameters and assumptions being operated under were invalid, or because the hypothesis is wrong. In the previous example, if a long string is entered and does not cause an access violation, is it because the input was correctly handled, or was the string not long enough? Questions like this must be considered, and the hypothesis must be restated to correct any faults, or the results must be accepted and the next hypothesis on the list can be addressed. How concerns like this are handled are more often a matter of policy than of a technical nature.

Conclusion

Software development is an error-prone process; flaws inevitably creep into any product despite quality control efforts. The prevalence of software in nearly every aspect of modern life leads to reliance on software and as that reliance grows, so do the consequences of software failure or exploitation. No one can say when or why an application will be attacked, so finding and preventing these failures before they occur becomes an important endeavor.

Remember, application auditing is a nontrivial task that requires a special set of knowledge, skills, and resources. While it does not take a genius to succeed, it does require focused effort, patience, and a little bit of luck. The information and methodology described herein are good first steps toward learning what is required. However, it needs to be said that there is not, nor will there ever be, a last step when it comes to application auditing. There is no single solution to solving the problem of insecure applications. Even by

auditing an application, there may remain undiscovered weaknesses that will surface months, years, or even decades later. Every weakness found and fixed, however, is one less that threatens the stability of modern life.

Notes

1. ZeroDay events refer to a newly released exploit into the public domain for which no signature is available to identify it. Because security devices are in large part knowledge-based, the security device must have knowledge of the exploit to protect against it. If the security device is not aware of the exploit, it cannot protect against it until a signature is made available. For those exploits that are not made public, most security devices are unable to protect their respective networks from exploitation.
2. The authors purposely avoid distinguishing "hackers" from "crackers," mostly due to the amount of paper wasted explaining the difference between the two. The Dark Side of the Force can seduce great hackers; get over it.
3. This point is especially meaningful with the introduction of XML. XML can describe all the information about Mozart's Symphony No. 40. A user might want to listen to the file or print out the sheet music, but depending on what the user wants, data is transformed appropriately to meet the request.
4. In the physical world, manipulating atoms is not practical for the average human being. We see a cup, move it, drink from it, break it, but we are handicapped about altering how the atoms form the cup. If the cup were made out of bits, however, we could alter each bit, perhaps changing the color of the cup, or even making the cup into a song or picture. In the digital world, you can do anything you want with bits; shape, form, even behavior are not immutable.

Malware and Computer Viruses

Robert M. Slade, CISSP

Malware is a relatively new term in the security field. It was created to address the need to discuss software or programs that are intentionally designed to include functions for penetrating a system, breaking security policies, or carrying malicious or damaging payloads. Because this type of software has started to develop a bewildering variety of forms such as backdoors, data diddlers, DDoS, hoax warnings, logic bombs, pranks, RATs, Trojans, viruses, worms, zombies, etc., the term *malware* has come to be used for the collective class of malicious software. The term is, however, often used very loosely simply as a synonym for virus, in the same way that virus is often used simply as a description of any type of computer problem. This chapter attempts to define the problem more accurately and to describe the various types of malware.

Viruses are the largest class of malware, both in terms of numbers of known entities and in impact on the current computing environment. Viruses will, therefore, be given primary emphasis in this chapter but will not be the only malware type examined.

Programming bugs or errors are generally not included in the definition of malware, although it is sometimes difficult to make a hard and fast distinction between malware and bugs. For example, if a programmer left a buffer overflow in a system and it creates a loophole that can be used as a backdoor or a maintenance hook, did he do it deliberately? This question cannot be answered technically, although we might be able to guess at it, given the relative ease of use of a given vulnerability.

In addition, it should be noted that malware is not only a collection of utilities for the attacker. Once launched, malware can continue an attack without reference to the author or user; and in some cases it will expand the attack to other systems. There is a qualitative difference between malware and the attack tools, kits, or scripts that have to operate under an attacker's control and which are not considered to fall within the definition of malware. There are gray areas in this aspect as well, because RATs and DDoS zombies provide unattended access to systems but need to be commanded in order to deliver a payload.

Potential Security Concerns

Malware can attack and destroy system integrity in a number of ways. Viruses are often defined in terms of the ability to attach to programs (or to objects considered to be programmable) and so must, in some way, compromise the integrity of applications. A number of viruses attach themselves to the system in ways that either keep them resident in the system or invoke them each time the system starts, and they compromise the overall system even if individual applications are not touched. RATs (remote-access Trojans/tools, basically remotely installed backdoors) are designed to allow a remote user or attacker to completely control a system, regardless of local security controls or policies. The fact that viruses modify programs is seen as evidence that viruses inherently compromise systems, and therefore the concept of a *good* or even *benign* virus is a contradiction in terms. The concept of good viruses will be discussed more in the detailed section concerning virus functions.

Many viruses or other forms of malware contain payloads (such as data diddlers) that may either erase data files or interfere with application data over time in such a way that data integrity is compromised and data may become completely useless.

In considering malware, there is an additional type of attack on integrity. As with attacks where the intruder takes control of your system and uses it to explore or assail further systems in order to hide his own identity, malware (viruses and DDoS zombies in particular) is designed to use your system as a platform to continue further assaults, even without the intervention of the original author or attacker. This can create problems within domains and intranets where equivalent systems trust each other, and it can also create bad will when those with whom you do business find out that your system is sending viruses or probes to theirs.

As noted, malware can compromise programs and data to the point where they are no longer available. In addition, malware generally uses the resources of the system it has attacked; and it can, in extreme cases, exhaust CPU cycles, available processes (process numbers, tables, etc.), memory, communications links and bandwidth, open ports, disk space, mail queues, etc. Sometimes this can be a direct denial-of-service (DoS) attack, and sometimes it is a side effect of the activity of the malware.

Malware, such as backdoors and RATs, is intended to make intrusion and penetration easier. Viruses such as Melissa and SirCam send data files from your system to others (in these particular cases, seemingly as a side effect of the process of reproduction and spread). Malware can be written to do directed searches and send confidential data to specific parties, and it can also be used to open covert channels of other types.

The fact that you are infected with viruses, or compromised by other types of malware, can become quite evident to others. This compromises confidentiality by providing indirect evidence of your level of security, and it may also create seriously bad publicity.

The Computing Environment With Regard to Malware

In the modern computing environment, everything — including many supposedly isolated mainframes — is next to everything else. Where older Trojans relied on limited spread for as long as users on bulletin board systems could be fooled, and early-generation viruses required manual disk and file exchange, current versions of malware use network functions. For distribution of contemporary malware, network functions used can include e-mail of executable content in file attachments, compromise of active content on Web pages, and even direct attacks on server software. Attack payloads can attempt to compromise objects accessible via the Net, can deny resource services by exhausting them, can corrupt publicly available data on Web sites, or spread plausible but misleading misinformation.

It has long been known that the number of variants of viruses or other forms of malware is directly related to the number of instances of a given platform. The success of a given piece of malware is also associated with the relative proportion of a given platform in the overall computing environment. Attacks are generally mounted at least semirandomly; attacks on incompatible targets are wasted and, conversely, attacks on compatible targets are successful and may help to escalate the attack.

Although it may not seem so to harried network administrators, the modern computing environment is one of extreme consistency. The Intel platform has severe dominance in hardware, and Microsoft has a near monopoly of operating systems and applications on the desktop. In addition, compatible application software (and the addition of functional programming capabilities in those applications) can mean that malware from one hardware and operating system environment works perfectly well in another.

The functionality added to application macro and script languages has given them the capability either to directly address computer hardware and resources or to easily call on utilities or processes that have such access. This means that objects previously considered to be data, and therefore immune to malicious programming, must now be checked for malicious functions or payloads.

In addition, these languages are very simple to learn and use; and the various instances of malware carry their own source code, in plaintext and sometimes commented, making it simple for individuals wanting to learn how to craft an attack to gather templates and examples of how to do so — without even knowing how the technology actually works. This enormously expands the range of authors of such software.

Overview and History

We are faced with a rapid evolution of computer viruses, and we are experiencing difficulties in addressing the effects of these viruses, just as in the biological world. IBM's computer virus research team has extensively examined the similarities and differences between biological and computer viruses and epidemiology. Many excellent papers are available through their Web site at http://www.research.ibm.com/antivirus/.

The evolution of computer viruses is dramatically accelerated when compared to the development of their biological counterparts. This is easy to understand when you examine the rapid development of computer technology as well as the rapid homogenization of computers, operating systems, and software.

Many claims have been made for the existence of viruses prior to the 1980s, but so far these claims have either been unaccompanied by proof or have referred to entities that can be considered viruses only under the broadest definition of the term. The Core Wars programming contests did involve self-replicating code, but usually within a structured and artificial environment. Examples of other forms of malware have been known almost since the advent of computing.

At least two Apple II viruses are known to have been created in the early 1980s. Fred Cohen's pioneering academic research was undertaken during the middle of that decade, and there is some evidence that the first viruses to be successful in the normal computing environment were created late in the 1980s. However, it was not until the end of the decade (and 1987 in particular) that knowledge of real viruses became widespread, even among security experts. For many years, boot-sector infectors and file infectors were the only types of common viruses. These programs spread relatively slowly, primarily distributed on floppy disks, and were thus slow to disseminate geographically. However, the viruses tended to remain in the environment for a long time.

During the early 1990s, virus writers started experimenting with various functions intended to defeat detection. (Some forms had seen limited trials earlier.) Among these were polymorphism, to change code strings in order to defeat scanners, and stealth, to attempt to confound any type of detection. None of these virus technologies had a significant impact. Most viruses using these advanced technologies were easier to detect because of a necessary increase in program size.

Although demonstration programs had been created earlier, the middle 1990s saw the introduction of macro and script viruses in the wild. These were initially confined to word-processing files, particularly files associated with the Microsoft Office suite. However, the inclusion of programming capabilities eventually led to script viruses in many objects that would normally be considered to contain data only, such as Excel spreadsheets, PowerPoint presentation files, and e-mail messages. This fact led to greatly increased demands for computer resources among anti-viral systems because many more objects had to be tested, and Windows OLE (Object Linking and Embedding) format data files presented substantial complexity to scanners. Macro viruses also increased new variant forms very quickly because the viruses carried their own source code, and anyone who obtained a copy could generally modify it and create a new member of the virus family.

E-mail viruses became the major new form in the late 1990s and early 2000s. These viruses may use macro capabilities, scripting, or executable attachments to create e-mail messages or attachments sent out to e-mail addresses harvested from the infected machine or other sources. E-mail viruses spread with extreme rapidity, distributing themselves worldwide in a matter of hours. Some versions create so many copies of themselves that corporate and even service provider mail servers are flooded and cease to function. Prolific e-mail viruses are very visible and thus tend to be identified within a short space of time, but many are macros or scripts and generate many variants.

With the strong integration of the Microsoft Windows operating system with its Internet Explorer browser, Outlook mailer, Office suite, and system scripting, recent viruses have started to blur the normal distinctions. A document sent as an e-mail file attachment can make a call to a Web site that starts active content, which installs a remote-access tool acting as a portal for the client portion of a distributed denial-of-service network. This convergence of technologies is not only making discussion more difficult but is also leading to the development of much more dangerous and (from the perspective of an attacker) effective forms of malware.

Because the work has had to deal with detailed analyses of low-level code, virus research has led to significant advances in the field of forensic programming. However, to date computer forensic work has concentrated on file recovery and decryption, so the contributions in this area still lie in the future.

Many computer pundits, as well as some security experts, have proposed that computer viruses are the result of the fact that currently popular desktop operating systems have only nominal security provisions. They further suggest that viruses will disappear as security functions are added to operating systems. This thesis ignores the facts — well established by Cohen's research and subsequently confirmed — that viruses use the most basic of computer functions, and a perfect defense against viruses is impossible. This is not to say that an increase in security measures by operating system vendors could not reduce the risk of viruses — the current danger could be drastically reduced with relatively minor modifications to system functions.

It is going too far to say (as some have) that the very existence of viral programs, and the fact that both viral strains and the numbers of individual infections are growing, means that computers are finished. At the

present time, the general public is not well informed about the virus threat, so more copies of viral programs are being produced than are being destroyed.

Indeed, no less an authority than Fred Cohen has championed the idea that viral programs can be used to great effect. An application using a viral form can improve performance in the same way that computer hardware benefits from parallel processors. It is, however, unlikely that viral programs can operate effectively and usefully in the current computer environment without substantial protective measures built into them.

Malware Types

Viruses are not the only form of malicious software. Other forms include worms, Trojans, zombies, logic bombs, and hoaxes. Each of these has its own characteristics, and we will discuss each of the forms below. Some forms of malware combine characteristics of more than one class, and it can be difficult to draw hard and fast distinctions with regard to individual examples or entities; but it is important to keep the specific attributes in mind.

It should be noted that we are increasingly seeing convergence in malware. Viruses and Trojans are used to spread and plant RATs, and RATs are used to install zombies. In some cases, hoax virus warnings are used to spread viruses. Virus and Trojan payloads may contain logic bombs and data diddlers.

Viruses

A computer virus is a program written with functions and intent to copy and disperse itself without the knowledge and cooperation of the owner or user of the computer. All researchers have not yet agreed on a final definition. A common definition is "a program that modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen from his seminal research in the middle 1980s, although Dr. Cohen's actual definition is in mathematical form. (The term *computer virus* was first defined by Dr. Cohen in his graduate thesis in 1984. Cohen credits a suggestion from his advisor, Leonard Adelman [of RSA fame], for the use of the term.) Another possible definition is an entity that uses the resources of the host (system or computer) to reproduce itself and spread without informed operator action.

Cohen's definition is specific to programs that attach themselves to other programs as their vector of infection. However, common usage now holds viruses to consist of a set of coded instructions that are designed to attach to an object capable of containing the material, without knowledgeable user intervention. This object may be an e-mail message, program file, document, floppy disk, CD-ROM, short message system (SMS) message on cellular telephones, or any similar information medium.

A virus is defined by its ability to reproduce and spread. A virus is not merely anything that goes wrong with a computer, and a virus is not simply another name for malware. Trojan horse programs and logic bombs do not reproduce themselves.

A worm, which is sometimes seen as a specialized type of virus, is currently distinguished from a virus because a virus generally requires an action on the part of the users to trigger or aid reproduction and spread. (There will be more on this distinction in the section on worms later in this chapter.) The actions on the part of the users are generally common functions, and the users generally do not realize the danger of their actions or the fact that they are assisting the virus.

The only requirement that defines a program as a virus is that it reproduces. There is no necessity that viruses carry a payload, although a number of viruses do. In many cases (in most cases of successful viruses), the payload is limited to some kind of message. A deliberately damaging payload, such as erasure of the disk or system files, usually restricts the ability of the virus to spread because the virus uses the resources of the host system. In some cases, a virus may carry a logic bomb or time bomb that triggers a damaging payload on a certain date or under a specific, often delayed, condition.

Because a virus spreads and uses the resources of the host, it affords the kind of power to software that parallel processors provide to hardware. Therefore, some have theorized that viral programs could be used for beneficial purposes, similar to the experiments in distributed processing that are testing the limits of cryptographic strength. (Various types of network management functions and updating of system software are seen as candidates.) However, the fact that viruses change systems and applications is seen as problematic in its own right. Many viruses that carry no overtly damaging payload still create problems with systems. A number of virus and worm programs have been written with the obvious intent of proving that viruses could carry a

useful payload, and some have even had a payload that could be said to enhance security. Unfortunately, all such viruses have created serious problems. The difficulties of controlling viral programs have been addressed in theory, but the solutions are also known to have faults and loopholes. (One of the definitive papers on this topic is available at http://www.frisk.is/~bontchev/papers/goodvir.html.)

Types of Viruses

There are a number of functionally different types of viruses, such as a file infector, boot-sector infector (BSI), system infector, e-mail virus, multipartite, macro virus, or script virus. These terms do not necessarily indicate a strict division. A file infector may also be a system infector. A script virus that infects other script files may be considered to be a file infector — although this type of activity, while theoretically possible, is unusual in practice. There are also difficulties in drawing a hard distinction between macro and script viruses.

Later in this chapter there is a section enumerating specific examples of malware, where the viruses noted in the next few paragraphs are discussed in detail. We have tried to include examples that explain and expand on these different types.

File Infectors

A file infector infects program (object) files. System infectors that infect operating system program files (such as command.com in DOS) are also file infectors. File infectors can attach to the front of the object file (prependers), attach to the back of the file and create a jump at the front of the file to the virus code (appenders), or overwrite the file or portions of it (overwriters). A classic is Jerusalem. A bug in early versions caused it to add itself over and over again to files, making the increase in file length detectable. (This has given rise to the persistent myth that it is a characteristic of a virus that it will fill up all disk space eventually; by far, the majority of file infectors add minimally to file lengths.)

Boot-Sector Infectors

Boot-sector infectors (BSIs) attach to or replace the master boot record, system boot record, or other boot records and blocks on physical disks. (The structure of these blocks varies, but the first physical sector on a disk generally has some special significance in most operating systems and usually it is read and executed at some point in the boot process.) BSIs usually copy the existing boot sector to another unused sector, and then copy themselves into the physical first sector, ending with a call to the original programming. Examples are Brain, Stoned, and Michelangelo.

System Infectors

System infector is a somewhat vague term. The phrase is often used to indicate viruses that infect operating system files, or boot sectors, in such a way that the virus is called at boot time and has or may have preemptive control over some functions of the operating system. (The Lehigh virus infected only COMMAND.COM on MS-DOS machines.) In other usage, a system infector modifies other system structures, such as the linking pointers in directory tables or the MS Windows system registry, in order to be called first when programs are invoked on the host computer. An example of directory table linking is the DIR virus family. Many e-mail viruses target the registry: MTX and Magistr can be very difficult to eradicate.

Companion Virus

Some viral programs do not physically touch the target file at all. One method is quite simple and may take advantage of precedence in the system. In MS-DOS, for example, when a command is given, the system checks first for internal commands, then .com, .exe, and .bat files in that order. The .exe files can be infected by writing a .com file in the same directory with the same filename. This type of virus is most commonly known as a companion virus, although the term *spawning virus* is also used.

E-Mail Virus

An e-mail virus specifically, rather than accidentally, uses the e-mail system to spread. While virus-infected files may be accidentally sent as e-mail attachments, e-mail viruses are aware of e-mail system functions. They generally target a specific type of e-mail system (Microsoft's Outlook is the most commonly used), harvest e-mail addresses from various sources, and may append copies of themselves to all e-mails sent or generate e-mail messages containing copies of themselves as attachments. Some e-mail viruses may monitor all network traffic and follow up legitimate messages with messages that they generate. Most e-mail viruses are technically

considered to be worms because they do not often infect other program files on the target computer, but this is not a hard and fast distinction. There are known examples of e-mail viruses that are file infectors, macro viruses, script viruses, and worms. Melissa, LoveLetter, Hybris, and SirCam are all widespread current examples, and the CHRISTMA exec is an older example of the same type of activity.

E-mail viruses have made something of a change to the epidemiology of viruses. Traditionally, viruses took many months to spread but stayed around for many years in the computing environment. Many e-mail viruses have become "fast burners" that can spread around the world, infecting hundreds of thousands or even millions of machines within hours. However, once characteristic indicators of these viruses become known, they die off almost immediately when users stop running the attachments.

Multipartite

Originally the term *multipartite* was used to indicate a virus that was able to infect both boot sectors and program files. (This ability is the origin of the alternate term *dual infector.*) Current usage tends to mean a virus that can infect more than one type of object or that infects or reproduces in more than one way. Examples of traditional multipartites are Telefonica, One Half, and Junkie, but these programs have not been very successful.

Macro Virus

A macro virus uses macro programming of an application such as a word processor. (Most known macro viruses use Visual Basic for Applications in Microsoft Word; some are able to cross between applications and functions in, for example, a PowerPoint presentation and a Word document, but this ability is rare.) Macro viruses infect data files and tend to remain resident in the application by infecting a configuration template such as MS Word's Normal.dot. Although macro viruses infect data files, they are not generally considered to be file infectors; a distinction is generally made between program and data files. Macro viruses can operate across hardware or operating system platforms as long as the required application platform is present. (For example, many MS Word macro viruses can operate on both the Windows and Macintosh versions of MS Word.) Examples are Concept and CAP. Melissa is also a macro virus, in addition to being an e-mail virus; it mailed itself around as an infected document.

Script Virus

Script viruses are generally differentiated from macro viruses in that script viruses are usually stand-alone files that can be executed by an interpreter, such as Microsoft's Windows Script Host (.vbs files). A script virus file can be seen as a data file in that it is generally a simple text file, but it usually does not contain other data and generally has some indicator (such as the .vbs extension) that it is executable. LoveLetter is a script virus.

Virus Examples and Encyclopedias

Examples of recent viruses, in very brief form, can be found at http://www.osborne.com/virus_alert/. More comprehensive information on a much greater number of viruses can be found at the various virus encyclopedia sites. Two of the best are:

1. F-Secure: http://www.f-secure.com/v-descs/
2. Sophos: http://www.sophos.com/virusinfo/analyses/

Others can be found at:

- http://www.viruslist.com/eng/viruslist.asp http://www.symantec. com/avcenter/vinfodb.html
- http://www.antivirus.com/vinfo/virusencyclo/ http://www.cai.com/ virusinfo/encyclopedia/
- http://antivirus.about.com/library/blency.htm http://vil.mcafee.com/
- http://www.pandasoftware.com/library/defaulte.htm

Virus Structure

In considering computer viruses, three structural parts are considered important: the replication or infection mechanism, the trigger, and the payload.

Infection Mechanism

The first and only necessary part of the structure is the infection mechanism. This is the code that allows the virus to reproduce and thus to be a virus. The infection mechanism has a number of parts to it.

The first function is to search for, or detect, an appropriate object to infect. The search may be active, as in the case of some file infectors that take directory listings in order to find appropriate programs of appropriate sizes; or it may be passive, as in the case of macro viruses that infect every document as it is saved. There may be some additional decisions taken once an object is found. Some viruses may actually try to slow the rate of infection to avoid detection. Most will check to see if the object has already been infected.

The next action will be the infection itself. This may entail the writing of a new section of code to the boot sector, the addition of code to a program file, the addition of macro code to the Microsoft Word Normal.dot file, the sending of a file attachment to harvested e-mail addresses, or a number of other operations. There are additional subfunctions at this step as well, such as the movement of the original boot sector to a new location or the addition of jump codes in an infected program file to point to the virus code. There may also be changes to system files, to try to ensure that the virus will be run every time the computer is turned on. This can be considered the insertion portion of the virus.

At the time of infection, a number of steps may be taken to try to keep the virus safe from detection. The original file creation date may be conserved and used to reset the directory listing to avoid a change in date. The virus may have its form changed in some kind of polymorphism. The active portion of the virus may take charge of certain system interrupts in order to make false reports when someone tries to look for a change to the system. There may also be certain prompts or alerts generated in an attempt to make any odd behavior noticed by the user appear to be part of a normal, or at least innocent, computer error.

Trigger

The second major component of a virus is the payload trigger. The virus may look for a specific number of infections, a certain date or time, or a particular piece of text. A section of code does not have to contain either a trigger or a payload to be defined as a virus.

Payload

If a virus does have a trigger, then it usually has a payload. The payload can be pretty much anything, from a simple one-time message, to a complicated display, to reformatting the hard disk. However, the bigger the payload, the more likely it is that the virus will get noticed. A virus carrying a very destructive payload will also eradicate itself when it wipes out its target. Therefore, while you may have seen lists of payload symptoms to watch for, such as text messages, ambulances running across the screen, letters falling down, and such, checking for these payloads is not a very good way to keep free of viruses. The successful ones keep quiet.

Stealth

A great many people misunderstand the term *stealth*. It is often misused as the name of a specific virus. At other times, there are references to stealth viruses as if they were a class such as file infectors or macro viruses. In fact, stealth refers to technologies that can be used by any virus and by other forms of malware as well, and often it is used as a reference to all forms of anti-detection technology. Stealth is used inconsistently even within the virus research community.

A specific usage of the term refers to an activity also known as *tunneling*, which (in opposition to the usage in virtual private networks) describes the act of tracing interrupt links and system calls in order to intercept calls to read the disk, or performing other measures that could be used to determine that an infection exists. A virus using this form of stealth would intercept a call to display information about the file (such as its size) and return only information suitable to the uninfected object. This type of stealth was present in one of the earliest MS-DOS viruses, Brain. (If you gave commands on an infected system to display the contents of the boot sector, you would see the original boot sector and not the infected one.)

Polymorphism (literally many forms) refers to a number of techniques that attempt to change the code string on each generation of a virus. These vary from using modules that can be rearranged to encrypting the virus code itself, leaving only a stub of code that can decrypt the body of the virus program when invoked. Polymorphism is sometimes also known as self-encryption or self-garbling, but these terms are imprecise and not recommended. Examples of viruses using polymorphism are Whale and Tremor. Many polymorphic viruses

use standard mutation engines such as MtE. These pieces of code actually aid detection because they have a known signature.

A number of viruses also demonstrate some form of active detection avoidance, which may range from disabling on-access scanners in memory to deletion of anti-virus and other security software (Zonealarm is a favorite target) from the disk.

Worms

A worm reproduces and spreads, like a virus and unlike other forms of malware. Worms are distinct from viruses, although they may have similar results. Most simply, a worm may be thought of as a virus with the capacity to propagate independently of user action. That is, they do not rely on (usually) human-initiated transfer of data between systems for propagation; instead, they spread across networks of their own accord, primarily by exploiting known vulnerabilities in common software.

Originally, the distinction was made that worms used networks and communications links to spread and that a worm, unlike a virus, did not directly attach to an executable file. In early research into computer viruses, the terms *worm* and *virus* tended to be used synonymously because it was felt that the technical distinction was unimportant to most users. The technical origin of the term *worm program* matched that of modern distributed processing experiments: a program with segments working on different computers, all communicating over a network (Shoch and Hupp, 1982).

In fact, the use and origin of the term *worm* in relation to computer programs is rather cloudy. There are references in early computing to *wormhole* programs that escaped from their assigned partitions. The wormhole reference may note the similarity that random damage bears to the characteristic patterns of holes in worm-eaten wood, or relate to the supposition in science fiction stories that wormholes may carry you to random places. The Shoch and Hupp article contains a quote from John Brunner's novel, *The Shockwave Rider,* that describes a *tapeworm* program, although this entity bears little resemblance to modern malware.

The first worm to garner significant attention was the Internet Worm of 1988. Recently, many of the most prolific virus infections have not been strictly viruses, but have used a combination of viral and worm techniques to spread more rapidly and effectively. LoveLetter was an example of this convergence of reproductive technologies. While infected e-mail attachments were perhaps the most widely publicized vectors of infection, LoveLetter also spread by actively scanning attached network drives and infecting a variety of common file types. This convergence of technologies will be an increasing problem in the future. Code Red and a number of Linux programs (such as Lion) are modern examples of worms. (Nimda is an example of a worm, but it also spreads in a number of other ways; so it could be considered to be an e-mail virus and multipartite as well.)

Hoaxes

Hoax virus warnings or alerts have an odd double relation to viruses. First, hoaxes are usually warnings about "new" viruses — new viruses that do not, of course, exist. Second, hoaxes generally carry a directive to the user to forward the warning to all addresses available to them. Thus, these descendants of chain letters form a kind of self-perpetuating spam.

Hoaxes use an odd kind of social engineering, relying on the naturally gregarious nature of people and their desire to communicate a matter of urgency and importance, using the human ambition to be the first to provide important new information.

Hoaxes do, however, have common characteristics that can be used to determine whether their warnings are valid:

- Hoaxes generally ask the reader to forward the message.
- Hoaxes make reference to false authorities such as Microsoft, AOL, IBM, and the FCC (none of which issue virus alerts), or to completely false entities.
- Hoaxes do not give specific information about the individual or office responsible for analyzing the virus or issuing the alert.
- Hoaxes generally state that the new virus is unknown to authorities or researchers.
- Hoaxes often state that there is no means of detecting or removing the virus.

- Many of the original hoax warnings stated only that you should not open a message with a certain phrase in the subject line. (The warning, of course, usually contained that phrase in the subject line. Subject-line filtering is known to be a very poor method of detecting malware.)
- Hoaxes often state that the virus does tremendous damage and is incredibly virulent.
- Hoax warnings very often contain A LOT OF CAPITAL-LETTER SHOUTING AND EXCLAMATION MARKS!!!!!!!!!!
- Hoaxes often contain technical-sounding nonsense (technobabble) such as references to nonexistent technologies like "nth complexity binary loops."

It is wisest in the current environment to doubt all virus warnings, unless they come from a known and historically accurate source such as a vendor with a proven record of providing reliable and accurate virus alert information, or preferably an independent researcher or group. It is best to check *any* warnings received against known virus encyclopedia sites. It is best to check more than one such site — in the initial phases of a fast burner attack, some sites may not have had time to analyze samples to their own satisfaction; and the better sites will not post unverified information.

A recent example of a hoax, referring to SULFNBK.EXE, got a number of people to clear this legitimate utility off their machines. The origin was likely the fact that the Magistr virus targets Windows system software, and someone with an infection did not realize that the file is actually present on all Windows 98 systems.

Trojans

Trojans, or Trojan horse programs, are the largest class of malware aside from viruses. However, use of the term is subject to much confusion, particularly in relation to computer viruses.

A Trojan is a program that pretends to do one thing while performing another, unwanted action. The extent of the pretense may vary greatly. Many of the early PC Trojans merely used the filename and a description on a bulletin board. Log-in Trojans, popular among university student mainframe users, mimicked the screen display and the prompts of the normal log-in program and could, in fact, pass the username and password along to the valid log-in program at the same time as they stole the user data. Some Trojans may contain actual code that does what it is supposed to be doing while performing additional nasty acts.

Some data security writers consider that a virus is simply a specific example of the class of Trojan horse programs. There is some validity to this usage because a virus is an unknown quantity that is hidden and transmitted along with a legitimate disk or program, and any program can be turned into a Trojan by infecting it with a virus. However, the term *virus* more properly refers to the added, infectious code rather than the virus/target combination. Therefore, the term *Trojan* refers to a deliberately misleading or modified program that does not reproduce itself.

An additional confusion with viruses involves Trojan horse programs that may be spread by e-mail. In years past, a Trojan program had to be posted on an electronic bulletin board system or a file archive site. Because of the static posting, a malicious program would soon be identified and eliminated. More recently, Trojan programs have been distributed by mass e-mail campaigns, by posting on Usenet newsgroup discussion groups, or through automated distribution agents (bots) on Internet relay chat (IRC) channels. Because source identification in these communications channels can be easily hidden, Trojan programs can be redistributed in a number of disguises, and specific identification of a malicious program has become much more difficult.

Social Engineering

A major aspect of Trojan design is the social engineering component. Trojan programs are advertised (in some sense) as having a positive component. The term *positive* can be in dispute, because a great many Trojans promise pornography or access to pornography — and this still seems to be depressingly effective. However, other promises can be made as well. A recent e-mail virus, in generating its messages, carried a list of a huge variety of subject lines, promising pornography, humor, virus information, an anti-virus program, and information about abuse of the recipient's e-mail account. Sometimes, the message is simply vague and relies on curiosity.

It is instructive to examine some classic social engineering techniques. Formalizing the problem makes it easier to move toward effective solutions and making use of realistic, pragmatic policies. Effective implemen-

tation of such policies, however good they are, is not possible without a considered user education program and cooperation from management.

Social engineering really is nothing more than a fancy name for the type of fraud and confidence games that have existed since snakes started selling apples. Security types tend to prefer a more academic-sounding definition, such as the use of nontechnical means to circumvent security policies and procedures. Social engineering can range from simple lying (such as a false description of the function of a file), to bullying and intimidation (in order to pressure a low-level employee into disclosing information), to association with a trusted source (such as the username from an infected machine), to dumpster diving (to find potentially valuable information people have carelessly discarded), to shoulder-surfing (to find out personal identification numbers and passwords).

Remote-Access Trojans (RATs)

Remote-access Trojans are programs designed to be installed, usually remotely, after systems are installed and working (and not in development, as is the case with logic bombs and backdoors). Their authors would generally like to have the programs referred to as *remote administration tools* so as to convey a sense of legitimacy.

All networking software can, in a sense, be considered remote access tools — we have file transfer sites and clients, World Wide Web servers and browsers, and terminal emulation software that allows a microcomputer user to log on to a distant computer and use it as if on-site. The RATs considered to be in the malware camp tend to fall somewhere in the middle of the spectrum. Once a client such as Back Orifice, Netbus, Bionet, or SubSeven is installed on the target computer, the controlling computer is able to obtain information about the target computer. The master computer will be able to download files from, and upload files to, the target. The control computer will also be able to submit commands to the victim, which basically allows the distant operator to do pretty much anything to the prey. One other function is quite important: all of this activity goes on without any alert given to the owner or operator of the targeted computer.

When a RAT program has been run on a computer, it will install itself in such a way as to be active every time the computer is started subsequent to the installation. Information is sent back to the controlling computer (sometimes via an anonymous channel such as IRC) noting that the system is active. The user of the command computer is now able to explore the target, escalate access to other resources, and install other software, such as DDoS zombies, if so desired.

Once more, it should be noted that remote access tools are not viral. When the software is active, the master computer can submit commands to have the installation program sent on, via network transfer or e-mail, to other machines. In addition, RATs can be installed as a payload from a virus or Trojan.

Rootkits, containing software that can subvert or replace normal operating system software, have been around for some time. RATs differ from rootkits in that a working account must be either subverted or created on the target computer in order to use a rootkit. RATs, once installed by a virus or Trojan, do not require access to an account.

DDoS Zombies

DDoS (distributed denial-of-service) is a modified denial-of-service (DoS) attack. Denial-of-service attacks do not attempt to destroy or corrupt data; rather, they attempt to use up a computing resource to the point where normal work cannot proceed. The structure of a DDoS attack requires a master computer to control the attack, a target of the attack, and a number of computers in the middle that the master computer uses to generate the attack. These computers in between the master and the target are variously called agents or clients, but are usually referred to as running zombie programs.

Again, note that DDoS programs are not viral, but checking for zombie software protects not only your system but also prevents attacks on others. It is, however, still in your best interest to ensure that no zombie programs are active. If your computers are used to launch an assault on some other system, you could be liable for damages.

The efficacy of this platform was demonstrated in early 2000 when a couple of teenagers successfully paralyzed various prominent online players in quick succession, including Yahoo!, Amazon, and eBay.

Logic Bombs

Logic bombs are software modules set up to run in a quiescent state — but to monitor for a specific condition or set of conditions and to activate their payloads under those conditions. A logic bomb is generally implanted in or coded as part of an application under development or maintenance. Unlike a RAT or Trojan, it is difficult to implant a logic bomb after the fact. There are numerous examples of this type of activity, usually based upon actions taken by a programmer to deprive a company of needed resources in the event of employment termination.

A Trojan or a virus may contain a logic bomb as part of the payload. A logic bomb involves no reproduction and no social engineering.

A persistent legend in regard to logic bombs involves what is known as the *salami scam*. According to the story, this involves siphoning off small amounts of money (in some versions, fractions of a cent) and crediting it to the account of the programmer over a very large number of transactions. Despite the fact that these stories appear in a number of computer security texts, this author has a standing challenge to anyone to come up with a documented case of such a scam. Over a period of eight years, the closest anyone has come is a story about a fast-food clerk who diddled the display on a drive-through window and collected an extra dime or quarter from most customers.

Pranks

Pranks are very much a part of the computer culture — so much so that you can now buy commercially produced joke packages that allow you to perform "Stupid Mac (or PC, or Windows) Tricks." There are countless pranks available as shareware. Some make the computer appear to insult the user; some use sound effects or voices; some use special visual effects. A fairly common thread running through most pranks is that the computer is, in some way, nonfunctional. Many pretend to have detected some kind of fault in the computer (and some pretend to rectify such faults, of course making things worse). One entry in the virus field is Parascan, the paranoid scanner. It pretends to find large numbers of infected files, although it does not actually check for any infections.

Generally speaking, pranks that create some kind of announcement are not malware; viruses that generate a screen or audio display are actually quite rare. The distinction between jokes and Trojans is harder to make, but pranks are intended for amusement. Joke programs may, of course, result in a denial of service if people find the prank message frightening.

One specific type of joke is the *Easter egg*, a function hidden in a program and generally accessible only by some arcane sequence of commands. These may be seen as harmless but they do consume resources, even if only disk space, and also make the task of ensuring program integrity much more difficult.

Malware and Virus Examples

It is all very well to provide academic information about the definitions and functions of different types of malware. It may be difficult to see how all this works in practice. In addition, it is often easier for people to understand how a particular technology works when presented with an actual example.

Here, then, are specific examples of viruses and malware. All of these have been seen and been successful, to an extent, in the wild (outside of research situations). One benefit of looking at malware in this way is that the discussion is removed from the realms of the possible to the actual. For example, there has been a great deal of debate over the years about whether a virus can do damage to hardware. Theoretically, it is possible. In actual fact, it has not happened.

Viruses do dominate in this section, and there are reasons for this. First, there are more examples of viruses to draw from. This chapter is not meant to, and cannot, be an encyclopedia of the tens of thousands of viruses; but it is important to give examples of the major classes of viruses. Second, the possible range of Trojans is really only limited by what can be done with software. People generally do not feel that there is much difference between a Trojan that reformats the hard disk and one that only erases all the files. From the user's perspective, the effect is pretty much the same; and the defensive measure that should have been taken (do not run unknown software) is also identical.

This material not only provides technical details but also looks at the history and some social factors involved. Social engineering is often involved in malware, and it is instructive to look at strategies that have been successful to determine policies that will protect users.

Boot-Sector Infectors

Brain

Technically, the Brain family (Pakistani, Pakistani Brain, Lahore, and Ashar), although old and seldom seen anymore, raises a number of interesting points. Brain itself was the first known PC virus, aside from those written by Fred Cohen for his thesis. Unlike Cohen's file viruses, however, Brain is a boot-sector infector.

Brain has been described as the first stealth virus. A request to view the boot sector of an infected disk on an infected system will result in a display of the original (pre-infection) boot sector. However, the volume label of an infected diskette is set to "©Brain," "©Ashar," or "Y.C.1.E.R.P," depending on the variant. Every time a directory listing is requested, the volume label is displayed; so it is difficult to understand why the virus uses stealth in dealing with the display of the boot sector. In one of the most common Brain versions, there is unencrypted text giving the name, address, and telephone numbers of Brain Computer Services in Pakistan. The virus is copyrighted by "Ashar and Ashars" or "Brain & Amjads."

Brain is not intentionally or routinely destructive, and it is possible that the virus was intended to publicize the company. This was the earliest known PC virus, and viruses did not inspire the same revulsion that they tend to do today. Even some time after the later and more destructive viruses, Lehigh and Jerusalem, viruses were still seen as possibly neutral or even in some way beneficial. It may be that the author saw a self-reproducing program that lost, at most, 3 kb of disk space as simply a novelty. In a way, such a virus as this would not be dissimilar to the easter egg applet pranks used by programmers working for major application publishers to express their individuality.

Fridrik Skulason, whose F-Prot has provided the engine for a number of anti-virus products over the years, exhaustively analyzed the later Ohio and Den Zuk versions of the Brain virus.

The Ohio (Den Zuk 1) and Den Zuk (Venezuelan, Search) variants contain some of the same code as Brain in order to prevent overlaying by Brain. However, Ohio and Den Zuk identify and overwrite Brain infections with themselves. They can be described as single-shot anti-virus utilities targeting the Brain virus (at the expense, however, of causing the Ohio and Den Zuk infections). Skulason also found that the Den Zuk version would overwrite an Ohio infection. (This seeking activity gives rise to one of Den Zuk's aliases: *Search*.)

It was also suspected that denzuko might have referred to the Search for Brain infections. Extensive searches for the meaning of the words *den zuk* and *denzuko* in a number of languages, as an attempt to find clues to the identity of the virus author, turned up closely related words meaning *sugar* and *knife* as well as *search*. However, these turned out to be quite beside the point.

There is text in both Den Zuk and Ohio that suggests they were written by the same author. Ohio contains an address in Indonesia (and none in Ohio — the name derives from Ohio State University, where it was first identified). Both contain a ham-radio license number issued in Indonesia. Both contain the same programming bug. The FAT (file allocation table) and data areas are overwritten if a floppy disk with a higher capacity than 360 kb is infected. Den Zuk is a more sophisticated exercise in programming. Skulason concluded, therefore, that Ohio was in fact an earlier version of Den Zuk.

The virus' author, apparently a college student in Indonesia, confirmed Skulason's hypotheses. There had been attempts to trace the virus' origins through the words *denzuk* and *denzuko*. In fact, Den Zuko turned out to be the author's nickname, derived from John Travolta's character in the movie *Grease*.

Stoned (and Variants)

The Stoned virus seems to have been written by a high school student in New Zealand — hence its other main alias, *New Zealand*. All evidence suggests that he wrote the virus only for study and that he took precautions against the release of the code. These safeguards proved insufficient, as it turned out. It is reported that his brother stole a copy and decided to infect the machines of friends.

The original version of Stoned is said to have been restricted to infecting floppy disks. The current, most common version of Stoned, however, infects all disks. It is an example of a second class of boot-sector-infecting viral programs in that it places itself in the master boot record or partition boot record of a hard disk instead

of the boot sector (as it does on floppy disks). In common with most BSIs, Stoned moves the original sector into a new location on the disk. On hard disks and double-density floppies, this movement is not usually a problem. On high-density floppies, however, system information can be overwritten, resulting in loss of data. One version of Stoned reportedly does not infect 3½-inch diskettes; this version may well be the template for Michelangelo, which does not infect 720 kb disks either.

Michelangelo, Monkey, and Other Stoned Variants

Stoned has spawned a large number of mutations ranging from minor variations in the spelling of the payload message to the functionally different Empire, Monkey, and No-Int variations.

Michelangelo is generally believed by researchers to have been built on or mutated from the Stoned virus. The similarity of the replication mechanism, down to the inclusion of the same bugs, puts this theory beyond any reasonable doubt. Any successful virus is likely to be copied. Michelangelo is unusual only in the extent to which the payload has been modified.

Roger Riordan reported and named the virus in Australia in February of 1991. He suspected that the virus had entered the victim company on disks of software from Taiwan, but this hypothesis remains unproven. The date indicates the existence of the virus prior to March 6, 1991. This demonstrates that the virus can survive its own deletion of disk information every March 6, even though it destroys itself along with the system tracks of disks overwritten on that date. This resiliency is not really surprising — few computer users understand that boot viruses can, in principle, infect any disk from any other disk, regardless of whether the disk is bootable, contains any program files, or contains any files at all.

Riordan determined that March 6 was the trigger date. It is often assumed from the name of the virus that it was intended to trigger on March 6 because that is the birthday of Michelangelo Buonarotti, the Renaissance artist, sculptor, and engineer. However, there is no text in the body of the virus, no reference to Michelangelo, and no evidence of any sort that the author of the virus was aware of the significance of that particular date. The name is simply the one that Riordan chose to give it, based on the fact that a friend with the same birth date knew that it was also Michelangelo's.

By the beginning of 1992, commercial production software was being shipped on Michelangelo-infected floppies, and at least one company was shipping infected PC systems. It has been suggested that, by the end of February of that year, when the general public was becoming aware of the problem, the number of infected floppies out in the field may have been in the millions. Fortunately, most infected machines were checked and diagnosed before March 6 of that year.

The replication mechanism of Michelangelo is basically that of Stoned. It replaces the original boot sector on a floppy disk with a copy of itself. The virus moves the original boot sector to sector 3 (for 360 kb diskettes) or 14 (for 1.2 or 1.44 MB diskettes), and the virus contains a "loader" that points to this location. After the virus loads itself into memory, the original boot sector is run; to the user, the boot process appears to proceed normally. On hard disks, the original partition sector is moved to (0,0,7).

Michelangelo is no stealth virus. Examination of the boot blocks shows a clear difference between a valid sector and the one that is infected. (The absence of the normal system messages should be a tip-off — Michelangelo contains no text whatsoever.) In addition, Michelangelo reserves itself 2 kb at the top of memory. A simple run of DOS' CHKDSK utility will show total conventional memory on the system; and if a 640 kb machine shows 655,360 bytes, then the computer is not infected with Michelangelo. (If the number is less, there may still be reasons other than a virus; and if the number is 655,360, that does not, of course, prove that no virus is present or active.)

Removal is a simple matter of placing the original sector back where it belongs, thus wiping out the infection. This can be done with sector-editing utilities, or even with DEBUG, although it would normally be easier and safer to simply use an anti-virus utility. There have been many cases where a computer has been infected with both Stoned and Michelangelo. In this situation, the boot sector cannot be recovered, because both Stoned and Michelangelo use the same "landing zone" for the original sector; and the infection by the second virus overwrites the original boot sector with the contents of the first virus.

When an infected computer boots up, Michelangelo checks the date via Interrupt 1Ah. If the date is March 6, the virus then overwrites the first several cylinders of the disk with the contents of memory. Interrupt 1Ah is not usually available on the earliest PCs and XTs (with some exceptions). However, the disk that is overwritten is the disk from which the system is booting; a hard disk can be saved simply by booting from a floppy. Also, the damage is triggered only at boot time, although this is not altogether a positive. The fact that the damage

occurs during the boot process means that the payload, like the infection mechanism, is no respecter of operating systems — it and can and does trash non-DOS operating systems such as UNIX.

A number of suggestions were made in early 1992 as to how to deal with Michelangelo without using anti-virus software. Because so many anti-viral programs — commercial, shareware, and freeware — identified the virus, it seems odd that people were so desperate to avoid this obvious step of using a scanning program to find the virus.

Some people recommended backing up data, which is always a good idea. And, given that Michelangelo is a boot-sector infector, it would not be stored on a tape backup. However, diskettes are a natural target for BSIs. Today, diskettes are much less favored for major backup purposes. Zip disks, tapes, and other high-capacity writeable media are cheap and highly available. At that time, however, many popular backup programs used proprietary non-DOS disk formats for reasons of speed and additional storage. These, if infected by Michelangelo, would become unusable.

Changing the computer clock was also a popular suggestion. Because Michelangelo was set to go off on March 6, theoretically you could just set the computer clock to make sure that it never reached March 6. However, many people did not understand the difference between the MS-DOS clock and the system clock read by Interrupt 1Ah. The MS-DOS DATE command did not always alter the system clock. Network-connected machines often have time-server functions so that the date would be reset to conform to the network. The year 1992 was a leap year, and many clocks did not deal with it properly. Thus, for many computers, March 6 came on Thursday, not Friday. This suggestion comes up time and again for dealing with viruses with a known trigger date (CIH, for example) and was trotted out again for dealing with the Y2K bug.

An even sillier suggestion was to test for Michelangelo by setting the date to March 6 and then rebooting the computer. This strategy became known as *Michelangelo roulette*. One vendor actually reported an incident where a customer switched on a machine on the fatal morning and when the machine promptly died, the customer switched on the other machines in the office to see if the same thing happened. It did.

Many people suggested a modem avoidance strategy. Such a strategy is, of course, no defense worth mentioning against any boot-sector virus. Neither the master/partition boot record nor the boot sector is an identifiable, transferable file. Neither can be transmitted by an everyday user as a file over a modem or Ethernet connection, although an infected disk can be transferred over a network connection as a binary image. Although dropper programs are theoretically possible, they are rarely used as a means of disseminating a virus through unsuspecting users. The danger of getting a Michelangelo infection from a BBS was, therefore, so small that for all practical purposes it did not exist. Warning against bulletin boards, or, more recently, Web sites, merely proscribes a major source of advice and utility software.

Unlike the Columbus Day/Datacrime hypefest of 1989, the epidemic of Michelangelo in the spring of 1992 had its basis in fact. Vendors were making unsubstantiated claims for the numbers of infections, which, in retrospect, turned out to have been surprisingly accurate. More importantly, the research community as a whole was seeing large numbers of infections. The public was seeing them as well. No fewer than 15 companies shipped commercial products that turned out to be infected with the Michelangelo virus.

Two producers of commercial anti-viral programs released crippled freeware versions of their scanners. The programs did briefly mention that they checked only for Michelangelo, but certainly gave users the impression that they were checking the whole system. Happily, the trend over recent years has been to produce small, single-shot programs for dealing urgently with high-profile viruses rather than a crippled version of a free package. Even this approach has its drawbacks — recently, there was an instance where a Hybris infection was almost overlooked because the freeware program used could detect only a single variant. Oddly, it was a later variant than the one actually found on the machine in question. It seems that the vendor assumed that anyone using it would already have updates of their product for the previous versions. Because the vendor in question was also responsible for one of the free Michelangelo scanners, perhaps the average vendor's sense of ethical responsibility has not been raised as far as one could hope.

Because of the media attention, a number of checks were made that would not have been done otherwise. Hundreds and even thousands of copies of Michelangelo were found within single institutions. Because many copies had been found and removed, the number of hits on March 6 was not spectacular. Predictably, perhaps, media reports on March 6 started to dismiss the Michelangelo scare as another over-hyped rumor, completely missing the reality that millions of machines had possibly been struck.

File Infectors

Lehigh

Lehigh only infects COMMAND.COM, the operating system interpreter program in MS-DOS, which rather restricts its capacity to spread because bootable floppy disks became much less common with the rise of hard disk drives and almost completely vanished with the advent of Windows. (The target of infection means that Lehigh can be considered a system infector under the more recent definition of that term.) Nevertheless, it received a great deal of publicity and had a direct impact on the anti-virus scene. Ken van Wyk, who was working at Lehigh at the time (and went on to join CERT [Carnegie Mellon University's Computer Emergency Response Team]), set up the VIRUS-L/comp.virus mailing list and newsgroup. Unfortunately, VIRUS-L seems to have disappeared, but it was for a number of years the primary source of accurate virus information and, in large measure, responsible for ensuring that the anti-virus research community did in fact become a community.

The Lehigh virus overwrote the slack space at the end of the COMMAND.COM file. This meant that the virus did not increase the size of infected files. A later report of a 555-byte increase in file size was due to confusion over the size of the overwriting code. When an infected COMMAND.COM was run (usually upon booting from an infected disk), the virus stayed resident in memory. When any access was made to another disk, via the TYPE, COPY, DIR, or other normal DOS commands, COMMAND.COM files would be infected. The virus kept a counter of infections: after four infections, the virus would overwrite the boot and FAT areas of disks with bytes copied from BIOS.

Lehigh (the virus, not the campus) is remarkably stealth free. The primary defense of the virus was that, at the time, no one would have been looking for it. The virus altered the date stamp of infected COMMAND.COM files. If attempting an infection on a write-protected disk, the virus would not trap the Write Protect Error message. This message is a serious giveaway if seen as a result of typing dir — generating the directory listing should not require writing to the diskette (unless output is redirected).

The virus was limited in its target population to those disks that had a COMMAND.COM file and, more particularly, those that contained a full operating system. The virus was also self-limiting in that it would destroy itself once activated and would activate after only four reproductions. The Lehigh virus never did spread beyond the campus in that initial attack. Although it is found in a number of private virus collections and may be released into the wild from time to time, the virus has no real chance of spreading.

Jerusalem

In terms of the number of infections (copies or reproductions) that a virus produces, boot-sector viral programs long held an advantage in the microcomputer environment. Among file-infecting viral programs, however, the Jerusalem virus was the clear winner. It has another claim to fame as well: it almost certainly has the largest number of variants of any virus program known to date, at least in its class of parasitic file infectors.

Initially known to some as the Israeli virus, the version reported by Y. Radai in early 1988 (also sometimes referred to as *1813* or *Jerusalem-B*) was the most commonly encountered version. Although it was the first to be widely disseminated and was the first to be discovered and publicized, analysis suggests that it was the outcome of previous viral experiments.

A few things are common to pretty much all of the Jerusalem family. They usually infect both .com and .exe files. When an infected file is executed, the virus "goes TSR (terminate and stay resident)" — that is, it installs itself into memory. Thus, it remains active even after the originally infected program is terminated. The .exe programs executed after the program goes resident are infected by appending the virus code to the end of the file. Prepending code infects .com files. Most variants carry some kind of date logic-bomb payload, often triggered on Friday the 13th. Sometimes the logic bomb is simply a message; often, it deletes programs as they are accessed.

Although Jerusalem tends to work well with .com files, the differing structure of .exe files has presented Jerusalem with a number of problems. Early versions of Jerusalem, not content with one infection, will reinfect .exe files again and again so that they continually grow in size. This growth renders pointless the attempt at stealth that the programmer built in when he ensured that the file creation date was conserved and unchanged in an infected file. Also, .exe programs that use internal loaders or overlay files tend to be infected in the wrong place and have portions of the original program overwritten. Although the virus was reported to slow down systems that were infected, it seems to have been the continual growth of .exe files that led to the detection of the virus.

The great number of variants has contributed to severe naming and identification problems. Because a number of the variants are based on the same code, the signatures for one variant often match another — thus generating even more naming confusion. This confusion is not unique to the Jerusalem family, of course, and is an ongoing concern in the anti-virus research community, while systems administrators are growing increasingly forceful and vociferous in their demands for a unified nomenclature.

An early infection was found in an office belonging to the Israeli defense forces, giving rise to the occasional synonym IDF. This synonym was actually problematical because it was more often used as a synonym for the unrelated Frodo virus.

The common Jerusalem payload of file deletion on Friday the 13th (yet another alias) begged a question as to why the logic bomb had not gone off on Friday, November 13, 1987. Subsequent analysis has shown that the virus will activate the payload only if the year is not 1987. The next following Friday the 13th was May 13th, 1988. Because the last day that Palestine existed as a nation was May 13, 1948, it was felt that the virus might have been an act of political terrorism. This supposition led to another alias, the PLO virus. However, Israel celebrates its holidays according to the Jewish calendar (no surprises there), and the independence celebrations were slated for three weeks before May 13, 1988. These facts, and the links between Jerusalem and the sURIV family, suggest that there is no intentional political link. It is almost certain that the Jerusalem virus is, in fact, two viral programs combined. The two viruses, and others in the development family, have been found.

sURIV 1.01 is a .com-file infector — .com is the easier file structure and therefore the easier program to infect. sURIV 2 is an .exe-only infector and has considerably longer and more complex code. sURIV 3 infects both types of program files and has considerable duplication of code; it is, in fact, simply the first two versions concatenated together.

Although the code in the sURIV programs and the 1813 version of Jerusalem is not absolutely identical, all the same features are duplicated. The payload date for sURIV is April 1, and the year has to be later than 1988. Although this seems to suggest that sURIV is a descendant of Jerusalem, the reverse is probably the case. Certainly the code is less sophisticated in the sURIV variants.

More recent viruses that infect Windows portable executable (PE) files, as well as Lindose/Winux, which infects both Windows PE and Linux ELF files, are considered to be an advance in virus technology. In fact, they are simply following in the footsteps of Jerusalem.

The Jerusalem virus was immensely successful as a template for variants. The code is reasonably straightforward and, for those with some familiarity with assembly programming, an excellent primer for writing viral programs affecting both .com and .exe files. It has a number of annoying bugs, however. It can misinfect some .exe files. It can conflict with Novell NetWare, which requires the use of Interrupt 21h subfunctions that are also used by the virus. One of the *Sunday* variants is supposed to delete files on the seventh day of the week. The author did not realize that computers start counting from zero and that Sunday is actually the *zero* day of the week — so there is no seventh day, and the file deletions never actually happen.

E-mail Viruses

CHRISTMA Exec

CHRISTMA exec, the Christmas Tree virus/worm, sometimes referred to as the BITNET chain letter, was probably the first major malware attack across networks. It was launched on December 9, 1987, and spread widely on BITNET, EARN, and IBM's internal network (VNet). It has a number of claims to a small place in history. It was written, unusually, in REXX. It was mainframe-hosted (on VM/CMS systems) rather than microcomputer-hosted — quaint as that distinction sounds today, when the humblest PC can run UNIX.

CHRISTMA presented itself as a chain letter inviting the recipient to execute its code. This involvement of the user led to the definition of the first e-mail virus rather than a worm. When it was executed, the program drew a Christmas tree and mailed a copy of itself to everyone in the account holder's equivalent to an address book, the user files NAMES and NETLOG. Conceptually, there is a direct line of succession from this worm to the social engineering worm/Trojan hybrids of today.

W97M/Melissa (Mailissa)

She came from alt.sex.

Now, as the old joke goes, that I have your attention …

In this instance, however, the lure of sex was certainly employed to launch the virus into the wild. The source of the infestation of the Melissa Word macro virus (more formally identified as some variation on W97M/Melissa) was a posting on the Usenet newsgroup alt.sex. The message had a Word document attached. (More details of macro viruses are given later in regard to the Concept virus.) The posting suggested that the document contained account names and passwords for Web sites carrying salacious material. As one might expect in such a newsgroup, a number of people read the document. It carried a macro that used the functions of Microsoft Word and the Microsoft Outlook mailer program to reproduce and spread itself — rather successfully, as it turns out. Melissa is not the fastest-burning e-mail-aware malware to date, but it certainly held the record for awhile.

Many mail programs, in the name of convenience, are becoming more automated. Much of this automation has focused on running attached files, or scripting functions included in HTML-formatted messages, without requiring the intervention of the victim.

To be susceptible to the effects of Melissa, a victim needed to be running Microsoft Word 97 or later, or Microsoft Outlook 98 or later. It was also necessary to receive an infected file and read it into Word without disabling the macro capability. However, all of these conditions are normal for many users. Receiving infected documents has never been a problem, from WM/Concept onward. Melissa increased the likelihood that any given individual user would eventually receive an infected document by the sheer weight of numbers. However, by judicious social engineering, the virus also increased the chances of persuading a victim to open an infected document. Many mail programs will now detect the type of a file from its extension and start the appropriate program automatically.

On execution, the virus first checks to see whether an infectable version of Word is running. If so, Melissa reduces the level of security on Word so that no future warnings of macro content are displayed. Under Word 2000, the virus blocks access to the menu item that allows you to raise your security level and sets your macro virus detection to the lowest level — that is, to none. Restoring the security level requires the deletion of the Normal.dot file and the consequent loss of legitimate macros and customizations.

The virus checks for the registry key HKEY_CURRENT_USER\Software\Microsoft\Office\Melissa?\ with a value of "… by Kwyjibo." (The "Kwyjibo" entry seems to be a reference to the "Bart the Genius" episode of *The Simpsons* television cartoon program wherein Bart Simpson used this word to win a Scrabble match.) If that key is not found, the macro starts up Outlook and sends itself as an attachment to the top 50 names in each of your address lists. Most people have only one (the default is Contacts); but if there is more than one, then Outlook will send more than 50 copies of the message. Outlook also sorts address lists so that other mailing lists are at the top of the list. In addition, under a Microsoft Exchange Server, the macro can send copies out to the global address lists on the server. Therefore, a single infected machine may distribute far more than 50 copies of the message/virus in the next "hop."

Like most macro viruses, Melissa worked by infecting the global template and infecting all documents thereafter. Each document created or reviewed was infected when closed. Each infected document activated the macro when the file was opened. Avoiding Outlook did not offer protection from the virus; it only meant that the 50 copies would not be sent out automatically. If Microsoft Word was used, but not Outlook, the machine would still be infected, and infected documents could still be sent out in the normal course of operations.

The virus cannot invoke the mass-mailer dispersal mechanism on Macintosh systems, but it can be stored and resent from Macs.

As with any Word macro virus, the source code travels with the infection and it was very easy to create modifications to Melissa. Many Melissa variants with different subjects and messages started to appear shortly after the original virus appeared. The first similar Excel macro virus was called *Papa*, although this and its progeny never had the same global impact as Melissa. In fact, the source code was published more widely than usual in newgroups, on the Web, and elsewhere.

In one distressing instance, a major security organization issued a flash advisory including a range of information of varying quality and relevance. Unfortunately, it also included the entire source code, trivially modified so that it would not run without some tweaking.

As with many more recent mail-borne nuisances, a number of fixes such as sendmail and procmail recipes for mail servers and mail filtering systems were devised very quickly. However, these fixes were often not fully tested or debugged. One version would trap most of the warning messages about Melissa. Mail filters can, of course, become problems. In the mailing of the author's initial report on the virus, it bounced from one system because of an automated filter that interpreted the message as a hoax virus warning.

W95.Hybris

The Hybris worm started to make its mark in late September 2000. It is disseminated by an e-mail message that is often but by no means always sent from hahaha@sexyfun.net. This address is forged to make it harder to trace the infected source. However, the sexyfun.net domain was later set up and used as a Hybris information resource. The worm may sometimes check the language settings of the host computer and select a "story" relating to Snow White and the Seven Dwarfs in English, French, Spanish, or Portuguese, used as message text to accompany the copy of the worm when it is mailed out, and implying that the attached file is a kind of pornographic screen saver.

When the worm attachment is executed, the WSOCK32.DLL file is modified or replaced so that it can track e-mail and other Internet traffic. When the worm detects an e-mail address, it sends infected e-mail to that address. It also connects to alt.comp.virus and uploads encrypted plug-in modules to the group. If it finds newer plug-ins, the worm downloads them for its own use. For several months, alt.comp.virus was almost unusable because of the sheer numbers of plug-ins clogging the group.

Worms

The Morris Worm (Internet Worm)

In the autumn of 1988, most people were blissfully ignorant of viruses and the Internet. However, I recall that Virus-L had been established and was very active. At that time the list was still an exploder re-mailer, rather than a digest; but postings were coming out pretty much on a daily basis. However, there were no postings on November 3 or on November 4. It was not until November 5, actually, that I found out why.

The Morris Worm did not actually bring the Internet in general and e-mail in particular to the proverbial grinding halt. It was able to run and propagate only on machines running specific versions of the UNIX operating system on specific hardware platforms. However, given that the machines that are connected to the Internet also comprise the transport mechanism for the Internet, a "minority group" of server-class machines, thus affected, degraded the performance of the Net as a whole. Indeed, it can be argued that, despite the greater volumes of mail generated by Melissa and LoveLetter and the tendency of some types of mail servers to achieve meltdown when faced with the consequent traffic, the Internet as a whole has proved to be somewhat more resilient in recent years.

During the 1988 mailstorm, a sufficient number of machines had been affected to impair e-mail and distribution-list mailings. Some mail was lost, either by mailers that could not handle the large volumes that backed up or by mail queues being dumped in an effort to disinfect systems. Most mail was substantially delayed. In some cases, mail would have been rerouted via a possibly less efficient path after a certain time. In other cases, backbone machines, affected by the problem, were simply much slower at processing mail. In still others, mail-routing software would crash or be taken out of service, with a consequent delay in mail delivery. Ironically, electronic mail was the primary means of communication of the various parties attempting to deal with the trouble. By Sunday, November 6, mail was flowing, distribution lists and electronic periodicals were running, and the news was getting around. However, an enormous volume of traffic was given over to one topic — the Internet worm.

In many ways, the Internet worm is the story of data security in miniature. The worm used trusted links, password cracking, security holes in standard programs, standard and default operations, and, of course, the power of viral replication.

"Big Iron" mainframes and other multi-user server systems are generally designed to run constantly, and they execute various types of programs and procedures in the absence of operator intervention. Many hundreds of functions and processes may be running all the time, expressly designed to neither require nor report to an operator. Some processes cooperate with each other; others run independently. In the UNIX world, such small utility programs are referred to as daemons, after the supposedly subordinate entities that take over mundane tasks and extend the power of the wizard, or skilled operator. Many of these utility programs deal with the communications between systems. Mail, in the network sense, covers much more than the delivery of text messages between users. Network mail between systems may deal with file transfers, the routing of information for reaching remote systems, or even upgrades and patches to system software.

When the Internet worm was well established on a machine, it would try to infect another. On many systems this attempt was all too easy — computers on the Internet were meant to generate activity on each other, and some had no protection in terms of the type of access and activity allowed.

The finger program is one that allows a user to obtain information about another user. The server program *fingerd* is the daemon that listens for calls from the finger client. The version of fingerd common at the time of the Internet Worm had a minor problem: it did not check how much information it was given. It would take as much as it could hold and leave the rest to overflow. The *rest*, unfortunately, could be used to start a process on the computer, and this process was used as part of the attack. This kind of buffer overflow attack continues to be very common, taking advantage of similar weaknesses in a wide range of applications and utilities.

The sendmail program is the engine of most mail-oriented processes on UNIX systems connected to the Internet. In principle, it should only allow data received from another system to be passed to a user address. However, there is a debug mode that allows commands to be passed to the system. Some versions of UNIX were shipped with the debug mode enabled by default. Even worse, the debug mode was often enabled during installation of sendmail for testing and then never turned off.

When the worm accessed a system, it was fed with the main program from the previously infected site. Two programs were used, one for each infected platform. If neither program could work, the Worm would erase itself. If the new host was suitable, the worm looked for further hosts and connections.

The program also tried to break into user accounts on the infected machine. It used standard password-cracking techniques such as simple variations on the name of the account and the user. It carried a dictionary of words likely to be used as passwords, and would also look for a dictionary on the new machine and attempt to use that as well. If an account were cracked, the worm would look for accounts that this user had on other computers, using standard UNIX tools.

The worm did include a means of checking for copies already running on a target computer. However, it took some time to terminate the program; and the worm regularly produced copies of itself that would not respond to the request for termination at all. The copies of the Worm did destroy themselves — having first made a new copy. In this way, the identifying process ID number would continually change.

The worm was not intentionally destructive. However, the mere presence of the program had implications for the infected systems and for those associated with them. The multiple copies of the program that ran on the host machines had a serious impact on other processes. Also, communications links and processes were used to propagate the worm rather than to support the legitimate work for which they were intended.

Linux Worms

By spring 2001, a number of examples of Linux malware had been seen. Interestingly, while the Windows viruses generally followed the CHRISTMA exec style of having users run the scripts and programs, the new Linux worms were similar to the Internet/Morris/UNIX worms in that they rely primarily on bugs in automatic networking software.

Ramen

The Ramen worm makes use of security vulnerabilities in default installations of Red Hat Linux 6.2 and 7.0 using specific versions of the wu-ftp, rpc.statd, and LPRng programs. The worm defaces Web servers by replacing index.html and scans for other vulnerable systems. It does this initially by opening an ftp connection and checking the remote system's ftp banner message. If the system is vulnerable, the worm uses one of the exploitable services to create a working directory; it then downloads a copy of itself from the local (attacking) system.

Compromised systems send out e-mail messages to two Hotmail and Yahoo! accounts, and ftp services are disabled. Ramen's SYN scanning may disrupt network services if multicasting is supported by the network.

Lion

Lion uses a buffer overflow vulnerability in the bind program to spread. When it infects, Lion sends a copy of output from the ifconfig commands etc/passwd and /etc/shadow to an e-mail address in the china.com domain. Next, the worm adds an entry to etc/inetd.conf and restarts inetd. This entry would allow Lion to download components from a (now closed) Web server located in China. Subsequently, Lion scans random class B subnets in much the same way as Ramen, looking for vulnerable hosts. The worm may install a rootkit onto infected systems. This backdoor disables the syslogd daemon and adds a Trojanized SSH (secure shell) daemon.

The worm replaces several system executables with modified versions. The /bin/in.telnetd and /bin/mjy files provide additional backdoor functionality and attempt to conceal the rootkit's presence by hiding files and processes.

Adore (Linux/Red)

Adore is a Linux worm similar to Linux/Ramen and Linux/Lion. It uses vulnerabilities in wu-ftpd, bind, lpd, and RPC.statd that enable an intruder to gain root access and run unauthorized code. The worm attempts to send IP configuration data, information about running processes, and copies of /etc/hosts and /etc/shadow to e-mail addresses in China. It also scans for class B IP addresses.

Adore drops a script called 0anacron into the /etc/cron.daily directory so that the script runs as a daily cron job. The cron utility executes scheduled tasks at predetermined times. This script removes the worm from the infected host. A modified version of the system program /bin/ps that conceals the presence of the worm's processes replaces the original.

Code Red

Code Red uses a known vulnerability to target Microsoft IIS (Internet Information Server) Web servers. Despite the fact that a patch for the loophole had been available for five months prior to the release of Code Red, the worm managed to infect 350,000 servers within nine to thirteen hours.

When a host gets infected, it starts to scan for other hosts to infect. It probes random IP addresses, but the code is flawed by always using the same seed for the random number generator. Therefore, each infected server starts probing the same addresses that have been done before. (It was this bug that allowed the establishment of such a precise count for the number of infections.)

During a certain period of time the worm only spreads, but then it initiates a denial-of-service (DoS) attack against www1.whitehouse.gov. However, because this particular machine name was only an overflow server, it was taken offline prior to the attack and no disruptions resulted.

The worm changed the front page of an infected server to display certain text and a background color of red — hence the name of the worm.

Code Red definitely became a media virus. Although it infected at least 350,000 machines within hours, it had probably almost exhausted its target population by that time. Despite this, the FBI held a rather ill-informed press conference to warn of the worm.

Code Red seems to have spawned quite a family, each variant improving slightly on the random probing mechanism. In fact, there is considerable evidence that Nimda is a descendent of Code Red.

Nimda variants all use a number of means to spread. Like Code Red, Nimda searches random IP addresses for unpatched Microsoft IIS machines. Nimda will also alter Web pages in order to download and install itself on computers browsing an infected Web site using a known exploit in Microsoft Internet Explorer's handling of Java. Nimda will also mail itself as a file attachment and will install itself on any computer on which the file attachment is executed. Nimda is normally e-mailed in HTML format and may install automatically when viewed using a known exploit in Microsoft Internet Explorer. Nimda will also create e-mail and news files on network shares and will install itself if these files are opened.

Macro Viruses

Concept

WM/Concept was by no means the first macro virus. HyperCard viruses were already commonplace in the Macintosh arena when WM/Concept appeared, and a number of anti-virus researchers had explored WordBasic and other malware-friendly macro environments (notably Lotus 1–2–3) long before the virus appeared in 1995.

However, WM/Concept was the first macro virus to be publicly described as such, and certainly the most successful in terms of spread. For awhile, it was easily the most widely found virus in the world. Oddly enough, however, its appearance was greeted with disbelief in some quarters. After all, a Word file is usually thought of as data rather than a program file.

People cling to the belief that, because executable files run programs and data files contain data, there is a clear-cut distinction between the two file types. In fact, this has never been true; and the von Neumann architecture makes such a differentiation impossible. What may be perceived as a data file may be, in reality,

a program. A PostScript file is, in fact, a program read and acted upon by a PostScript interpreter program. A printer normally executes this program, but a program such as GhostView can also interpret a PostScript file and print it to the screen on the host computer.

The first in-the-wild examples specifically targeted Microsoft Word v6.0, but code for viruses infecting Excel and Ami Pro also appeared very quickly. All versions of Word for Windows and Word 6 and later for the Macintosh include a sophisticated macro language (WordBasic in older versions, and later Visual Basic for Applications, or VBA). Such applications are capable of all the functions normally associated with a high-level programming language such as Basic. In fact, macro languages used by Windows applications are based on Microsoft's Visual Basic.

Concept spread far and (for its time) rapidly. It got something of a boost when two companies accidentally shipped it in infected documents on CD-ROM. The first instance was a Microsoft CD called MicroSoft Windows '95 Software Compatibility Test. The CD was shipped to a number of large original equipment manufacturing (OEM) companies in the summer of 1995 as a means of checking compatibility with Windows 95, which was due for imminent release. However, the CD contained a document called oemltr.doc, which was infected with Concept. A few months later, Microsoft UK distributed the virus on another CD, The Microsoft Office 95 and Windows 95 Business Guide, in a document called helpdesk.doc.

Concept was fairly obvious and could be forestalled and even fixed (with patience) without the aid of anti-virus software. When a Concept-infected file was opened, a message box appeared containing the number 1 and an OK button. You could also detect the virus' presence by checking the Tools/Macros submenu for the presence of macros.

A WM/Concept.A infection is characterized by the presence of the macros AAAZFS, AAAZAO, AutoOpen, Payload, and FileSaveAs. Any document might legitimately use AutoOpen or FileSaveAs. However, macros with the names Payload, AAAZFS, and AAAZAO are something of a giveaway. The macros are not encrypted, so it is easy to spot the virus. On the other hand, this lack of encryption also made it easy to modify the code. Virus writers learned almost immediately to conceal the internals of their macros by implementing them as execute-only macros, which cannot be edited or easily viewed.

Although Concept.A has a payload macro, it has no actual payload. Famously, it contains the string "That's enough to prove my point," which explains the name Concept (as in "proof of concept").

Concept.A was a fairly harmless affair, as viruses go: it tampered with Word 6's global template (normally Normal.dot, or Normal on a Macintosh) so that files were saved as templates and ran the infective AutoOpen macro. This gave Mac users an additional advantage in that template files on the Mac have a different icon to document files. As long as the virus infected only template files, this icon was a frequently found heads-up to Mac users that they might have a virus problem. However, in later versions of Word, the distinction between documents and templates is less absolute; and that particular heuristic has become less viable.

In a sense, the main importance of Concept was that the code could be altered very quickly to incorporate a destructive payload, alternative infection techniques, and evasion of the first attempts at detecting it. This virus has been described as the first cross-platform virus in that it works on any platform. However, this description is not altogether accurate: it only infected systems running Word 6 or Word 95, although versions are known that can infect Word 97 and later.

Script Viruses

VBS/LoveLetter

LoveLetter first hit the nets on May 3, 2000. It spread rapidly, arguably faster than Melissa had the previous year.

The original LoveLetter came in an e-mail with a subject line of "I LOVE YOU." The message consisted of a short note urging you to read the attached love letter. The attachment filename, LOVE-LETTER-FOR-YOU.TXT.vbs, was a fairly obvious piece of social engineering. The .TXT bit was supposed to make people think that the attachment was a text file and thus safe to read. At that point, many people had no idea what the .vbs extension signified; and in any case they might have been unaware that, if a filename has a double extension, only the last filename extension has any special significance. Putting vbs in lower case was likely meant to play down the extension's significance. However Windows, like DOS before it, is not case sensitive when it comes to filenames, and the .vbs extension indicates a Visual Basic script.

If Windows 98, Windows 2000, Internet Explorer 5, Outlook 5, or a few other programs are installed, then so is Windows Script Host (WSH); and there is a file association binding the .vbs extension to WSCRIPT.EXE. In

that case, double-clicking on the file attachment is enough to start WSH and interpret the contents of the "love letter."

The infection mechanism included the installation of some files in the Windows and System directories. These files were simply copies of the original .vbs file — in one case keeping the name of LOVE-LETTER-FOR- YOU.TXT.vbs, but in other cases renaming files to fool people into thinking that they were part of the system (MSKERNEL32.vbs and WIN32DLL.vbs).

The virus made changes to the registry so that these files would be run when the computer started up. Today, many organizations routinely quarantine or bounce files with a .vbs extension (especially a double extension) at the mail gateway.

LoveLetter infects files with the extensions .vbs, .vbe, .js, .jse, .css, .wsh, .sct, .hta, .jpg, .jpeg, .mp2, and .mp3. The infection routine searches local drives and all mounted network drives, so shared directories can be an additional source of infection. The routines overwrite most of these files with a copy of the script (that is, the original file is not preserved anywhere, although the new file has a different name) and change the filenames from (for example) picture.jpg to picture.jpg.vbs. In some cases, the virus simply deletes the original file. MPEGs, however, are not overwritten. The original file, say song.mp3, is marked as hidden; and a new file, song.mp3.vbs, is created with a copy of the virus. The .vbs extension must, of course, be added for the virus to be effective.

Once the virus has copied itself all over a host machine, it starts to spread to other machines. If Outlook is present, the virus will use any addresses associated with the mail program to send copies of itself (but once only). As with Melissa, this means that when a copy of LoveLetter was received, it would appear to come from someone known to the recipient. In addition, the program tries to make a connection to IRC, using the mIRC chat program, and spread that way. The Love Bug (as it was also known) creates another copy of the file, LOVE-LETTER-FOR-YOU.HTM, in the Windows System directory, and then sends that copy to any user who joins the IRC channel while the session is active.

When a system is infected, the worm attempts to download a Trojan application from a Web site in the Philippines by changing the start-up URL in Internet Explorer. The file, named WIN-BUGSFIX.exe, will try to collect various password files and e-mail them to an address in the Philippines. If the file is executed, the Trojan also creates a hidden window called BAROK and remains resident and active in memory. However, this site was probably overloaded in the early hours of the LoveLetter infection, and was quickly taken down.

A very large number of LoveLetter "cleaners" were made available. Interestingly, most of them were Visual Basic scripts themselves. Unfortunately, at least two variants of the virus pretended to be disinfecting tools and did more damage than the original virus.

Because the virus is an unencrypted script file, it carries its own source code with it. This means that variants started appearing within hours. Over a dozen were reported in the weekend after the virus first struck, and many more have been observed since. One of the more successful of these thanked the recipient for the order of a Mother's Day gift and claimed that the recipient's credit card had been charged $326.92 as per the attached invoice. Obviously, this ruse relied on people being too angry to think about how anybody could charge their credit card when they had not given the number to a vendor. Certainly, the variants showed a certain amount of innovation in the field of social engineering, if not in the actual code. One derivative targets UNIX systems using shell scripts but uses a very similar mechanism.

There have been estimates of damage stemming from LoveLetter in the billions of dollars. It is very difficult to justify those figures. Certainly, a number of e-mail systems were clogged, including those of some very large organizations. Many administrators shut down mail entirely rather than turn to filtering. In addition, the resetting of registry entries is likely to be somewhat time-consuming.

Text in the virus includes the string "Manila, Philippines." There are also the two Philippine e-mail addresses in the code and the Web site's URL. However, all charges against the individual long thought to have been the culprit were eventually dropped by the Manila Department of Justice.

Combinations and Convergence

BadTrans

BadTrans is a Win32 e-mail virus with backdoor functionality. It was found in the wild in April 2001.

The worm uses MAPI functions to access and respond to unread messages. The Trojan component is a version of Hooker, a password-stealing Trojan, and mails system information to ld8dl1@mailandnews.com.

On infection, the worm copies itself to \Windows as inetd.exe and drops the hkk32.exe Trojan, also to the Windows folder. The password stealer is executed and then moved to the system directory as kern32.exe, dropping a keystroke logging DLL (dynamic link library) at the same time. The worm modifies win.ini (Windows 9x) or the registry (Windows NT/2000) so that it is run on start-up.

When infective mail is sent, the worm randomly selects the attachment filename from a number of variants, some of them obviously influenced by previous worms. The subject field in worm messages is the same as in the original message, preceded by "Re:" so that it appears to be a response to that message. The message body also looks like a reply to the original message, which the body quotes in full. At the end of the quote, there is a single line, "Take a look to the attachment." The worm attempts to avoid answering the same mail twice or answering its own messages from other victim systems by adding two spaces to the end of the subject field and not responding to any mail with such a subject line. This mechanism is unreliable, however, because mail servers are likely to discard trailing spaces. In this event, an infective message received on a machine already infected will generate a response from the local instance of the worm, thus initiating a potential loop. A loop can also be initiated if the worm is unable to mark answered messages, as can happen with certain mail clients. Such a loop could result in a mail server meltdown.

Hoaxes

Good Times

Good Times is probably the most famous of all false alerts, and it was certainly the earliest that got widely distributed. Some controversy persists over the identity of the originators of the message, but it is possible that it was a sincere, if misguided, attempt to warn others. The hoax probably started in early December of 1994. In 1995, the FCC variant of the hoax began circulating.

It seems most likely that the Good Times alert was started by a group or an individual who had seen a computer failure without understanding the cause and associated it with an e-mail message that had Good Times in the subject line. (In fact, there are indications that the message started out on the AOL system, and it is known that there are bugs in AOL's mail software that can cause the program to hang.) The announcement states that there was a message identified by the title of Good Times that, when read, would crash a computer. The message was said to be a virus, although there was nothing viral about that sort of activity (even if it were possible).

At the time of the original Good Times message, e-mail was almost universally text based. Suffice it to say that the possibility of a straightforward text message carrying a virus in an infective form is remote. The fact that the warning contained almost no details at all should have been an indication that the message was not quite right. There was no information on how to detect, avoid, or get rid of the virus, except for its warning not to read messages with Good Times in the subject line. (The irony of the fact that many of the warnings contained these words seems to have escaped most people.)

Pathetically (and far from uniquely), a member of the vx community (Virus eXchange, those who write and spread viruses) produced a Good Times virus. Like the virus named after the older Proto-T hoax, the *real* Good Times was an uninteresting specimen, having nothing in common with the original alert. It is generally known as GT-Spoof by the anti-virus community, and was hardly ever found in the field.

Hoaxes are depressingly common and tend to have a number of common characteristics. Here is an annotated version of one:

> There is a virus out now sent to people via e-mail … it is called the A.I.D.S. VIRUS.

There are, in fact, an AIDS virus or two, but they are simple file-infecting viruses that have nothing to do with e-mail.

> It will destroy your memory, sound card and speakers, drive.

Many hoaxes suggest this kind of massive damage, including damage to hardware.

> And it will infect your mouse or pointing device as well as your keyboards.

Hoaxes also tend to state that the new virus has extreme forms of infection. In this case, it would be impossible for a virus to infect pointing devices or keyboards unless those pieces of equipment have memory and processing capabilities. None of these hoax warnings really detail how the virus is supposed to pass itself along.

> Making what you type not able to register on the screen. It self-terminates only after it eats 5MB of hard drive space

More damage claims …

> It will come via e-mail called "OPEN: VERY COOL! :)"

And the virus has no other characteristics, according to this alert.

> PASS IT ON QUICKLY & TO AS MANY PEOPLE AS POSSIBLE!!

This, of course, is the real virus, getting the user to spread it.

Trojan

The AIDS Trojan Extortion Scam

In the fall of 1989, approximately 10,000 copies of an "AIDS Information" package were sent out from a company calling itself PC Cyborg. Some were received at medical establishments; a number were received at other types of businesses. The packages appeared to have been professionally produced. Accompanying letters usually referred to them as sample or review copies. However, the packages also contained a very interesting license agreement:

> In case of breach of license, PC Cyborg Corporation reserves the right to use program mechanisms to ensure termination of the use of these programs. These program mechanisms will adversely affect other program applications on microcomputers. You are hereby advised of the most serious consequences of your failure to abide by the terms of this license agreement.

Further in the license is the sentence: "Warning: Do not use these programs unless you are prepared to pay for them."

The disks contained an installation program and a very simple AIDS information file and risk assessment. The installation program appeared to only copy the AIDS program onto the target hard disk, but in reality did much more. A hidden directory was created with a nonprinting character name, and a hidden program file with a nonprinting character in the name was installed. The autoexec.bat file was renamed and replaced with one that called the hidden program and then the original autoexec. The hidden program kept track of the number of times the computer was rebooted and, after a certain number, encrypted the hard disk. The user was then presented with an invoice and a demand to pay the license fee in return for the encryption key. Two major versions were found to have been shipped. One, which waited for 90 reboots, was thought to be the real attempt; an earlier version, which encrypted after one reboot, alerted authorities and was thought to be an error on the part of the principals of PC Cyborg.

The Panamanian address for PC Cyborg, thought by some to be a fake, turned out to be real. Four principals were identified, as well as an American accomplice who seems to have had plans to send 200,000 copies to American firms if the European test worked. The trial of the American, Joseph Popp, was suspended in Britain because his bizarre behavior in court was seen as an indication that he was unfit to plead. An Italian court, however, found him guilty and sentenced him in *absentia*.

RATs

BackOrifice

BackOrifice was developed by the hacker group Cult of the Dead Cow in order to take control of Windows 95 and 98 systems. A newer version, BackOrifice2000 (BO2K), was created in July 1999 in order to control Windows NT and 2000 systems.

As with all RATs, the BackOrifice2000 backdoor has two major parts: client and server. The server part needs to be installed on a computer system to gain access to it with the client part. The client part connects to the server part via network and is used to perform a wide variety of actions on the remote system. The client part has a dialogue interface that eases the process of hacking the remote computer.

In the same package there is also a configuration utility that is used to configure the server part of BO2K. It asks the user to specify networking type (TCP or UDP); port number (1-65535); connection encryption type, simple (XOR) or strong (3DES); and password for encryption that will be the password for the server access also.

The configuration utility allows flexibility in configuring the server part. It can add or remove plug-ins (DLLs) from the server application, configure file transfer properties, TCP and UDP settings, built-in plug-in activation, encryption key, and start-up properties. The start-up properties setup allows configuration of automatic installation to systems, server file names, process names, process visibility, and also NT-specific properties (NT service and host process names).

The file from which the server part started can be deleted. After that, BO2K will be active in memory each time Windows starts and will provide access to the infected system for hackers who have the client part and the correct password.

The active server part can hide its process or prevent its task from being killed from the Task Manager (on NT). The backdoor uses a smart trick on NT by constantly changing its PID (process ID) and by creating the additional process of itself that will keep the backdoor alive even if one of the processes is killed. The server part adds a random (but large) number of spaces and 'e' at the end of its name; thus, the server part file cannot be deleted from Windows (invalid or long name error). The server file can be only deleted from DOS.

DDoS Zombies

Trin00

Also known as Trinoo, this is a distributed tool used to launch coordinated UDP flood DoS attacks from many sources.

An intruder can actually communicate with a Trinoo master computer by communicating with port 27665, typically by Telnet. The master sends UDP packets to daemons on destination port 27444. The daemons send UDP flood packets to the target.

The binary for the trinoo daemon contains IP addresses for one or more trinoo master systems. When the trinoo daemon is executed, the daemon announces its availability by sending a UDP packet containing the string HELLO to its programmed trinoo master IP addresses on port 31335.

The trinoo master stores a list of known daemons. The trinoo master can be instructed to send a broadcast request to all known daemons to confirm availability. Daemons receiving the broadcast respond to the master with a UDP packet containing the string PONG.

The trinoo master then communicates with the daemons, giving instructions to attack one or more IP addresses for a specified period of time.

All communications to the master on port 27665/tcp require a password, with a default of *betaalmostdone*, which is stored in the daemon binary in encrypted form. All UDP communications with the daemon on port 27444 require the UDP packet to contain the string l44 (that is a lower-case letter L, not a one).

Tribe Flood Network (TFN)

TFN, much like Trinoo, is a distributed tool used to launch coordinated DoS attacks from many sources against one or more targets. In addition to the ability to generate UDP flood attacks, a TFN network can generate TCP SYN flood, ICMP echo request flood, and ICMP directed broadcast (e.g., smurf) DoS attacks. TFN has the capability to generate packets with spoofed source IP addresses.

A TFN master is executed from the command line to send commands to TFN daemons. The master communicates with the daemons using ICMP echo reply packets with 16-bit binary values embedded in the ID field and any arguments embedded in the data portion of the packet. The binary values, which are definable at compile time, represent the various instructions sent between TFN masters and daemons.

Detection/Protection

When dealing with malware, the only safe assumption is that everything that can go wrong will go wrong, and at the worst possible time. Until the need for this level of security diligence is accepted as the general business case, the information security practitioner will have an uphill battle.

However, training and explicit policies can greatly reduce the danger to users. Some guidelines that can really help in the current environment are:

- Do not double-click on attachments.
- When sending attachments, provide a clear and specific description as to the content of the attachment.
- Do not blindly use Microsoft products as a company standard.
- Disable Windows Script Host. Disable ActiveX. Disable VBScript. Disable JavaScript. Do not send HTML-formatted e-mail.
- Use more than one scanner, and scan everything.

Whether these guidelines are acceptable in a specific environment is a business decision based on the level of acceptable risk. But remember: whether risks are evaluated, and whether policies are explicitly developed, every environment has a set of policies (some are explicit, while some are implicit), and every business accepts risk. The distinction is that some companies are aware of the risks that they choose to accept.

Protective tools in the malware area are generally limited to anti-virus software. To this day there are three major types, first discussed by Fred Cohen in his research. These types are known as signature scanning, activity monitoring, and change detection. These basic types of detection systems can be compared with the common intrusion detection system (IDS) types, although the correspondence is not exact. A scanner is like a signature-based IDS. An activity monitor is like a rule-based IDS or an anomaly-based IDS. A change detection system is like a statistical-based IDS. These software types will be examined very briefly.

Scanners

Scanners examine files, boot sectors, and memory for evidence of viral infection, and many may detect other forms of malware. They generally look for viral signatures, sections of program code that are known to be in specific malicious programs but not in most other programs. Because of this, scanning software will generally detect only known malware and must be updated regularly. (Currently, with fast-burner e-mail viruses, this may mean daily or even hourly.) Some scanning software has resident versions that check each file as it is run.

Scanners have generally been the most popular form of anti-viral software, probably because they make a specific identification. In fact, scanners offer somewhat weak protection because they require regular updating. Scanner identification of a virus may not always be dependable: a number of scanner products have been known to identify viruses based on common families rather than definitive signatures. In addition, scanners fail "open;" if a scanner does not trigger an alert when scanning an object, that does not mean the object is not infected or that it is not another type of malware.

It is currently popular to install anti-viral software as a part of filtering firewalls or proxy servers. It should be noted that such automatic scanning is demonstrably less effective than manual scanning and subject to a number of failure conditions.

Activity Monitors

An activity monitor performs a task very similar to an automated form of traditional auditing; it watches for suspicious activity. It may, for example, check for any calls to format a disk or attempts to alter or delete a program file while a program other than the operating system is in control. It may be more sophisticated, and check for any program that performs "direct" activities with hardware, without using the standard system calls.

Activity monitors represent some of the oldest examples of anti-viral software, and are usually effective against more than just viruses. Generally speaking, such programs followed in the footsteps of the earlier anti-Trojan software, such as BOMBSQAD and WORMCHEK in the MS-DOS arena, which used the same "check what the program tries to do" approach. This tactic can be startlingly effective, particularly given the fact that so much malware is slavishly derivative and tends to use the same functions over and over again.

It is, however, very hard to tell the difference between a word processor updating a file and a virus infecting a file. Activity monitoring programs may be more trouble than they are worth because they can continually ask for confirmation of valid activities. The annals of computer virus research are littered with suggestions for virus-proof computers and systems that basically all boil down to the same thing: if the operations that a computer can perform are restricted, viral programs can be eliminated. Unfortunately, so is most of the usefulness of the computer.

Heuristic Scanners

A recent addition to scanners is intelligent analysis of unknown code, currently referred to as heuristic scanning. It should be noted that heuristic scanning does not represent a new type of anti-viral software. More closely akin to activity monitoring functions than traditional signature scanning, this looks for suspicious sections of code that are generally found in viral programs. While it is possible for normal programs to try to "go resident," look for other program files, or even modify their own code, such activities are telltale signs that can help an informed user come to some decision about the advisability of running or installing a given new and unknown program. Heuristics, however, may generate a lot of false alarms, and may either scare novice users or give them a false sense of security after "wolf" has been cried too often.

Change Detection

Change detection software examines system and program files and configurations, stores the information, and compares it against the actual configuration at a later time. Most of these programs perform a checksum or cyclic redundancy check (CRC) that will detect changes to a file even if the length is unchanged. Some programs will even use sophisticated encryption techniques to generate a signature that is, if not absolutely immune to malicious attack, prohibitively expensive, in processing terms, from the point of view of a piece of malware.

Change detection software should also note the addition of completely new entities to a system. It has been noted that some programs have not done this and allowed the addition of virus infections or malware.

Change detection software is also often referred to as integrity-checking software, but this term may be somewhat misleading. The integrity of a system may have been compromised before the establishment of the initial baseline of comparison.

A sufficiently advanced change-detection system, which takes all factors including system areas of the disk and the computer memory into account, has the best chance of detecting all current and future viral strains. However, change detection also has the highest probability of false alarms because it will not know whether a change is viral or valid. The addition of intelligent analysis of the changes detected may assist with this failing.

Gratuitous Summary Opinion

Malware is a problem that is not going away. Unless systems are designed with security as an explicit business requirement, which current businesses are not supporting through their purchasing decisions, malware will be an increasingly significant problem for networked systems.

It is the nature of networks that a problem for a neighboring machine may well become a problem for local systems. To prevent this, it is critical that the information security professional help business leaders recognize the risks incurred by their decisions and help mitigate those risks as effectively and economically as possible. With computer viruses and similar phenomena, each system that is inadequately protected increases the risk to all systems to which it is connected. Each system that is compromised can become a system that infects others. If you are not part of the solution in the world of malware, you are most definitely part of the problem.

Glossary

This glossary is not a complete listing of malware-related terms. Many others can be found in the security glossary posted at http://victoria.tc.ca/ techrev/secgloss.htm and mirrored at http://sun.soci.niu.edu/~rslade/ secgloss.htm.

Activity monitor: A type of anti-viral software that checks for signs of suspicious activity, such as attempts to rewrite program files, format disks, etc. Some versions of activity monitor will generate an alert for such operations, while others will block the behavior.

ANSI bomb: Use of certain codes (escape sequences, usually embedded in text files or e-mail messages) that remap keys on the keyboard to commands such as DELETE or FORMAT. ANSI (the American National Standards Institute) is a short form that refers to the ANSI screen formatting rules. Many early MS-DOS programs relied on these rules and required the use of the ansi.sys file, which also allowed keyboard remapping. The use of ansi.sys is very rare today.

Anti-viral: Although an adjective, frequently used as a noun as a short form for anti-virus software or systems of all types.

AV: An abbreviation used to distinguish the anti-viral research community (AV) from those who call themselves *virus researchers* but who are primarily interested in writing and exchanging viral programs (vx). Also an abbreviation for anti-virus software. *See also* vx.

Backdoor: A hidden software or hardware mechanism that can be triggered to permit system protection mechanisms to be circumvented. The function will generally provide unusually high, or even full, access to the system either without an account or from a normally restricted account. Synonymous with trap door, which was formerly the preferred usage. Usage *back door* is also very common.

BSI: A boot-sector infector; a virus that replaces the original boot sector on a disk, which normally contains executable code.

Change detection: Anti-viral software that looks for changes in the computer system. A virus must change something, and it is assumed that program files, disk system areas, and certain areas of memory should not change. This software is very often referred to as *integrity checking* software, but it does not necessarily protect the integrity of data, nor does it always assess the reasons for a possibly valid change. Change detection using strong encryption is sometimes also known as *authentication software*.

Companion virus: A type of viral program that does not actually attach to another program, but which interposes itself into the chain of command so that the virus is executed before the infected program. Most often, this is done by using a similar name and the rules of program precedence to associate itself with a regular program. Also referred to as a *spawning virus*.

DDoS: Distributed denial of service. A form of network denial-of-service (DoS) attack in which a master computer controls a number of client computers to flood the target (or victim) with traffic, using backdoor agent, client, or zombie software on a number of client machines.

Disinfection: In virus work, the term can mean either the disabling of a virus's ability to operate, the removal of virus code, or the return of the system to a state identical to that prior to infection. Because these definitions can differ substantially in practice, discussions of the ability to disinfect an infected system can be problematic. Disinfection is the means users generally prefer to use in dealing with virus infections, but the safest means of dealing with an infection is to delete all infected objects and replace with safe files from backup.

Dropper: A program, not itself infected, that will install a virus on a computer system. Virus authors sometimes use droppers to seed their creations in the wild, particularly in the case of boot-sector infectors. The term *injector* may refer to a dropper that installs a virus only in memory.

False negative: There are two types of false reports from anti-viral or anti-malware software. A false negative report is when an anti-viral reports no viral activity or presence when there is a virus present. References to false negatives are usually only made in technical reports. Most people simply refer to an anti-viral *missing* a virus. In general security terms, a false negative is called a *false acceptance* or *Type II error*.

False positive: The second kind of false report that an anti-viral can make is to report the activity or presence of a virus when there is, in fact, no virus. False positive has come to be very widely used among those who know about viral and anti-viral programs. Very few use the analogous term, *false alarm*. In general security terms, a false positive is known as a *false rejection* or *Type I error*.

File infector: A virus that attaches itself to, or associates itself with, a file, usually a program file. File infectors most often append or prepend themselves to regular program files, or they overwrite program code. The file infector class is often also used to refer to programs that do not physically attach to files but associate themselves with program filenames. (*See* system infector, companion.)

Heuristic: In general, heuristics refer to trial-and-error or seat-of-the-pants thinking rather than formal rules. In anti-viral jargon, however, the term has developed a specific meaning regarding the examination of program code for functions or opcode strings known to be associated with viral activity. In most cases, this is similar to activity monitoring but without actually executing the program; in other cases, code is run under some type of emulation. Recently, the meaning has expanded to include generic signature scanning meant to catch a group of viruses without making definite identifications.

Infection: In a virus, the process of attaching to or associating with an object in such a way that, when the original object is called, or the system is invoked, the virus will run in addition to or in place of the original object.

Kit: Usually refers to a program used to produce a virus from a menu or a list of characteristics. Use of a virus kit involves no skill on the part of the user. Fortunately, most virus kits produce easily identifiable code.

Packages of anti-viral utilities are sometimes referred to as toolkits, occasionally leading to confusion of the terms.

Logic bomb: A resident computer program that triggers the perpetration of an unauthorized act when particular states of the system are realized.

Macro virus: A macro is a small piece of programming in a simple language, used to perform a simple, repetitive function. Microsoft's Word Basic and VBA macro languages can include macros in data files and have sufficient functionality to write complete viruses.

Malware: A general term used to refer to all forms of malicious or damaging software, including viral programs, Trojans, logic bombs, and the like.

Multipartite: Formerly a viral program that infects both boot sector/MBRs and files. Possibly now a virus that will infect multiple types of objects or reproduces in multiple ways.

Payload: Used to describe the code in a viral program that is not concerned with reproduction or detection avoidance. The payload is often a message but is sometimes code to corrupt or erase data.

Polymorphism: Techniques that use some system of changing the form of the virus on each infection to try to avoid detection by signature-scanning software. Less sophisticated systems are referred to as *self-encrypting*.

RAT (Remote-Access Trojan): A program designed to provide access to, and control over, a network-attached computer from a remote computer or location, in effect providing a backdoor.

Scanner: A program that reads the contents of a file looking for code known to exist in specific viral programs.

Script virus: It is difficult to make a strong distinction between script and macro programming languages, but generally a script virus is a stand-alone object contained in a text file or e-mail message. A macro virus is generally contained in a data file, such as a Microsoft Word document.

Social engineering: Attacking or penetrating a system by tricking or subverting operators or users rather than by means of a technical attack. More generally, the use of fraud, spoofing, or other social or psychological measures to get legitimate users to break security policy.

Stealth: Various technologies used by viral programs to avoid detection on disk. The term properly refers to the technology and not a particular virus.

System infector: A virus that redirects system pointers and information in order to infect a file without actually changing the infected program file. (This is a type of stealth technology.) Or, a virus that infects objects related to the operating system.

Trojan horse: A program that either pretends to have, or is described as having, a (beneficial) set of features but that, either instead or in addition, contains a damaging payload. Most frequently, the usage is shortened to *Trojan*.

Virus, computer: Researchers have not yet agreed on a final definition. A common definition is "a program that modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen, although Dr. Cohen's actual definition is in mathematical form. Another possible definition is "an entity that uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action."

vx: An abbreviated reference to the "Virus eXchange" community; those people who consider it proper and right to write, share, and release viral programs, including those with damaging payloads. Probably originated by Sara Gordon, who has done extensive studies of the virus exchange and security-breaking community and who has an aversion to using the Shift key.

Wild, in the: A jargon reference to those viral programs that have been released into, and successfully spread in, the normal computer user community and environment. It is used to distinguish those viral programs that are written and tested in a controlled research environment, without escaping, from those that are uncontrolled *in the wild*.

Worm: A self-reproducing program that is distinguished from a virus by copying itself without being attached to a program file, or that spreads over computer networks, particularly via e-mail. A recent refinement is the definition of a worm as spreading without user action, for example by taking advantage of loopholes and trapdoors in software.

Zombie: A specialized type of backdoor or remote access program designed as the agent, or client (middle layer) component of a DDoS (Distributed Denial of Service) network.

Zoo: Jargon reference to a set of viral programs of known characteristics used to test anti-viral software.

Acknowledgments

The author would like to thank David Harley and Lee Imrey for their valuable contributions to this chapter.

An Introduction to Hostile Code and Its Control

Jay Heiser

VIRUSES AND OTHER FORMS OF HOSTILE CODE, OR "MALWARE," BECAME A UNIVERSALLY EXPERIENCED PROBLEM EARLY IN THE PC ERA, AND THE THREAT CONTINUES TO GROW. *The ICSA Virus Prevalence Survey* reported in 1999 that the infection rate had almost doubled during each of the previous four years. Malware has the potential to subvert firewalls, hijack VPNs, and even defeat digital signature. Hostile code is the most common source of security failure, and it has become so prevalent that its control must be considered a universal, baseline practice. Without an understanding of malware — what it is, what it can do, and how it works — malware cannot be controlled. It is ironic that despite the increasing rate of hostile code infection, the attention given this subject by academics and engineering students is declining. Attack code sophistication and complexity continues to increase, but fortunately, the appropriate response is always good system hygiene and administration.

DEFINITION OF HOSTILE CODE

Hostile code is program data surreptitiously introduced into a computer without the explicit knowledge or consent of the person responsible for the computer. Whatever the purported intent of its creator, code inserted covertly by an outside party can never be considered benign. If it is not approved, it has to be treated as hostile code. Vendors of anti-virus (AV) software have identified approximately 50,000 known viruses. In reality, only about 5 percent of these viruses are ever reported "in the wild," most commonly on Joe Wells's Wild List. (The Wild List is a regularly updated report of malware that has actually been observed infecting real systems. See Exhibit 23-1 for the URL.) Most of these are variations on a few hundred

well-known examples, and only a small number of viruses account for most attacks. Complicating an understanding of hostile code, simple terms such as "virus" and "Trojan horse" are used imprecisely, blurring a potentially useful distinction between cause and effect. This chapter familiarizes the practitioner with the most common malware terminology, and helps them recognize different contexts in which their meaning changes.

INFECTION AND REPRODUCTION

Analysis of the transmission mechanism for a specific example of hostile code starts by determining two things: (1) if it is self-reproducing, and (2) if it requires the unwitting assistance of a victim. While fear of autonomous attack by self-replicating code is understandable, *manual insertion* is the most reliable way for an attacker to install hostile code. If assailants can gain either physical or remote access to a system, then they have the opportunity to install malware. Many network services, such as FTP, TFTP, and HTTP (and associated poorly written CGI scripts), have been used to upload hostile code onto a victim system. Hacker Web sites contain details on remote buffer overflow exploits for both NT and UNIX, making it possible for script kiddies to install code on many unpatched Web servers. Manual insertion is not very glamorous, but it works.

Cyberplagues, code designed to reproduce and spread itself, takes one of two different forms. A **virus** is hostile code that parasitically attaches to some other code, and is dependent on that code for its transmission. This is completely analogous to a biological virus, which alters the genetic

content of its victim, using its victim for reproduction. Unfortunately, the word "virus" has also taken on a secondary meaning as a generic moniker for all forms of hostile code. This meaning is perpetuated by using the term "anti-virus" to describe commercial software products that actually search for a number of forms of malware. A true virus can only spread with the participation of its victim. Host infection occurs when a contaminated file is executed, or when a floppy with an infected boot sector is read. Because users do not log directly into them, servers are less likely to contract viruses than are workstations. However, users who have write access to data on servers, either group configuration files or shared data, will infect files on the server that can spread to all users of the server. If they are write protected, server executables can only be infected when someone with write privilege, such as an administrator, runs a file containing a virus.

A **worm** is self-reproducing hostile code that has its own discrete existence. It is a stand-alone executable that uses remote services to reproduce itself and spread to other systems through a network. This is analogous to a biological bacterium (within the parasite pantheon, some experts distinguish a bacterium from a worm). Worms do not require the victim's participation — they rely on technical vulnerabilities that are the result of bugs or poor configuration. Because they spread by exploiting network vulnerabilities, and do not require a victim's participation, servers are just as vulnerable to worms as workstations are. They are probably more vulnerable, because they typically have more network services running.

A **Trojan horse** is an artifact with an ulterior hostile effect that appears desirable to the victim, tricking the victim into transferring it through a security perimeter so that its hostile intent can be manifested within the protected area. Examples of Trojan horses on computers are e-mailed greeting cards and games that include a hostile payload. The term "Trojan horse" is often applied to any hostile code that is nonreproducing. This secondary usage is imprecise and misleading; it does not explain the infection process, the trigger event, or the effect. This meaning is used in two different contexts. Most recently, it refers to nonreproducing hostile remote control applications, such as Back Orifice and NetBus, which often — but not always — spread as the payload of an e-mailed Trojan horse. NetBus, for example, is often surreptitiously bundled with the Whack-a-Mole video game. More traditionally, and especially on UNIX hosts, the term refers to a manually inserted hostile executable that has the same name as a legitimate program, or as a hostile program that mimics the appearance of a legitimate program, such as a login screen. An effective security practitioner is sensitive to these different meanings for commonly used terms.

Logic bombs are manually inserted, nonreproducing code created by system insiders, usually for revenge. For example, a system administrator

might create a utility that is designed to delete all the files on a computer two weeks after that employee leaves a job. There have been cases where software vendors have included logic bombs in their product to encourage prompt payment. These software vendors have usually lost in court.

The term **"backdoor"** most accurately applies to a capability. A backdoor is a hidden mechanism that circumvents existing access controls to provide unauthorized access. Historically, some software developers have left backdoors into their application to facilitate troubleshooting. Backdoors can also be provided through system configuration. If a UNIX system administrator or intruder creates a copy of the shell and sets it to be SUID root, it could also be considered a form of backdoor.

Executable Content

Every new technology brings new risks. The convenience of executable content, data files that have some sort of programming and execution capability, is undeniable, but executable content is also a marvelously convenient mechanism for hostile capability.

Macro viruses are hostile code applications written in the macro language of application software. The ability to automatically launch a macro when a file is opened, and the power to access virtually any system function from within that macro, make some applications particularly vulnerable. Microsoft Word documents are the most widely shared form of executable content, making them an efficient malware vector. In late 1995, Concept was the first macro virus observed in the wild. Within two years, Microsoft Word macro viruses had become the most frequently reported form of malware.

Self-extracting archives include executable zip files, Windows setup files, and UNIX shell archives (shar files). As a convenience to the recipient, a set of files (usually compressed) is bundled into a single executable file, along with a script to extract files into the appropriate directories, and make any necessary changes to system configuration files. When the archive is executed, it extracts its components into a temporary directory; and if an installation script is included, it is automatically launched. A user executing such a self-extracting object must trust the intentions and abilities of the archive's creator. It is a simple matter to modify an existing archive to include a piece of malware, transmogrifying a legitimate file into a Trojan horse.

Mobile code is a form of executable content becoming increasingly prevalent on the Internet. Java, JavaScript, ActiveX, and Shockwave are used to create Web-based objects that are automatically downloaded and locally executed when they are browsed. The environments used to run mobile code reside either within the browser or in downloadable browser plug-ins. The level of system access afforded mobile code interpreters varies, but

the user's browser has full access to the user's system privileges — use of mobile code requires a trust in the technical capabilities and configuration of the mobile code execution environment. At the time of this writing, no hostile mobile code exploits have ever been documented in the wild.

Complex Life Cycles

Replicating hostile code has a life cycle, just like biological pathogens, and the increasing sophistication of malware life cycles is enabling malware to take greater advantage of infrastructure opportunities both to evade controls and to maximize infection rate. **Propagation** is the life stage in which malware reproduces itself in a form suitable for the actual **infection**. As described in several examples below, some replicating code has multiple propagation methods. After infection, hostile programs often enter a **dormancy** period, which is ended by a **triggering event**. The trigger may be a specific date and time, a specific user action, the existence of some specific data on the computer, or possibly some combination of any of the above. When the trigger event occurs, an action is taken. The virus code that performs this action is referred to as the **payload**. When the action is performed, it is sometimes referred to as **payload delivery**. The payload may delete data, steal data and send it out, attempt to fool the user with bogus messages, or possibly do nothing at all. Self-replicating hostile code completes its life cycle by propagating itself.

A 1999 attack called Explorezip provides a good example of malware with a complex life cycle. Explorezip is a worm; it does not infect files. It also has a hostile payload that attacks and deletes certain kinds of data files, such as Word documents. It first spreads as a Trojan horse, masquerading as a legitimate message from a known correspondent. Explorezip actually mails itself — the owner of an infected PC does not send the message personally. If the recipient clicks and launches the Explorezip code attached to the phony mail message, their PC becomes infected. The next time their computer starts, the hostile code is activated. It immediately begins to reproduce using a secondary mechanism, spreading across the intranet looking for vulnerable Windows shares so it can copy itself to other PCs. The triggering event for the primary infection mechanism is the reception of mail. Whenever an infected victim receives a new mail message, Explorezip replies with a bogus message containing a copy of itself, potentially spreading itself to another organization. Once an infection has occurred, shutting off the e-mail server may not halt its spread because it can also reproduce through the network using file sharing. This combination of two infection mechanisms complicated the response to Explorezip. Explorezip increases the chance of a successful infection by appropriating its victim's e-mail identity; it is a spoof that takes advantage of correspondent trust to lull recipients into accepting and executing an e-mail attachment that they may otherwise avoid.

EXPLOITS

Autonomous Attacks

Viruses and worms are autonomous. They are self-guided robots that attack victims without direction from their creator. Happy99 spreads as a Trojan horse, purportedly a fun program to display fireworks in a window (sort of a New Year's celebration). While it is displaying fireworks, it also patches WSOCK.DLL. This Winsock modification hooks any attempts to connect or send e-mail. When the victim posts to a newsgroup or sends e-mail, Happy99 invokes its own executable, SKA.DLL, to send a UUENCODED copy of itself to the news group or the mail recipients. As illustrated in Exhibit 23-2, Caligula is a Word macro virus that when triggered searches for PGP key rings (a PGP key ring is the data file that includes a user's encrypted private key for Pretty Good Privacy mail and file encryption). If it finds a PGP key ring, it FTPs it to a Web site known to be used for the exchange and distribution of viruses. Caligula is an example of autonomous code that steals data.

Melissa is designed to covertly e-mail infected documents to the first 50 e-mail addresses in a victim's address book. The document — which might contain sensitive or embarrassing information intended only for internal

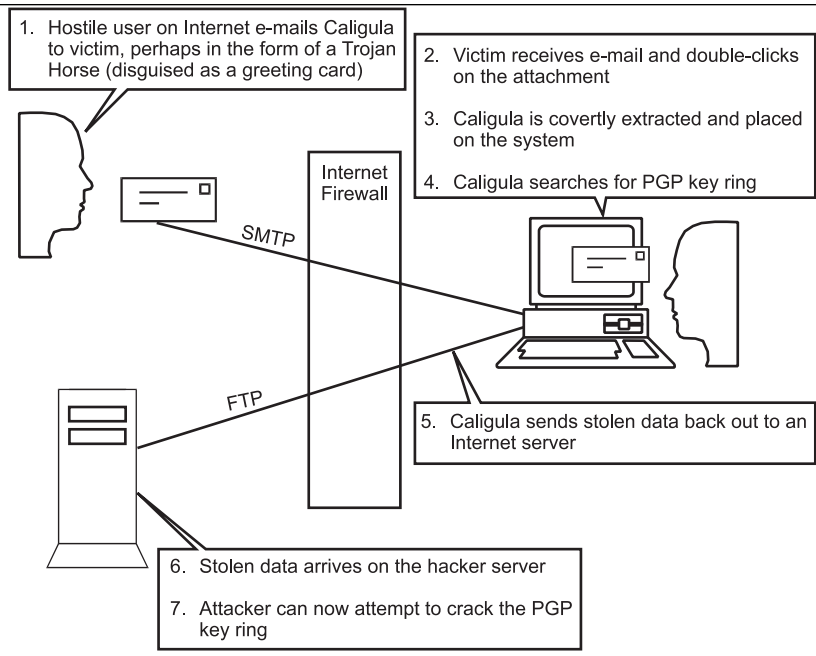

Exhibit 23-2. How Caligula steals data.

use — will be unwittingly sent to those 50 addresses. While it probably was not designed to steal data, a Melissa infection can easily result in the loss of privacy. At the time of this writing, there are at least 20 different families of mail-enabled hostile code. Caligula, Happy99, Explorezip, and Melissa are all examples of malware that take advantage of network capabilities. As shown in Steps 1 and 5 of Exhibit 23-2, most firewalls are configured to allow all incoming SMTP traffic, and all outgoing FTP connections. Attack code can easily use these protocols to circumvent a firewall and perform its intended task without human direction. However, autonomous attacks lack flexibility. Attackers desiring a more flexible and personal mechanism must use some form of interactive attack.

Interactive Attacks

Fancifully named programs, such as BackOrifice and NetBus, represent a significant change in the use of hostile code to attack computers. If installed on a victim's PC, these programs can serve as backdoors, allowing the establishment of a surreptitious channel that provides an attacker virtually total access to the PC across the Internet. A pun on Microsoft's BackOffice, BackOrifice (or BO) is the first Windows backdoor to be widely spread. Once a BO server has been inserted on a PC, either manually or as a Trojan horse, it can be remotely accessed using either a text or graphical client. The BO server allows intruders to execute commands, list files, silently start network services, share directories, upload and download files, manipulate the registry, list processes, and kill processes. Reminiscent of UNIX attacks, it allows a Windows machine to be a springboard for attacks on other systems. BO supports the use of accessory plug-ins, and several have been developed (continuing the naming convention with catchy puns like Butt Trumpet). Plug-ins allow BO to be wrapped into a self-extracting executable or to ride piggyback on another program. Once it has been installed, another plug-in announces itself on an IRC group. Several dozen surreptitious channel remote control applications are available. These programs can be used as legitimate system administration tools, and their creators steadfastly maintain that this is their purpose. Certainly, attackers also exploit commercial remote control applications, such as pcAnywhere. However, hostile backdoor exploits have special features designed to make them invisible to their victims, and they have other capabilities that facilitate data theft.

Once accidentally installed by the hapless victim, these programs listen for connection attempts on specific ports. Starting in late 1998, CERT reported a high rate of connection attempts on these ports across the Internet. Systems connected to the Internet full-time, such as those using cable modems or DSL, can expect to be scanned several times a week. The appeal of these programs to an attacker should be obvious. Someone motivated to

steal or alter specific data can easily do so if they can install a remote control application on a suitable target host and access it over a network. Kiddie scripts are available to piggyback NetBus or BackOrifice onto any executable that an attacker feels a victim would be willing to execute, creating a customized Trojan horse. Attackers too lazy to "trojanize" the remote control server program themselves can just send potential victims a video game that is already prepared as a NetBus Trojan, such as Whack-a-Mole. Once a vulnerable system is created or found, the keystroke recording feature can be used to compromise the passwords, which control access to secret keys, threatening a variety of password-protected security services, including S-MIME, PGP, and SSL. Most VPN clients are only protected by a password. If this password were to be compromised through a surreptitious backdoor's keystroke recording function, someone who later used the backdoor to remotely connect to the infected PC would be able to appropriate the victim's identity and corresponding VPN privileges. This could lead to the compromise of a corporate network.

MEME VIRUSES

Just the threat of a virus is sufficient to impact productivity — **virus hoaxes** can cause more disruption than actual viruses. Typically, a naïve user receives an e-mail message warning them of the dire consequences of some new form of computer virus. This message, full of exclamation points and capital letters, instructs the user to warn as many people as possible of some imminent danger (an example is shown in Exhibit 23-3). Viral hoax creators take advantage of a human need to feel important, and enough users are willing to forward these messages to their friends and co-workers that the deception spreads quickly and widely. Just like actual viruses, some virus hoaxes can live for years, flaring up every six to twelve months in a flurry of unproductive e-mail. When thousands of corporate users receive a bogus warning simultaneously, the effect on corporate productivity can be significant. No e-mail warning from an individual about a new virus should be taken seriously before doing research. Every vendor of anti-virus software has a Web page cataloging known hostile code, and several excellent Web sites are dedicated to the exposure and discussion of viral hoaxes. Virus hoax response can only be accomplished procedurally, and must be addressed in the organizational policy on hostile code or e-mail usage. Users must be instructed to report concerns to the IS department, and not take it upon themselves to inform the entire world. The Internet has proven to be an extraordinarily efficient mechanism for misinformation dissemination, and virus scares are not the only form of disruptive hoax. Well-meaning users are also prone to spreading a variety of similar practical joke messages. Classic e-mail pranks include chain letters, "make a wish" requests for a dying boy who collects business cards, and petitions to the government for some upcoming fictitious decision.

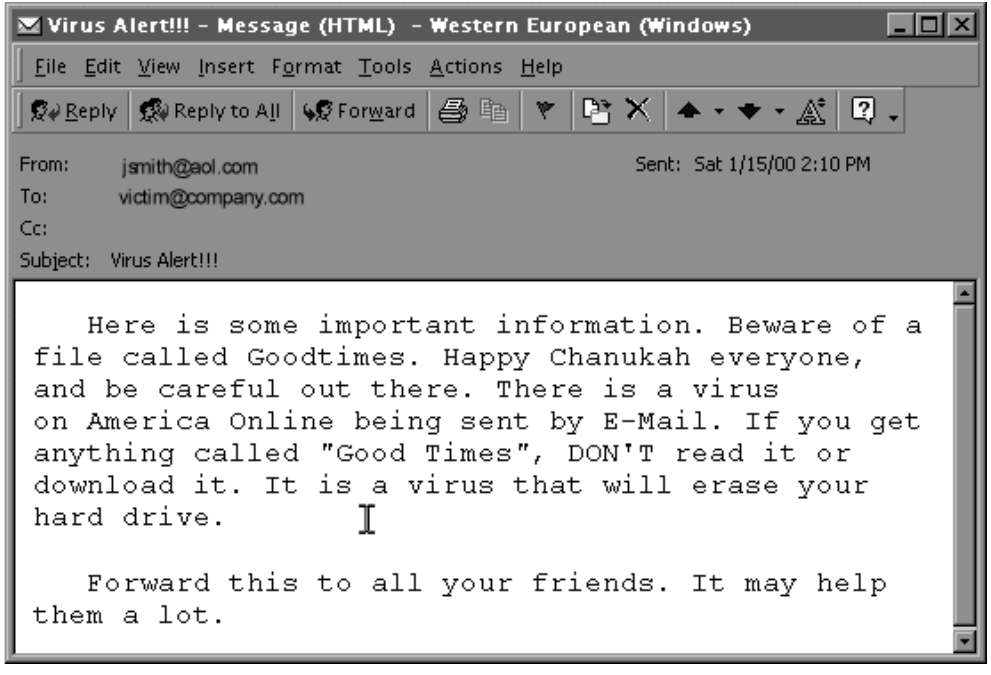

Exhibit 23-3. Hoaxes are easy to recognize.

COUNTERMEASURES

Hostile code control requires a comprehensive program simultaneously addressing both technical and human issues. It is safe to assume that some infections will occur, so prepare a recovery strategy before it is needed.

Policy and Procedure

The first step in computer security is always well-conceived policy establishing organizational priorities and basic security rules. Hostile code infections are prevented through procedural and technical countermeasures; policy must address both. Users need to be aware of the danger associated with the acceptance and use of files from external sources, and trained not to automatically double-click on e-mail attachments. Anti-virus (AV) software must be installed on every desktop and updated regularly. Corporate policy needs to set rules for e-mail. In addition to hostile code, organizational e-mail policy should address chain letters, hoaxes, and other forms of harmful internal communication. Policy must address response and cleanup. A malware response team should be appointed and charged with creating procedures for the rapid response to and recovery from an infection.

Creating policy is just the first step; it must be implemented through guidelines and procedures. Effective implementation involves more than just the publication of a set of rules. If corporate staff understands the nature of the threat, is aware of their role in spreading infection, and is provided with simple but effective behavioral guidelines, they will become the allies of the IS department. Awareness is not a one-time event provided to new hires. Existing staff must be periodically reminded of their responsibility to protect their organization. Media scares about new forms of hostile code can be an opportunity to educate the users and help them understand that security is an ongoing process. Clamp down on hoaxes and chain mail immediately. Remember the fable about the little boy who cried wolf. Users subjected to continuous warnings about dangers that never appear will become inured, and will not respond appropriately when an actual event occurs.

Good Hygiene

Maintaining optimal configuration and following best practices for administration results in robust systems that are resistant to security threats. Effective configuration management ensures that all systems will be appropriately configured for both performance and security, and it facilitates their recovery in case of a disaster or failure. System security should be as tight as practical, protecting sensitive system configuration and corporate data from unauthorized or accidental deletion or change. Excessive use of administrative privileges increases the risk of a failure. Every time

someone is logged in with full administrative privileges, the negative consequences of a mistake are increased. Accidentally executing hostile code while logged in as an administrator can be disastrous. UNIX users should not login as root, but should use the **sudo** command to temporarily access root privileges when needed. When NT users read mail or work on documents, they should be logged into an account that is not a member of the administrative group. Human attackers and worms need access to network services in order to compromise systems remotely, so both servers and workstations should avoid running unnecessary network applications.

System and Data Backups. The performance of regular and complete system data backups is the most effective security countermeasure. No security administrator can ever guarantee that a system will not fail, or that some unforeseen attack will not succeed. Having complete restore capability is a last-ditch defense, but it is a reliable defense. Organizational policy should mandate system backups and provide standards for backup storage. Depending on the volume and significance of the information, this policy might direct that some data be backed up on a daily basis or even in real-time, while other data be backed up on a weekly basis. Backups must be stored off-site. While redundant systems, such as RAID, provide a high level of reliability, if a site becomes unusable, the data would probably be inaccessible. Always test restoration capability. While it is helpful to perform a read test whenever data is backed up, this test does not guarantee that the tapes can be used to perform a restore. Develop procedures for periodically testing file restoration. It is inconvenient to back up laptops, but increasingly they contain large amounts of critical corporate data. Requirements for portable computers should be included as part of the data backup policy.

Anti-virus Software

When properly managed, AV software can be highly effective. It uses a variety of mechanisms to identify potentially hostile code; scanning is the most effective. Anti-virus scanning engines methodically search through system executables and other susceptible files for evidence of known malware. A file called the *virus definition* file contains signatures of known hostile code. The signature is a sequence of bits that researchers have identified as being unique to a specific example of hostile code. Searching every executable, Word document, and boot record for each of 50,000 signatures would take an unacceptably long time. Viral code can only be inserted at certain spots within an existing executable, so scanning engines increase performance by only searching specific parts of an executable. Over the years, virus writers have devised several methods to defeat virus scanners. Polymorphic viruses mutate, changing their appearance every time they reproduce; but when they execute, they revert to their original form

within system memory. Modern anti-virus software actually runs executables within a CPU simulator first, so that polymorphic viruses can decrypt themselves safely in a controlled environment where their signatures can be recognized. Unfortunately, anti-virus scanners are blissfully unaware of new hostile code until the AV vendors have the opportunity to analyze it and update their definition files. AV software vendors share newly discovered examples of hostile code, allowing each vendor the opportunity to update their own definition files. Most AV vendors update their definitions every four weeks, unless they become aware of some especially harmful virus and provide an interim update. This latency prevents scanning from ever being 100 percent effective, and is the reason why users must be trained to protect themselves. Several techniques have been developed to detect previously unknown hostile code, such as heuristics and behavior blocking, but results have been mixed. It is relatively easy to anticipate certain behaviors that file and boot sector viruses will follow. For example, most AV products can be configured to prevent writing to the master boot record. Monitoring more complex behaviors increases the potential for user disruption from false positives.

AV vendors offer several choices as to when scanning occurs. Scanning can be performed manually, which is a good idea when the virus definition files have been updated, especially if there is reason to believe that a previously undetectable form of hostile code might be present. Scanning can also be scheduled to occur periodically. The most reliable way to prevent the introduction of malware to a PC is to automatically scan files that potentially contain hostile code before accepting them. Before e-mail became a universal means for file exchange, floppy disks with infected boot sectors were the most common infection vector. During the past few years, hostile code has been more likely to spread via e-mail. AV software with real-time capabilities can be configured to scan files for the presence of hostile code whenever a floppy disk is inserted, a file is copied or read, or an e-mail attachment is opened. PC anti-virus software real-time detection capabilities have proven effective at stopping the spread of recognized hostile code attached to e-mail messages. Running AV software in this mode does raise performance concerns, but the cost of faster hardware can be offset against the cost of downtime, cleanup, and loss of system integrity after a significant viral infection.

In addition to running AV software on the desktop, scanners can be server based. The automatic periodic scanning of file servers for hostile code will ensure that even if an individual desktop is misconfigured, malware stored on the server will eventually be discovered. An increasing number of products are available to scan e-mail attachments before the mail is placed in a user's incoming mailbox. It is a common misconception that a firewall is a total solution to Internet security. Firewalls are network perimeter security

devices that control access to specific network services — a limited task that they perform well. They are not designed to examine incoming data and determine whether it is executable or what it is likely to do. **Virus walls** are application-level countermeasures designed to screen out hostile code from e-mail. These products can often be run on the firewall or the mail server, but it is usually most practical to use a stand-alone machine for mail filtering, locating it between the firewall and the organizational mail server. Operating as an e-mail proxy, virus walls open each message, check for attachments, unarchive them, and scan them for recognizable hostile code using a commercial AV product. They are efficient at unzipping attachments, but they cannot open encrypted messages. If organizational policy allows incoming encrypted attachments, they can only be scanned at the desktop. E-mail scanners should be considered as an augmentation to desktop control — not as a replacement. Use different AV products on the virus wall and the desktop; the combination of two different products in series provides a better detection rate than either product alone. E-mail scanners can protect both incoming and outgoing mail; unfortunately, most organizations only scan incoming mail. Scanning outgoing mail can double the cost of a virus wall, but this should be balanced against the loss of goodwill or bad publicity that will occur when a customer or partner is sent a virus.

Exhibit 23-4 shows the different locations within an enterprise where hostile code can be controlled. An obvious location for the scanning of incoming content is the firewall, which is already a dedicated security device. However, the primary mission of a firewall is to provide access control at the transport level. From the purist point of view, it is inappropriate to perform application layer functions on a network security device. However, it is becoming common to provide this service on a firewall, and many organizations are doing it successfully. If the firewall has enough processing power to perform scanning in addition to its other duties, adding a scanning upgrade is an easy way to scan mail attachments and downloads. Be aware that the addition of new services to a firewall increases the risk of failure — it is easy to overload a firewall with add-ons. Mail scanning can also be performed on the mail server. This has the minor disadvantage of not protecting HTTP or FTP. The bigger disadvantage is the increased complexity and decreased performance of the mail server. Mail servers are often finicky, and adding additional functionality does not increase dependability. Organizations already using high-end firewall and mail servers should consider one or more dedicated proxy machines, which is the most scalable solution. It can easily be inserted immediately behind the firewall and in front of the mail server. Organizations that want immediate protection but do not have the desire or wherewithal to provide it in-house can contract with an outside provider. Increasingly, ISPs are offering a scanning option for incoming e-mail. Managed security service providers will remotely manage a firewall, including the maintenance of virus wall capabilities. The desktop is the

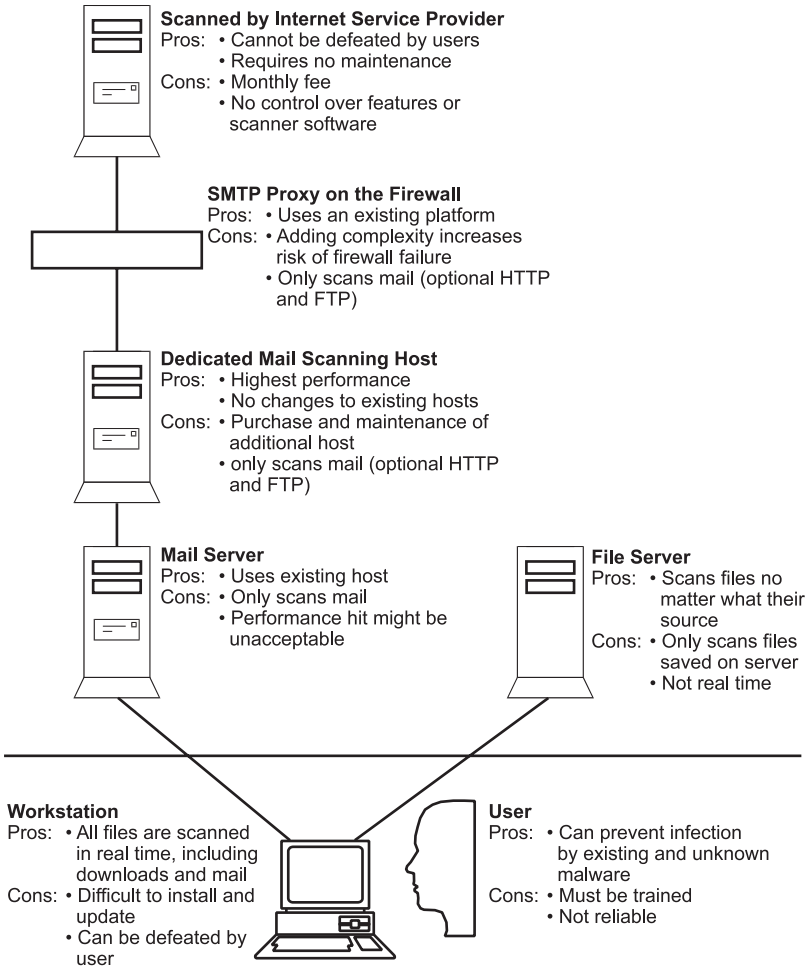

Exhibit 23-4. Hostile code control options.

most crucial place to control hostile code. If desktop systems could be reliably updated and users prevented from tampering with the configuration, there would be no need to scan anywhere else in the organization, but desktop scanning is difficult to maintain and the users cannot be trusted.

Cleaning. AV software not only detects hostile code, but also can be used to remove it. Removal of a virus from an executable is not always practical, but the AV vendors work very hard to provide automated cleaning of the hostile code most likely to be encountered in the wild. Although most users are capable of running a wizard and cleaning up their own system, organizational policy should provide them with guidance on what to

do when their AV software informs them an infection has been found. Even if users are allowed to clean up their own systems, their AV software should be configured to place a copy of all infected files in a quarantine area to facilitate later diagnosis. When infected, most organizations use their AV software to perform a cleanup; and if the cleanup is successful, the system is returned to production use. Any applications that cannot be repaired must be reinstalled or restored from a backup.

AV Software Configuration Should be Based on Policy. Several policy decisions have to be made in order to control hostile code with an anti-virus product. The most significant decision is whether the desktops will be individually administered or centrally administered. Even the worst product, when properly maintained and updated, outperforms the most effective product available if that product is improperly configured. It is not reasonable to expect users to make appropriate decisions concerning the configuration of their security software; and even when they are provided guidance, they cannot be trusted to reliably configure their own systems. Clearly, the trend is toward central administration, and the AV vendors are trying to accommodate this. Most AV products can be configured to periodically download definition files, automatically updating themselves. Software distribution tools available from Novell, Microsoft, and a number of independent software vendors can be used to push updates to user desktops. Use of a virus wall is also a form of central control. The choice of whether or not incoming files should be scanned before reaching the desktop is a policy decision. Likewise, policy should also address the scanning of outgoing files. Once policy exists that requires the centralized scanning of ingoing or outgoing mail, the choice of whether to scan on the firewall, on a dedicated mail scanning host, or on the existing mail server, is an implementation issue — not a policy decision.

Unless individual users experience problems, such as an unacceptably high number of false positives or a high rate of infection, desktop AV software will probably be configured to use the manufacturer's defaults on every internal system. Anti-virus software typically does not scan every file on the system — this would be a waste of time. On a Windows machine, the choice of files to be scanned is determined by their suffix. The vendor's recommendations for appropriate file types should not be changed unless hostile code has been consistently missed because of its file type. The software should be configured to automatically scan e-mail attachments and files at read time. Hostile code is rarely contracted through FTP or HTTP, but the overhead of scanning individual files is not noticeable, so the cost of scanning all Internet downloads is low.

Choosing a Product. The trade press is ill-equipped to evaluate anti-virus products. Reviews in popular computer magazines are more likely to

be misleading than helpful. At best, they tend to dwell on meaningless number games, comparing vendor's inflated claims for the number of recognized viruses. At worst, they concentrate on the attractiveness of the user interface. Only dedicated periodicals, such as *Virus Bulletin*, have the expertise to make valid comparisons between heavily marketed anti-virus products. The industry analyst firms usually have the expertise and objectivity to make useful recommendations on choice of virus control software. Organizations that subscribe to desktop or security bulletins from companies like this should see if they are eligible to receive reports on anti-virus products. Most AV vendors offer free mailing lists. These mailing lists serve a marketing function and tend to exaggerate the danger of newly discovered hostile code examples. Although AV vendor Web sites provide useful reference data on hostile code, their mailing lists are usually not helpful to the security practitioner. Several organizations test AV software and place their results on the Web. See Exhibit 23-1 for the URLs. *Virus Bulletin* (which is owned by an AV vendor), and the ICSA and Check-Mark (which are for-profit organizations) certify AV products and place the results on the Web. The Computer Science Department at the University of Hamburg is the only non-profit organization to methodically test AV products and regularly publish results.

Microsoft Word Macro Virus Control

Word macro viruses are the most prevalent form of hostile code. Microsoft Word documents support a programming language that is a variant of Visual Basic. Virtually anything that can be done on a PC can be done within a Word document using this language, including low-level machine language calls. They can be configured to execute automatically when a document is opened. Macros are a powerful tool for office automation, but they also place Word users at risk. There are several ways to reduce the macro virus risk, but none of them is foolproof. Word can be configured so that it does not automatically execute macros. When so configured, it will prompt the user for a decision whenever encountering a file with an autoexecute macro. Without training, users cannot be expected to make an appropriate decision, and even experienced users can accidentally push the wrong button. Just like executable viruses, macro viruses have become increasingly stealthy over time, and virus writers have developed several techniques for evading this automatic check. Word has the capability of storing documents in several formats. Only Word's native DOC format supports macros, so some organizations have chosen to distribute files in Rich Text Format (RTF). Windows 2000 can also store files in HTML with no loss of formatting, an even more portable format. Unfortunately, it is possible to change the extension on a DOC file to RTF or HTML and Word will still recognize it as a DOC file. Opening a DOC with an autoexecute macro — even when it is disguised with a different extension — will cause the macro to be executed. The safest choice is to

use an application that cannot run macros, such as Microsoft's free DOC file viewer. Downloadable from Microsoft's Web site, this utility can be safely used to view a file suspected of containing a macro virus.

Most macro viruses will infect NORMAL.DOT, the Word file containing default styles and macros. If the infection cannot be removed with AV software, remove NORMAL.DOT and Word will recreate it the next time it is started. Note that deleting NORMAL.DOT will result in a loss of all user-defined Word hot keys, macros, and changes to default styles. If this file is shared across the network, all users will contract the virus the next time they start Word. For this reason, a shared NORMAL.DOT file should always be configured as read-only.

Mobile Code Control: Java and ActiveX

Java is an interpreted programming language, while ActiveX is a Microsoft binary format. The two technologies are different, but from the point of view of a Web browser, they are alternate mechanisms for distributing code from a Web page to a user desktop for local execution. Mobile code is a security concern because it allows Web site operators control over what is executed on a user's desktop. It is important to remember that Java and ActiveX have never been exploited in a security-relevant way. The only known mobile code exploits have been demonstrations — there is no recorded example of an actual security failure involving mobile code on a production system. Unlike other more prevalent forms of malware, mobile code security remains a popular area of academic research, ensuring that security-relevant software bugs are identified and reported to the browser vendors.

Because it is a strongly typed language, Java is less susceptible to buffer overruns than C, making Java code more reliable and difficult to exploit. Java executes within a controlled environment called the Java virtual machine (JVM). When running within a browser, the 1.0 version of the JVM enforces its security policy using three different mechanisms. First, the applet class loader assigns a private namespace associated with the network origin of each downloaded applet, maintaining a separate and unique namespace for Java code loaded locally. Second, all applets pass through the applet code verifier, which checks for illegal code constructions. Finally, the Java security manager, a reference monitor, prevents the local reading and writing of files, and prevents applets associated with one host from accessing a different one. Sometimes referred to as the Java sandbox, the security manager only allows applets to do four things: they can run, they can access the screen, they can accept input, and they can connect back to their originating host. Several Java security bugs have been demonstrated in the laboratory by tricking the JVM into allowing applets access to hosts other than the originating host, or allowing them access to the local file system. Both Microsoft and Netscape quickly patched these

vulnerabilities. The limitations of Java 1.0 functionality should be clear. While it is an intrinsically safe environment, the lack of file system access limits its utility for transactions. Java 2.0 provides the capability for authorized applets to break out of the Java sandbox. The newer version of Java allows applets to be digitally signed. Compatible browsers will be able to allow controlled access to system resources on behalf of applets signed by approved parties.

ActiveX is Microsoft's trade name for compiled Windows executables that can be automatically distributed across the Internet as part of a Web page. It uses Microsoft's Component Object Module standard (COM). It does not have any form of sandbox, but uses a trust model similar to Java version 2.0. The Microsoft browser, Internet Explorer, checks the digital signature of any ActiveX objects presented to it by a Web server. Microsoft browsers support a hierarchy of security zones, each allowing greater access to system resources. Specific signers can be configured within the browser environment as being authorized for the access level of specific zones. A typical configuration might allow ActiveX originating from within an organization to have full access to a user's resources, but code originating from the Internet would have no special privileges. Unfortunately, if a user encounters an ActiveX object from an unrecognized signer, the default behavior is to ask the user what to do. Because the onus is on the user to determine what code is appropriate to operate, ActiveX has been widely criticized in the security community. For this model to work, users must be trained — which is relatively difficult. Microsoft provides a centralized configuration management tool for Internet Explorer, enabling an organization to centrally configure behavior on all desktops. Effective use of this capability should allow an organization to take full advantage of ActiveX internally without placing users at unnecessary risk.

Although neither Java nor ActiveX has ever been successfully exploited, several commercial products are available that protect desktops for both. Organizations wishing to ensure that mobile code is never activated on employee PCs can also control it at the perimeter. Many Web proxies, including those running directly on a firewall, can be configured to trap Java and ActiveX objects, shielding users from mobile code on the Internet. Security practitioners should be aware of the potential for mobile code failures, and know the countermeasures available in case a problem ever manifests itself. At the time of this writing, only the most sensitive organizations need to be concerned about mobile code risk.

WHY DOES HOSTILE CODE EXIST?

Why is so much malware floating around? The motivations behind the writing of hostile code are complex. In most cases, it is not necessarily an explicit desire to hurt other people, but it is often a form of self-actualization.

It is a hobby — carried to obsessive levels by some of the most successful virus writers. The quest for knowledge and the joy of parenthood are fun and satisfying. Virus creators are driven by Dr. Frankenstein's relentless curiosity on the nature of life itself. Once having created something that appears able to reproduce, it can be difficult to resist the temptation of experimenting in the ultimate laboratory, the Internet. Robert Morris, Jr., the creator of the Internet Worm, is probably not the only programmer who has experienced a sorcerer's apprentice moment and realized that their handiwork has succeeded beyond their wildest dreams — and beyond their sphere of control.

Many writers of self-replicating code belong to an extended virtual community where they socialize, exchanging ideas and code. Virus writers were early users of bulletin board systems, forums that have been transplanted to the Internet. The most desirable virus meeting places are closed, requiring the submission of a functioning virus as an initiation requirement. Created by neophytes, these initial efforts are typically simple variations of existing malware, which explains why such a high percentage of the thousands of identified hostile programs are closely related. Social status within the virus writing community is similar to other hacker subcultures. It is derived from technical prowess, which must be proven repeatedly as community members compete for superiority. Fame and respect derive from recognition within their social group of their superior skills, as demonstrated by clever coding and successfully propagating creations. There is undoubtedly a need on the part of some coders to overcome their inferiority feelings by exerting power of others as digital bullies, but studies of virus writers indicate that the challenge and social aspects are most significant. By attempting to evade AV software, virus writers demonstrate an awareness of the AV industry. Only the most socially obtuse programmer could fail to realize that AV software exists because people fear viruses and wish to avoid them.

Why Windows?

UNIX viruses are possible, but in practice, they are essentially nonexistent. There continue to be a few Macintosh viruses, but the overwhelming majority of malware attacks are aimed at Microsoft Windows systems. That which makes Windows most useful is also its greatest weakness — a characteristic not unique to computer security. Windows represents a monoculture — the majority of user workstations utilize the same operating environment, run the same application (Microsoft Word), and many use Microsoft Outlook for e-mail. As modern agriculture has shown that monoculture provides an opportunity for insects and disease, huge numbers of similar PCs are susceptible to a common infection. Exacerbating the low level of diversity is the high level of both internal and external connectivity, and the privileges granted to their unsophisticated operators make

Windows systems vulnerable. Users of Windows 98 are effectively the system administrator. NT is an operating system designed to meet the C2 requirements for access control, but normal users are often granted administrator privileges, effectively bypassing the system's built-in protection. Finally, the widespread use of a macro-enabled word processor means that executable content is pervasive. The combination of ubiquitous e-mail, a powerful word processor, weak access control, and unsophisticated users has resulted in macro viruses quickly becoming a universal threat.

CONCLUSION

While documented cases are low, a risk analyst needs to be aware that remotely inserted hostile code is an ideal way for motivated and skillful attackers to commit computer-based fraud or vandalize information. Malware already exists that steals passwords, and other forms of directed data theft are just as easy to accomplish. As easily customizable hostile code continues to proliferate, and as motivated external attackers become increasingly sophisticated, directed attacks will be carried out through e-mail. Organizations that are subject to either espionage or especially strong and unethical competitive pressure need to be on the lookout for customized attack code. Malware has been present throughout the PC era. While the cost of viral infections remains a matter of debate, despite the millions of dollars spent fighting malware, the rate of hostile code incidents continues to increase. The latest forms of Internet security countermeasures, such as firewalls, VPNs, and PKI, are vulnerable to software attack. Fortunately, control is relatively simple. A well-orchestrated combination of human effort and technical countermeasures has proven effective in maintaining an acceptably low rate of hostile code infection.

A Look at Java Security

Ben Rothke, CISSP

Introduction

Why should Java security concern you? Many push-based applications are being ported to Java. In addition, Java is one of the cornerstones of active content and an understanding of Java security basics is necessary for understanding the implications of push security issues.

A lot of people ask: "Why do I need Java security? I thought it was safe." Java as a language is basically safe and is built on top of a robust security architecture. But security breaches related to bugs in the browser, poorly written Java code, malicious Java programs, poorly written CGI scripts and JavaScript code, and others often occur. Moreover, placing the enforcement of a security policy in the browser, and thus in the hands of end users, opens up many opportunities for security measures to be defeated. In addition, many push vendors are relatively new start-ups that do not always understand mission-critical software and security needs. Such circumstances only exacerbate the security predicament.

While some people might opine that Java is too insecure to be used in production environments and that it should be completely avoided, doing so creates the situation where a tremendous computing opportunity is lost. While the company that decides to bypass Java relieves itself of Java security worries, that means that they also relinquish the myriad benefits that Java affords. In addition, a significant number of cutting-edge Internet-based activities, such as E-commerce, online trading, banking, and more, are all written in Java. Also, many firewall and router vendors are writing their management front-end applications in Java. When a company cuts itself off from Java, it may likely cut itself off from the next generation of computing technology.

Push-based programs are powerful and flexible Web tools, and where the Web is directed, but these programs, by their nature, are inherently buggy and untrustworthy. Now take a look at the Java security model.

A Quick Introduction to the Java Programming Language

The essence of Java is to be a portable and robust programming language for development of write-once programs. Java was created to alleviate the quandary of writing the same applications for numerous platforms that many large organizations faced in developing applications for large heterogeneous networks. To achieve this, the Java compiler generates class files, which have an architecturally neutral, binary intermediate format. Within the class file are Java bytecodes, which are implementations for each of the class' methods, written in the instruction set of a virtual machine. The class file format has no dependencies on byte-ordering, pointer size, or the underlying operating system, which allows it to be platform independent. The bytecodes are run via the runtime system, which is an emulator for the virtual machine's instruction set. It is these same bytecodes that enable Java to be run on any platform. Finally, two significant advantages that increase Java's security is that it is a well-defined and openly specified language.

While many systems subscribe to the security through obscurity model, Java achieves a significant level of security through being published. Anyone can download the complete set of Java source code and examine it for themselves. In addition, numerous technical security groups and universities have done their own audits of Java security.

The second area where Java security is increased is through its architectural definitions. Java requires that all primitive types in the language are guaranteed to be a specific size and that all operations defined must be performed in a specified order. This ensures that two correct Java compilers will never give different results for execution of a program, as opposed to other programming languages in which the sizes of the primitive types are machine- and compiler-dependent, and the order of execution is undefined except in a few specific cases.

Overview of the Java Security Model

The Java applet[1] security model introduced with the 1.0 release of Java SDK considers any Java code running in a browser from a remote source to be untrusted. The model anticipates many potential attacks, such as producing Java code with a malicious compiler (one that ignores any protection boundaries), tampering with the code in transit, etc. The goal of the Java security model is to run an applet under a set of constraints (typically referred to as a sandbox) that ensures the following:

- No information on the user's machine, whether on a hard disk or stored in a network service, is accessible to the applet.
- The applet can only communicate with machines that are considered to be as trusted as itself. Typically, this is implemented by only allowing the applet to connect back to its source.
- The applet cannot permanently affect the system in any way, such as writing any information to the user's machine or erasing any information.

From a technical perspective, this sandbox is implemented by a layer of modules that operate at different levels.

Language Layer

The language layer operates at the lowest layer of the Java language model and has certain features that facilitate the implementation of the security model at the higher levels.

Memory Protection

Java code cannot write beyond array boundaries or otherwise corrupt memory.

Access Protection

Unlike C++, Java enforces language-level access controls such as private classes or methods.

Bytecode Verifier

When a Java applet is compiled, it is compiled all the way down to the platform-independent Java bytecode where the code is verified before it is allowed to run. The function of bytecode verification is to ensure that the applet operates according to the rules set down by Java and ensures that untrusted code is snared before it can be executed.

While the language restrictions are implemented by any legal Java compiler, there is still the possibility that a malicious entity could craft its own bytecode or use a compromised compiler. To deal with this possibility, Sun Microsystems architected the Java interpreter to run any applet bytecode against a verifier program that scans the bytecode for illegal sequences. Some of the checks performed by the verifier are done statically before the applet is started. However, because the applet can dynamically load more code as it is running, the verifier also implements some checks at runtime.

The bytecode verifier is the mechanism that ensures that Java class files conform to the rules of the Java application. Although not all files are subject to bytecode verification, those that are have their memory boundaries enforced by the bytecode verifier.

Security Manager

The function of the Java security manager is to restrict the ways in which an applet uses the available interfaces, and the bulk of Java's security resources are implemented via the security manager.

At the highest level, the security manager implements an additional set of checks. The security manager is the primary interface between the core Java API and the operating system and has the responsibility for allowing or denying access to the system resources it controls.

This security manager can be customized or subclassed, which allows it to refine or change the default security policy. Changing the security manager at runtime is disallowed because an applet could possibly discover a way to install its own bogus security manager. All of the Java class libraries that deal with the file system or the network call the security manager to ensure that accesses are controlled.

From a technology perspective, the security manager is a single interface module that performs the runtime checks on potentially dangerous methods that an applet could attempt to execute.

Security Package

The security package is the mechanism that allows for the authentication of signed Java classes. Those are the classes that are specified in the java.security package.

Signed applets were introduced in version 1.1 of the Java SDK and specifically are collections of class files and their supporting files that are signed with a digital signature.

The way in which a signed applet operates is that a software developer obtains a certificate from a certificate authority (CA) and uses that certificate to sign their applications. When an end user browses a Web page the developer has signed, the browser informs the end user who signed the applet and allows the user to determine if he wants to run that applet.

Key Database

The key database works with the security manager to manage the keys used by the security manager to control access via digital signatures.

The Java Standard Applet Security Policy

The exact set of policies that are enforced by Java in a specific environment can be modified by creating a custom version of the security manager class. However, there is a standard policy that has been defined by Sun and is implemented by all Web browsers that implement Java applets. The standard policy basically states:[2]

- An applet can only connect back to its source. This means, for example, that if the applet source is outside a company firewall, the applet is only allowed to talk to a machine that is also outside the firewall.
- An applet cannot query system properties because these properties could hold important information that could be used to compromise the system or invade the user's privacy.
- An applet cannot load native libraries because native code cannot be restricted by the Java security model.
- An applet cannot add classes to system packages because it might violate some access-control restrictions.
- An applet cannot listen on socket connections. This means that an applet can connect to a network service (on its source machine), but it cannot accept connections from other machines.
- An applet cannot start another program on the client workstation. This way, an applet cannot then spawn some other program or rogue process on the workstation. From a programming perspective, an applet is not allowed to manipulate threads outside its own thread group.
- An applet cannot read or write to any files on the user's machine.
- An applet can only add threads to its own thread group.

Java Language Security

This is not the place to detail the security features of the Java programming language, but a few of its most significant security-based features include the following.

Lack of Pointer Arithmetic

Java security is extended through lack of pointer arithmetic because Java programs do not use explicit pointers. Pointers are simply memory locations in applications. Consequently, no one can program (either maliciously or accidentally) a forged pointer to memory. The mishandling of pointers is probably one of the largest sources of bugs in most programming languages. To get around the lack of pointers, all references to methods and instance variables in the Java class file are via symbolic names.

Garbage Collection

Java garbage collection is the process by which Java deallocates memory that it no longer needs. Most languages such as C and C++ simply allocate and deallocate memory on the fly. The use of garbage collection requires Java to keep track of its memory usage and to ensure that all objects are properly referenced. When objects in memory are no longer needed, the memory they use is automatically freed by the garbage collector so that it can be used for other applets. The Java garbage collection engine is a multithreaded application that runs in the background and complements the lack of memory pointers in that they prevent problems associated with bad pointers.

Compiler Checks

The Java compiler checks that all programming calls are legitimate.

E-Commerce and Java

Sun Microsystems has entered the E-commerce arena in a big way and envisions having Java at the forefront of E-commerce. To assist in that attempt, Sun has created a Java E-commerce architecture to promote it.

Components of the architecture are the Java Wallet, Commerce Client, Commerce API, and Commerce JavaBeans.

The Java Wallet is a family of products written in Java that enable secure electronic commerce operations. The Java Wallet combines the Java Commerce Client, Commerce JavaBeans components, the gateway security model, and the Java Commerce Messages to create a single platform for E-commerce. It should be noted that the components can be used independently of one another. The Java wallet is written in Java; thus, it can run in any Java-capable browser.

Threats

In *Java Security: Hostile Applets, Holes and Antidotes,* McGraw and Felten describe four classes of threats that Java is susceptible to:

1. *System modification*. This is the most severe class of threats where an applet can significantly damage the system on which it runs. Although this threat is the most severe, the defenses Java has to defend against it are extremely strong.
2. *Invasion of privacy*. This is the type of attack where private information about host, file, or user is disclosed. Java defends against this type of attack rather well because it monitors file access and applets can only write back to the channel in which they were originally opened.
3. *Denial of service*. Denial-of-service attacks are written to deny users legitimate access to system resources. Denial-of-service attacks take many forms, but are primarily applications or malicious applets that take more processes or memory allocation area than they should use, such as filling up a file system or allocating all of a system's memory. Denial-of-service attacks are the most commonly encountered Java security concern and, unfortunately, Java has a weak defense against them.
4. *Antagonism*. An antagonistic threat is one in which the applet simply annoys the user, such as by playing an unwanted sound file or displaying an undesired image. Many antagonistic attacks are simply programming errors. Most denial-of-service attacks can be classified as antagonistic threats, but the ones defined here are less annoying than their denial-of-service counterpart. Like their counterpart, Java has a weak defense against them.

Using Java Securely

By following some generic guidelines, and then customizing those guidelines for an environment's unique needs, Java can be safely used in most environments. Java security, like most computer security, is built on a lot of common sense. A few of the major issues are:

- *Make sure that your browser is up to date*. Many Java vulnerabilities have originated in browser design flaws. Staying with a relatively new release of a browser hopefully ensures that discovered security flaws have been ameliorated.

- *Stay on top of security alerts.* Keep track of advisories from CERT (www.cert.org), CIAC (www.ciac.llnl.gov), and the appropriate browser vendor.
- *Think before you visit a Web site.* If visiting www.whitehouse.gov, chances of downloading a hostile Java applet are much less than if visiting www.hackers.subterfuge.org. The bottom line, use your head when surfing the Web.
- *Know your risks.* Every company must assess its risks before it can really understand how to deal with the security risks involved with Java. If the risk of Java is too great (i.e., nuclear control centers), do not use Java; if the risks are more minimal (i.e., home), one can pretty much use Java with ease.

Third-Party Software Protection

There are numerous third-party software tools available to further secure Java and add protection against the potential security threats that Java can produce. Such products are a necessity for running push and active content applications.

- Finjan — SurfinGate & SurfinGate (www.finjan.com)
- Safe Technologies — eSafe Protect (www.esafe.com)
- Digitivity — Cage (www.digitivity.com)
- Security7 — SafeGate (www.security7.com)

Conclusions About Java Security

Java has an impressive security architecture and foundation, but one cannot rely on the sandbox model exclusively. Combined with poorly written PERL and CGI scripts, browser vulnerabilities, operating system holes, Web server holes, and more, there are plenty of potential openings in which a malicious or poorly written application could wreak havoc.

Knowing what one's risks are, combined with an understanding of Java's vulnerabilities and active protection of content, will prove that *Java security* is not an oxymoron.

Notes

1. An applet is defined as a Java program that is run from inside a Web browser. The html page loaded into the Web browser contains an <applet> tag, which tells the browser where to find the Java .class files. For example, the URL http://cnn.com/TECH/computing/JavaNews.html starts a Java applet in the browser window because the source code contains the entry <applet code=Ticker.class>.
2. This article cannot list all of the details of the standard policy. For a thorough listing, view the Java SDK documentation set.

THE RAID ADVANTAGE

Tyson Heyn

INSIDE

The Solution to Server Gridlock and Data Integrity, RAID Elements, The Array of RAID Levels, Interface Options

INTRODUCTION

Electronic data processing evolved from virtually nothing 50 years ago to its virtual omnipresence in the industrialized societies of the world today. The technologies that have been harnessed to manipulate data converted to its lowest common denominators (zeros and ones) have made a huge impact on the lives of people throughout the world. Digitized information, or data, is being used to enable everything from live conversations between continents via satellite, to the advancement of scientific discoveries and research, to controlling the temperatures of different rooms in a home. The recently emerged raft of online services provides not only the links to communicate with personal computers, but provides access to oceans of information to navigate, capture, and use by anyone with a computer. Businesses like banks and credit card companies use massive computing systems to provide everyday conveniences like easier and faster access to money, in turn making it easier to bill or manage accounts. Even supermarkets and retail department stores are using powerful, data-intensive information systems to do everything from managing inventories to monitoring consumer spending habits. The applications list goes on and on; everyone in virtually every walk of life is exposed in some manner or form to the impact of the ongoing revolution called the Information Age.

The engines behind this revolution, of course, are computers. Today's Pentium-class personal computers, RISC workstations, minicomputers, supercomputers, and even (still!) mainframes provide the power that drives this infinite mass of data that is relied on to make everything from bank transactions to the purchase of groceries as easy as possible. The flow of data between computers,

PAYOFF IDEA

Redundant arrays of independent disks (RAID) presents a solution to the problem of providing access to gigabytes of data to users quickly and reliably.

whether networked or linked via online services or the Internet, has become nothing less than a raging flood.

This astounding volume of data being transmitted between systems today has created an obvious need for data management. As a result, more and more servers — whether they are PCs, UNIX workstations, minicomputers, or supercomputers — have assumed the role of information or data traffic cops. The number of networked or connectable systems is increasing by leaps and bounds as well, thanks to the widespread adoption of the client/server computing model, the boom in home computer use, and the rise of Internet access service providers.

Hard disk storage plays an important role in enabling improvements to networked systems, because the vast and growing ocean of data has to reside somewhere. It also has to be readily accessible, placing a demand on storage system manufacturers to not only provide high-capacity products, but also products that can access data as fast as possible and to as many people at the same time as possible. Such storage also has to be secure, placing an importance on reliability features that best ensure that data will never be lost or otherwise rendered inaccessible to network system users.

RAID: THE SOLUTION TO SERVER GRIDLOCK AND DATA INTEGRITY

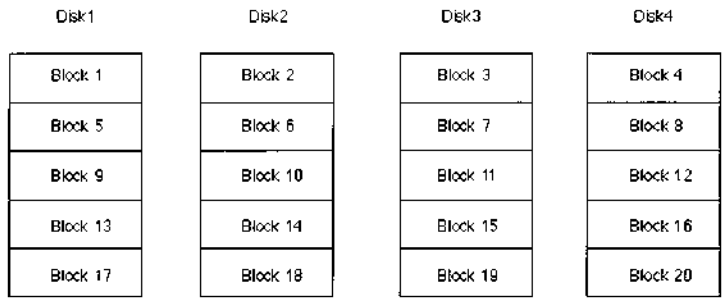
The solution to providing access to many gigabytes of data to users fast and reliably has been to assemble a number of drives together in a gang or array of disks. These are known as RAID subsystems, which stands for redundant arrays of independent disks. Simple RAID subsystems (Exhibit 1) are basically a clutch of up to five or six disk drives assembled in a cabinet and connected to a single controller board. The RAID controller orchestrates read and write activities in the same way a controller for a single disk drive does, and treats the array as if it were in fact a single or virtual drive. RAID management software that resides in the host system provides the means to manage data to be stored on the RAID subsystem.

RAID ELEMENTS

Despite its multidrive configuration, RAID subsystems disk drives remain hidden from users. The subsystem itself is the virtual drive, although it can be as large as 1000 Gbytes. The phantom virtual drive is created at a lower level within the host operating system through the RAID management software. Not only does the software set up the system to address the RAID unit as if it were a single drive, but it allows the subsystem to be configured in ways that best suit the general needs of the host system.

RAID subsystems can be optimized for performance, the highest capacity, fault tolerance, or a combination of two or three of these. Different so-called RAID levels have been defined and standardized in accordance with those general optimization parameters. There are six

EXHIBIT 1 — A Simple RAID Subsystem



such standardized levels of RAID, called RAID 0, 1, 2, 3, 4, or 5, depending on performance, redundancy, and other attributes required by the host system. The RAID software that is used to configure the desired RAID level of features in an array is described in more detail in the following paragraphs.

The RAID controller board is the hardware element that serves as the backbone for the array of disks. It not only relays the input/output (I/O) commands to specific drives in the array, but provides the physical link to each of the independent drives so they may easily be removed or replaced. The controller also serves to monitor the health or integrity of each drive in the array to anticipate the need to move data should it be placed in jeopardy by a faulty or failing disk drive. This feature is known as fault tolerance.

THE ARRAY OF RAID LEVELS

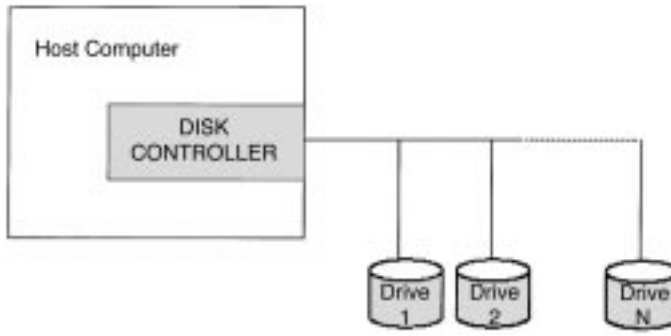
The RAID 1 through 5 standards offer users and system administrators a host of configuration options. These options allow the arrays to be tailored to their application environments. Each of the various configurations listed in the following paragraphs focuses on maximizing the abilities of an array in one or more of the following areas: capacity, data availability, performance, and fault tolerance.

RAID Level 0

An array configured to RAID Level 0 is an array optimized for performance, but at the expense of fault tolerance or data integrity.

RAID Level 0 is achieved through a method known as striping. The collection of drives (or virtual drive) in a RAID Level 0 array has data laid down in such a way that it is organized in stripes across the multiple drives. A typical array can contain any number of stripes, usually in mul-

EXHIBIT 2 — In a RAID Level 0 configuration, a virtual drive comprises several stripes of information. Each consecutive stripe is located on the next drive in the chain, evenly distributed over the number of drives in the array.



tiples of the number of drives present in the array. As an example, imagine a four-drive array configured with 12 stripes (four stripes of designated space per drive). Stripes 0, 1, 2, and 3 would be located on corresponding hard drives 0, 1, 2, and 3. Stripe 4, however, appears on a segment of drive 0 in a different location than Stripe 0; Stripes 5 through 7 appear accordingly on drives 1, 2, and 3. The remaining four stripes are allocated in the same even fashion across the same drives, such that data would be organized in the manner depicted in Exhibit 2. Practically any number of stripes can be created on a given RAID subsystem for any number of drives; 200 stripes on two disk drives is just as feasible as 50 stripes across 50 hard drives. Most RAID subsystems, however, tend to have between 3 and 10 stripes.

The reason RAID Level 0 is a performance-enhancing configuration is that striping enables the array to access data from multiple drives at the same time. In other words, because the data is spread out across a number of drives in the array, it can be accessed faster because its not bottled up on a single drive. This is especially beneficial for retrieving very large files, because they can be spread out effectively across multiple drives and accessed as if they were the size of any of the fragments they are organized into on the data stripes.

The downside to RAID Level 0 configurations is that it sacrifices fault tolerance, raising the risk of data loss because no room is made available to store redundant data. If one of the drives in the RAID 0 fails for any reason, there is no way of retrieving the lost data, as can be done in the following RAID implementations.

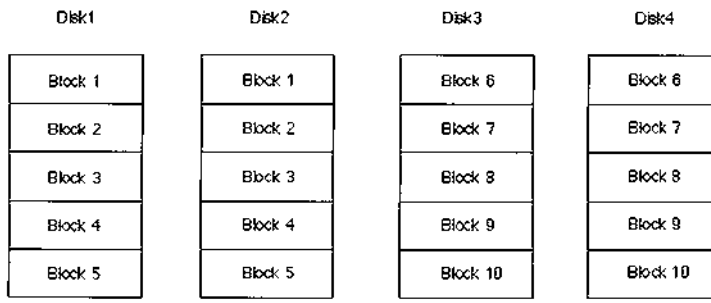
RAID Level 1

The RAID Level 1 configuration employs what is known as disk mirroring, which is done to ensure data reliability or a high degree of fault tolerance. RAID Level 1 also enhances read performance, but the improved performance and fault tolerance come at the expense of available capacity in the drives used.

In a RAID Level 1 configuration, the RAID management software instructs the subsystems controller to store data redundantly across a number of the drives (mirrored set) in the array. In other words, the same data is copied and stored on different disks (or mirrored) to ensure that, should a drive fail, the data is available somewhere else within the array. In fact, all but one of the drives in a mirrored set could fail and the data stored to the RAID Level 1 subsystem would remain intact. A RAID Level 1 configuration can consist of multiple mirrored sets, whereby each mirrored set can be a different capacity. Usually the drives making up a mirrored set are of the same capacity. If drives within a mirrored set are of different capacities, the capacity of a mirrored set within the RAID Level 1 subsystem is limited to the capacity of the smallest-capacity drive in the set; hence, the sacrifice of available capacity across multiple drives.

The read performance gain can be realized if the redundant data is distributed evenly on all of the drives of a mirrored set within the subsystem. The number of read requests and the total wait state times both drop significantly, in inverse proportion to the number of hard drives in the RAID, in fact. To illustrate, suppose three read requests are made to the RAID Level 1 subsystem (see Exhibit 3). The first request looks for data in the first block of the virtual drive; the second request goes to block 2, and the third seeks from block 3. The host-resident RAID man-

EXHIBIT 3 — A RAID Level 1 subsystem provides high data reliability by replicating (or mirroring) data between physical hard drives. In addition, I/O performance is boosted as the RAID management software allocates simultaneous read requests between several drives.



agement software can assign each read request to an individual drive. Each request is then sent to the various drives, and now — rather than having to handle the flow of each data stream one at a time — the controller can send three data streams almost simultaneously, which in turn reduces system overhead.

RAID Level 2

RAID Level 2 is rarely used in commercial applications, but is another means of ensuring data is protected in the event drives in the subsystem incur problems or otherwise fail. This level builds fault tolerance around Hamming error correction code (ECC), which is often used in modems and solid-state memory devices as a means of maintaining data integrity. ECC tabulates the numerical values of data stored on specific blocks in the virtual drive using a special formula that yields what is known as a checksum. The checksum is then appended to the end of the data block for verification of data integrity when needed.

As data gets read back from the drive, ECC tabulations are again computed, and specific data block checksums are read and compared against the most recent tabulations. If the numbers match, the data is intact; if there is a discrepancy, the lost data can be recalculated using the first or earlier checksum as a reference point.

The following example shows one method of ECC. Suppose the phrase being stored is HELLOTHERE. The checksum is computed for every 10 bytes of data.

Data being stored	H	E	L	L	O	T	H	E	R	E	
Numerical representation	72	69	76	76	79	84	72	69	82	69	
Checksum formula	× 1	× 2	× 3	× 4	× 5	× 6	× 7	× 8	x 9	x 10	
Multiplied out	72	138	228	304	395	504	504	414	738	690	
[Check]sum of all values	72	+138	+228	+304	+395	+504	+504	+414	+738	+690	= 3987

So, the data is stored on the drive as 72 69 76 76 79 84 72 69 82 69 3987.

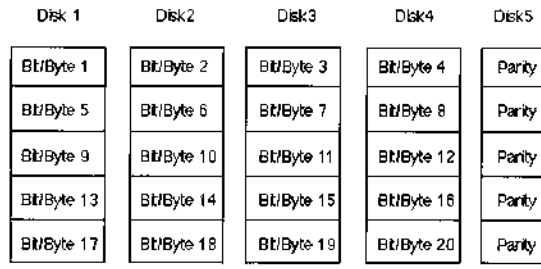
As the data is read back from the drive, the same calculations with the data segment are made. The newly computed checksum is compared against the previously stored checksum, thus verifying data integrity.

This form of ECC is actually different from the ECC technologies employed within the drives themselves. The topological formats for storing data in a RAID Level 2 array is somewhat limited, however, compared with the capabilities of other RAID implementations, which is the reason it is not often used in commercial applications.

RAID Level 3

This RAID level is really an adaptation of RAID Level 0 that sacrifices some capacity, for the same number of drives, but achieves a high level

EXHIBIT 4 — A RAID Level 3 configuration is very similar to a RAID Level 0 configuration in its utilization of data stripes dispersed over a series of hard drives to store data. In addition to these data stripes, a special drive is configured to hold parity information used to maintain data integrity throughout the RAID subsystem.



of data integrity or fault tolerance. It takes advantage of RAID Level 0 data-striping methods, except that data is striped across all but one of the drives in the array. This drive is used to store parity information that is used to maintain data integrity across all drives in the subsystem. The parity drive itself is divided up into stripes, and each parity drive stripe is used to store parity information for the corresponding data stripes dispersed throughout the array. This method achieves very high data transfer performance by reading from or writing to all of the drives in parallel or simultaneously, but retains the means to reconstruct data if a given drive fails, maintaining data integrity for the system (see Exhibit 4). RAID Level 3 is an excellent configuration for moving very large sequential files in a timely manner.

The stripes of parity information stored on the dedicated drive are calculated using the Exclusive OR (XOR) function. XOR is a logical function between the two series that carries most of the same attributes as the conventional OR function. The difference occurs when the two bits in the function are both nonzero: in XOR, the result of the function is zero, whereas with conventional OR it would be one, as described in Table 1.

By using XOR with a series of data stripes in the RAID, any lost data can easily be recovered. Should a drive in the array fail, the missing information can be determined in a manner similar to solving for a single variable in an equation (for example, solving for x in the equation, $4 + x = 7$). Similarly, in an XOR operation, it would be an equation like $1\ x = 1$. Thanks to XOR, there is always only one possible solution (in this case, 0), which provides a complete error recovery algorithm in a minimum amount of storage space.

TABLE 1 — Standard OR Function: Group A Group B

Group A	Group B	Result
0	0	0
1	0	1
0	1	1
1	1	1

RAID Level 4

This level of RAID is similar in concept to RAID Level 3, but emphasizes performance for different applications, e.g., database transaction processing versus large sequential files. Another difference between the two is that RAID Level 4 has a larger stripe depth, usually of two blocks, which allows the RAID management software to operate the disks much more independently than RAID Level 3, which controls the disks in unison. This essentially replaces the high data throughput capability of RAID Level 3 with faster data access in read-intensive applications.

A shortcoming of RAID Level 4 is rooted in an inherent bottleneck on the parity drive. As data gets written to the array, the parity-encoding scheme tends to be more tedious in write activities than with other RAID topologies. This more or less relegates RAID Level 4 to read-intensive applications with little need for similar write performance. As a consequence, like its Level 3 cousin, it does not see much common use in commercial applications.

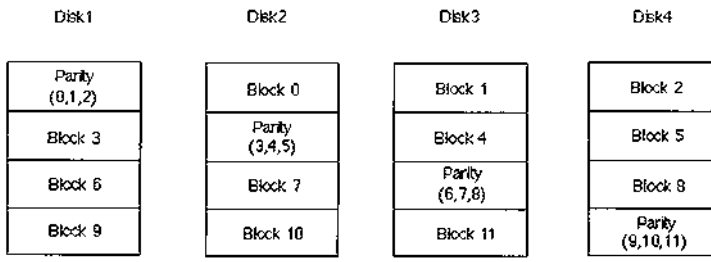
RAID Level 5

This is the last of the most commonly used RAID levels, and is probably the most frequently implemented. RAID Level 5 minimizes the write bottlenecks of RAID Level 4 by distributing parity stripes over a series of hard drives. In doing so it provides relief to the concentration of write activity on a single drive, which in turn enhances overall system performance (see Exhibit 5).

The way RAID Level 5 reduces parity write bottlenecks is relatively simple. Instead of allowing any one drive in the array to assume the risk of a bottleneck, all of the drives in the array assume write activity responsibilities. The distribution frees up the concentration on a single drive, improving overall subsystem throughput.

The RAID Level 5 parity-encoding scheme is the same as Levels 3 and 4. It maintains the ability of the system to recover any lost data should a single drive fail. This can happen as long as no parity stripe on an individual drive stores the information of a data stripe on the same drive. In

EXHIBIT 5 — RAID Level 5 overcomes the RAID Level 4 write bottleneck by distributing parity stripes over two or more drives within the system. This better allocates write activity over the RAID drive members, thus enhancing system performance.



other words, the parity information for any data stripe must always be located on a drive other than the one on which the data resides.

Other RAID Levels

Other, less-common RAID levels have been developed as custom solutions by independent vendors (they are not established standards):

- RAID Level 6, which emphasizes ultrahigh data integrity;
- RAID Level 10 (also known as RAID Levels 0 and 1), which focuses on high I/O performance and very high data integrity; and
- RAID Level 53, which combines RAID Levels 0 and 3 for uniform read and write performance.

Tailormade RAID

Perhaps the biggest advantage of RAID technology is the sheer number of possible adaptations available to users and systems designers. RAID offers the ability to customize an array subsystem to the requirements of its environment and the applications demanded of it. The inherent variety of configuration options of RAID provides several ways in which to satisfy specific application requirements (see Table 2). Customization, however, does not stop with a RAID level. Drive models, capacities, and performance levels have to be factored in, as well as what connectivity options are available.

INTERFACE OPTIONS

Differential SCSI (small computer systems interface), for example, allows a subsystem to be cabled as far as 18 feet from a host with no degrada-

TABLE 2 — RAID Configuration Options

RAID Level	Capacity	Data Availability	Data Throughput	Data Integrity
0	High	Read/write high	High I/O transfer rate	
1		Read/write high		Mirrored
2	High		High I/O transfer rate	ECC
3	High		High I/O transfer rate	Parity
4	High	Read high		Parity
5	High	Read/write high		Parity
6		Read/write high		Double parity
10		Read/write high	High I/O transfer rate	mirrored
53			High I/O transfer rate	Parity

tion to the data signal. Fast/Wide SCSI, another interface option, can be combined with differential SCSI or employed by itself; it essentially doubles the 10 Mbyte/s throughput of Fast SCSI, enabling data rates of up to 20 Mbytes/s. The newest parallel SCSI interface option is UltraSCSI, a 40 Mbyte/s interface standard.

An emerging new serial interface standard known as Fibre Channel-Arbitrated Loop (FC-AL) is yet another interface option for RAID subsystems, and is the most powerful of them all. FC-AL is capable of up to 200 Mbyte/s data throughputs (dual-loop configurations) while allowing RAID subsystems or other connected peripherals to be placed as far as 10 km from the host. It also enables easy connection of up to 126 disk drives on a single controller (compared with seven devices with conventional SCSI). The potential impact of FC-AL alone will undoubtedly be enormous on the evolution of RAID subsystems. FC-AL can be operated in either single- or dual-loop configurations. The dual loop allows another level of redundancy by allowing two separate data paths for all attached devices.

SCA: CLEANING UP THE CABLE MESS

Many of these interface options, including serial FC-AL and parallel UltraSCSI, support the SCSI Single Connector Attachment (SCA) standard. SCA is an elegant means of eliminating the miles of wiring involved with connecting several drives via conventional backplane architectures. Before SCA, conventional connections involved two cables per drive: one for power and the other for data transmission. Arrays with more than a few drives would amass a lot of spaghetti at the rear of the rack, and especially large arrays would have an unwieldy mess of wire to connect the drives. SCA, however, allows for drives to be plugged directly into a backplane without cables. It not only rids subsystems of the mass of cabling previously required, but facilitates hot plugging (removal or inser-

tion of a drive while the subsystem is online) and improves the reliability of the system as a whole because of the substantially reduced number of connections.

Tyson Heyn is Product Communications Manager at Seagate Technology, Inc. He specializes in high-end disk drives and technologies.

Malicious Code: The Threat, Detection, and Protection

Ralph Hoefelmeyer, CISSP
Theresa E. Phillips, CISSP

Malicious code is logically very similar to known biological attack mechanisms. This analogy is critical; like the evolution of biological mechanisms, malicious code attack mechanisms depend on the accretion of information over time. The speed of information flow in the Internet is phenomenally faster than biological methods, so the security threat changes on a daily if not hourly basis.

One glaring issue in the security world is the unwillingness of security professionals to discuss malicious code in open forums. This leads to the hacker/cracker, law enforcement, and the anti-virus vendor communities having knowledge of attack vectors, targets, and methods of prevention; but it leaves the security professional ignorant of the threat. Trusting vendors or law enforcement to provide information on the threats is problematic and is certainly not due diligence. Having observed this, one must stress that, while there is an ethical obligation to publicize the potential threat, especially to the vendor, and observe an embargo to allow for fixes to be made, exploit code should *never* be promulgated in open forums.

Macro and script attacks are occurring at the rate of 500 to 600 a month. In 2001, Code Red and Nimda caused billions of dollars of damage globally in remediation costs. The anti-virus firm McAfee.com claims that the effectiveness of the new wave of malicious codes was due to a one-two punch of traditional virus attributes combined with hacking techniques. Industry has dubbed this new wave of attacks *the hybrid threat*.

Exhibit 32-1. Viruses, 1986–2001.

Virus	First Observed	Type
Brain	1986	.com infector
Lehigh	1987	Command.com infector
Dark Avenger	1989	.exe infector
Michelangelo	1991	Boot sector
Tequila	1991	Polymorphic, multipartite file infector
Virus Creation Laboratory	1992	A virus builder kit; allowed non-programmers to create viruses from standard templates
Sme.g.,pathogen	1994	Hard drive deletion
Wm.concept	1995	Macro virus
Chernobyl	1998	Flash BIOS rewrite
Explore.zip	1999	File erasure
Magistr	2001	E-mail worm; randomly selects files to attach and mail

The goals in this chapter are to educate the information security practitioner on the current threat environment, future threats, and preventive measures.

CURRENT THREATS

Viruses

The classic definition of a virus is a program that can infect other programs with a copy of the virus. These are binary analogues of biological viruses. When these viruses insert themselves into a program — the program being analogous to a biological cell — they subvert the control mechanisms of the program to create copies of themselves. Viruses are not distinct programs — they cannot run on their own and need to have some host program, of which they are a part, executed to activate them. Fred Cohen clarified the meaning of *virus* in 1987 when he defined a virus as "a program that can 'infect' other programs by modifying them to include a possibly evolved copy of itself." Cohen earned a Ph.D. proving that it was impossible to create an accurate virus-checking program.

One item to note on viruses is the difference between damage as opposed to infection. A system may be infected with a virus, but this infection may not necessarily cause damage. Infected e-mail that has viral attachments that have not been run are referred to as *latent viruses*.

Exhibit 32-1 describes some examples of viruses released over the years. (Note: This is not an exhaustive list — there are arguably 60,000 known viruses.)

Worms

Worms are independent, self-replicating programs that spread from machine to machine across network connections, leveraging some network medium — e-mail, network shares, etc. Worms may have portions of themselves running on many different machines. Worms do not change other programs, although they may carry other code that does (e.g., a virus). Worms illustrate attacks against availability, where other weapons may attack integrity of data or compromise confidentiality. They can deny legitimate users access to systems by overwhelming those systems. With the advent of the *blended threat* worm, worm developers are building distributed attack and remote-control tools into the worms. Worms are currently the greatest threat to the Internet.

Morris Worm. Created by Robert T. Morris, Jr. in 1988, the Morris worm was the first active Internet worm that required no human intervention to spread. It attacked multiple types of machines, exploited several vulnerabilities (including a buffer overflow in fingered and debugging routines in *sendmail*), and used multiple streams of execution to improve its speed of propagation. The worm was intended to be a proof of concept; however, due to a bug in the code, it kept reinfecting already infected machines, eventually overloading them. The heavy load crashed the infected systems, resulting in the worm's detection. It managed to infect some 6200 computers — 10 percent of the Internet at that time — in a matter of hours. As a result of creating and unleashing this disruptive worm, Morris became the first person convicted under the Computer Fraud and Abuse Act.

Code Red Worm. The Code Red worm infected more than 360,000 computers across the globe on July 19, 2001. This action took less than 14 hours. The intention of the author of Code Red was to flood the White House with a DDoS attack. The attack failed, but it still managed to cause significant outages for other parties with infected systems. This worm used the ida and idq IIS vulnerabilities. The patch to correct this known vulnerability had been out for weeks prior to the release of the worm.

Nimda. Nimda also exploited multimode operations: it was an e-mail worm, it attacked old bugs in Explorer and Outlook, and it spread through Windows shares and an old buffer overflow in IIS. It also imitated Code Red 2 by scanning logically adjacent IP addresses. The net result was a highly virulent, highly effective worm that revealed that exploiting several old bugs can be effective, even if each hole is patched on most machines: all patches must be installed and vulnerabilities closed to stop a Nimda-like worm. Such a worm is also somewhat easier to write because one can use many well-known exploits to get wide distribution instead of discovering new attacks.

Exhibit 32-2. Trojan horses and payloads.

Trojan Horse	"Legitimate" Program	Trojan
PrettyPark	Screen Saver	Auto e-mailer; tries to connect to specific IRC channel to receive commands from attacker
Back Orifice	Program	Allows intruders to gain full access to the system
Goner	Screen Saver	Deletes AV files; installs DDoS client
W32.DIDer	Lottery game "ClickTilUWin"	Transmits personal data to a Web address

Trojan Horses

A Trojan horse, like the eponymous statue, is a program that masquerades as a legitimate application while containing another program or block of undesired, malicious, destructive code, deliberately disguised and intentionally hidden in the block of desirable code. The Trojan Horse program is not a virus but a vehicle within which viruses may be concealed. Exhibit 32-2 lists some Trojan horses, their distribution means, and payloads.

Operating System-Specific Viruses

DOS. DOS viruses are checked for by current anti-virus software. They are a threat to older machines and systems that are still DOS capable. DOS viruses typically affect either the command.com file, other executable files, or the boot sector. These viruses spread by floppy disks as well as e-mail. They are a negligible threat in today's environment.

Windows. Macro viruses take advantage of macros — commands that are embedded in files and run automatically. Word-processing and spreadsheet programs use small executables called macros; a macro virus is a macro program that can copy itself and spread from one file to another. If you open a file that contains a macro virus, the virus copies itself into the application's start-up files. The computer is now infected. When you next open a file using the same application, the virus infects that file. If your computer is on a network, the infection can spread rapidly; when you send an infected file to someone else, they can also become infected.

Visual Basic Script (VBS) is often referred to as *Virus Builder Script*. It was a primary method of infection via e-mail attachments. Now, many network or system administrators block these attachments at the firewall or mail server.

UNIX/Linux/BSD. UNIX, Linux, and BSD were not frequently targeted by malicious code writers. This changed in 2001, with new Linux worms target-

ing systems by exploiting flaws in daemons that automatically perform network operations. Examples are the Linux/Lion, which exploits an error in the bind program code and allows for a buffer overflow. Another example of a UNIX worm is SadMind. This worm uses a buffer overflow in Sun Solaris to infect the target system. It searches the local network for other Solaris servers, and it also searches for Microsoft IIS servers to infect and deface. Many of the UNIX variant exploits also attempt to download more malicious code from an FTP server to further corrupt the target system. The goal of UNIX attacks involves placing a root kit on the target system; these are typically social engineering attacks, where a user is induced to run a Trojan, which subverts system programs such as *login*.

Macintosh. Main attack avenues are bootable Macintosh disks, HyperCard stacks, and scripts. An example is the Scores virus, first detected in early 1988. This virus targeted EDS and contained code to search for the code words *ERIC* and *VULT*. It was later ascertained that these were references to internal EDS projects. This is notable in that this is the first example of a virus targeting a particular company. Scores infected applications and then scanned for the code words on the target system. Resources that were so identified were terminated or crashed when they were run. As cross-platform attacks become more common, Macintosh platforms will become increasingly vulnerable.

Cross-Platform. An example of cross-platform malicious code is the Lindose/Winux virus. This virus can infect both Linux Elf and Windows PE executables. Many installations of Linux are installed on dual-boot systems, where the system has a Linux partition and a Windows partition, making this a particularly effective attack mechanism.

Other attacks target applications that span multiple platforms, such as browsers. A good source of information on cross-platform vulnerabilities is http://www.sans.org/newlook/digests/SAC/cross.htm.

Polymorphic Viruses

Virus creators keep up with the state-of-the-art in antiviral technology and improve their malicious technology to avoid detection. Because the order in which instructions are executed can sometimes be changed without changing the ultimate result, the order of instructions in a virus may be changed to bypass the anti-virus signature. Another method is to randomly insert null operations instructions to the computer, mutating the sequence of instructions the anti-virus software recognizes as malicious. Such changes result in viruses that are polymorphic — they constantly change the structural characteristics that would have enabled their detection.

Script Attacks

Java and JavaScript. Java-based attacks exploit flaws in the implementation of Java classes in an application. A known early attack was the BrownOrifice applet. This applet exploited flaws in Netscape's Java class libraries.

JavaScript has been used in the Coolnow-A worm to exploit vulnerabilities in Microsoft Internet Explorer.

ActiveX. ActiveX controls have more capabilities than tools that run strictly in a sandbox. Because ActiveX controls are native code that run directly on a physical machine, they are capable of accessing services and resources that are not available to code that runs in a restricted environment. There are a few examples of ActiveX attack code as of this writing. There is example code called Exploder, which crashed Windows 95 systems. There is also a virus, the HTML.bother.3180, that uses ActiveX controls to perform malicious activity on the target system.

FUTURE THREATS: WHO WILL WRITE THEM?

The Script Kiddie Threat

There are automated hacking tools on the Internet, readily available at many hacker sites. These tools are of the point-and-click genre, requiring little to no programming knowledge. The security practitioner must visit these hacker sites to understand the current threat environment. Fair warning: these sites often have attack scripts, and many hackers use pornography to prevent or limit official perusal of their sites by legitimate authorities. The script kiddies are a serious threat due to their numbers. The recent *goner* worm was the work of three teenagers in Israel; other malicious code has been created by untrained people in Brazil, Finland, and China.

Criminal Enterprises

The amount of commerce moving to the Internet is phenomenal, in the multibillion-dollar range. Wherever there are large transactions, or high transaction volumes, the criminal element will attempt to gain financial advantage. Malicious code introduced by criminals may attempt to gain corporate financial information, intellectual property, passwords, access to critical systems, and personnel information. Their goals may be industrial espionage, simple theft by causing goods and services to be misdelivered, fraud, or identity theft.

Ideologues

Small groups of ideologues may use the Internet and malicious code to punish, hinder, or destroy the operations of groups or governments they find objectionable. Examples are the anti-WTO groups, which have

engaged in hacking WTO systems in Europe, and various anti-abortion groups in the United States. Also, individual citizens may take action, as recently seen in the Chinese fighter striking the American surveillance plane; many Chinese citizens, with tacit government approval, have launched attacks on American sites.

Terrorist Groups

Terrorist groups differ from ideologues in that they are generally better funded, better trained, and want to destroy some target. Since September 11, the seriousness of the terrorist threat cannot be stressed enough. The goals of a terrorist group may be to use malicious code to place root kits on systems responsible for dam control, electrical utilities' load balancing, or nuclear power plants. A speedy propagating worm, such as the Warhol, would be devastating if not quickly contained. Additionally, terrorist groups may use malicious code to manipulate financial markets in their favor; attacked companies may lose stock value over a short time, allowing for puts and calls to be made with foreknowledge of events.

Terrorists generally fall into two categories: (1) well-educated and dedicated, and (2) highly motivated Third- or Fourth-World peasants. An example of the first would be the Bader Meinhoff group; for the second, the Tamil Tigers of Sri Lanka.

Government Agencies

The Internet has allowed many government and corporate entities to place their functions and information to be readily accessible from the network. The flip side of this is that, logically, one can "touch" a site from anywhere in the world. This also means that one can launch attacks using malicious code from anywhere on the planet.

Intelligence agencies and military forces have already recognized that the Internet is another battlefield. The U.S. National Security Agency, FBI, and U.K. MI5 and MI6 all evince strong interest in Internet security issues. The U.S. Air Force has in place a cyber-warfare center at Peterson Air Force Base, Colorado Springs, Colorado. Its Web site is http://www.spacecom.af.mil/usspacecom/jtf-cno.htm. Note that their stated mission is:

> Subject to the authority and direction of USCINCSPACE, JTF-CNO will, in conjunction with the unified commands, services and DoD agencies, coordinate and direct the defense of DoD computer systems and networks; coordinate and, when directed, conduct computer network attack in support of CINCs and national objectives.

The intelligence and military attackers will be well-educated professionals with the financial and technical backing of nation-states. Their attacks will not fail because of bad coding.

Warhol

Nimda was the start of multiple avenues and methods of attack. After Code Red, researchers began to investigate more efficient propagation or infection methods. One hypothetical method is described in a paper by Nicholas Weaver of the University of California, Berkeley; the paper can be obtained at http://www.cs.berkeley.edu/~nweaver/warhol.html. Weaver named this attack methodology the *Warhol Worm*. There are several factors affecting malicious code propagation: the efficiency of target selection, the speed of infection, and the availability of targets. The Warhol method first builds a list of potentially vulnerable systems with high-speed Internet connections. It then infects these target systems because they are in the best position to propagate the malicious code to other systems. The newly infected system then receives a portion of the target list from the infecting system. Computer simulations by Weaver indicate that propagation rates across the Internet could reach one million computers in eight minutes. His initial assumptions were to start with a 10,000-member list of potentially vulnerable systems; the infecting system could perform 100 scans per second; and infecting a target system required one second.

Cross-Platform Attacks: Common Cross-Platform Applications

A very real danger is the monoculture of applications and operating systems (OS) across the Internet. Identified flaws in MS Windows are the targets of malicious code writers. Applications that span platforms, such as MS Word, are subject to macro attacks that will execute regardless of the underlying platform; such scripts may contain logic to allow for cross-platform virulence.

Intelligent Scripts

These scripts detect the hardware and software on the target platform, and they have different attack methods scripted specifically for a given platform/OS combination. Such scripts can be coded in Java, Perl, and HTML. We have not seen an XML malicious code attack method to date; it is really only a matter of time.

Self-Evolving Malicious Code

Self-evolving malicious code will use artificial neural networks (ANNs) and genetic algorithms (GA) in malicious code reconstruction. These platforms will change their core structures and attack methods in response to the environment and the defenses encountered. We see some of this in Nimda, where multiple attack venues are used. Now add an intelligence capability to the malicious code, where the code actively seeks information on new vulnerabilities; an example would be scanning the Microsoft patch site for patches, creation of exploits that take advantage of these

patch fixes, and release of the exploit. These will have far larger payloads than current attacks and may require a home server site for evolution. As networks evolve, these exploits may *live* in the network.

The development of distributed computing has led to the idea of *parasitic computing*. This model would allow the intelligent code to use the resources of several systems to analyze the threat environment using the distributed computing model. The parasitic model also allows exploits to steal cycles from the system owner for whatever purpose the exploit builder desires to use them for, such as breaking encryption keys.

Router Viruses or Worms

Attack of routers and switches is of great concern; successful cross-platform attacks on these devices could propagate across the Internet in a manner akin to the aforementioned Warhol worm.

Analysis of Formal Protocol Description. This attack method requires a formal analysis of the protocol standard and the various algorithms used to implement the protocol. We have seen an example of this with the SNMP v1 vulnerability, released publicly in February 2002. The flaw is not in the protocol but in the implementation of the protocol in various applications.

Further research of protocols such as the Border Gateway Protocol (BGP), Enhanced Interior Gateway Routing Protocol (EIGRP), testing the implementation versus the specification, may lead to other vulnerabilities.

Test against Target Implementations. The malicious code builders simply gain access to the target routing platform and the most prevalent version of the routing software and proceed to test various attack methods until they succeed. Also, with privileged access to a system, attackers may reverse-engineer the implementation of the target protocols underlying software instance. An analysis of the resulting code may show flaws in the logic or data paths of the code.

The primary target of router attacks will be the BGP. This protocol translates routing tables from different vendors' routing platforms for interoperability. It is ubiquitous across the Internet. By targeting ISPs' routers, the attackers can potentially take down significant portions of the Internet, effectively dropping traffic into a black hole. Other methods use packet-flooding attacks to effect denial-of-service to the network serviced by the router. Router or switch operating system vulnerabilities are also targeted, especially because these network devices tend not to be monitored as closely as firewalls, Web servers, or critical application servers.

Wireless Viruses

Phage is the first virus to be discovered that infects hand-held devices running the PalmOS. There were no confirmed reports of users being

affected by the virus, and it is considered a very low threat. It overwrites all installed applications on a PalmOS handheld device.

Wireless phones are another high-risk platform. An example is the Short Messaging Service (SMS) exploit, where one sends malformed data headers to the target GSM phone from an SMS client on a PC, which can crash the phone.

In June of 2001, the Japanese I-mode phones were the targets of an e-mail that caused all I-mode phones to dial 110, the Japanese equivalent of 911. Flaws in the software allowed embedded code in the e-mail to be executed.

The growing wireless market is sure to be a target for malicious code writers. Additionally, the software in these mobile devices is not implemented with security foremost in the minds of the developers, and the actual infrastructures are less than robust.

Active Content

Active content, such as self-extracting files that then execute, will be a great danger in the future. The security and Internet communities have come to regard some files as safe, unlike executable files. Many organizations used Adobe PDF files instead of Microsoft Word, because Adobe was perceived as safe. We now see exploits in PDF files. Additionally, there is now a virus, SWF/LFM-926, which infects Macromedia Flash files.

PROTECTION

Defense-in-Depth

A comprehensive strategy to combat malicious code encompasses protection from, and response to, the variety of attacks, avenues of attack, and attackers enumerated above. Many companies cocoon themselves in secure shells, mistakenly believing that a perimeter firewall and anti-virus software provide adequate protection against malicious code. Only when their systems are brought to a halt by a blended threat such as the Code Red worm do they recognize that, once malicious code penetrates the first line of defense, there is nothing to stop its spread throughout the internal network and back out to the Internet. Malicious code has multiple ways to enter the corporate network: e-mail, Web traffic, instant messenger services, Internet chat (IRC), FTP, handheld devices, cell phones, file sharing programs such as Napster, peer-to-peer programs such as NetMeeting, and unprotected file shares through any method by which files can be transferred. Therefore, a sound protection strategy against malicious code infiltration requires multiple overlapping approaches that address the people, policies, technologies, and operational processes of information systems.

Exhibit 32-3. Safe computing practices for the Windows user community.

1. Install anti-virus software. Make sure the software is set to run automatically when the system is started, and do not disable real-time protection.
2. Keep anti-virus software up-to-date. Configure systems to automatically download updated signature files from the company-approved server or vendor site on a regular basis.
3. Install the latest operating system and application security patches.
4. Do not share folders or volumes with other users. If drive sharing is necessary, do not share the full drive and do password-protect the share with a strong password.
5. Make file extensions visible. Windows runs with the default option to "hide file extensions for known file types." Multiple e-mail viruses have exploited hidden file extensions; the VBS/LoveLetter worm contained an e-mail attachment, a malicious VBS script, named "LOVE-LETTER-FOR-YOU.TXT.vbs; the .vbs extension was hidden.
6. Do not forward or distribute non-job-related material (jokes, animations, screen savers, greeting cards).
7. Do not activate unsolicited e-mail attachments and do not follow the Web links quoted in advertisements.
8. Do not accept unsolicited file transfers from strangers in online peer-to-peer computing programs such as Instant Messaging or IRC.
9. Beware of virus hoaxes. Do not forward these messages, and do not follow the instructions contained therein.
10. Protect against infection from macro viruses:
    If Microsoft Word is used, write-protect the global template.
    Consider disabling macros in MS Office applications through document security settings.
    Consider using alternate document formats such as rtf (Rich Text Format) that do not incorporate executable content such as macros.
11. Check ALL attachments with anti-virus software before launching them. Scan floppy disks, CDs, DVDs, Zip disks, and any other removable media before using them.
12. Turn off automatic opening of e-mail attachments or use another mail client. BadTrans spread through Microsoft Internet Explorer-based clients by exploiting a vulnerability in auto-execution of embedded MIME types.
13. Establish a regular backup schedule for important data and programs and adhere to it.

Policy

An organization's first step in the battle against malicious code is the development and implementation of a security policy addressing the threat to information systems and resources (see Exhibit 32-3). The policy describes proactive measures the organization has taken to prevent infection; safe computing rules and prevention procedures that users must follow; tools and techniques to implement and enforce the rules; how to recognize and report incidents; who will deal with an outbreak; and the consequences of noncompliance. The policy should make employees assume responsibility and accountability for the maintenance of their computers.

When users understand why procedures and policies are implemented, and what can happen if they are not followed, there tends to be a higher level of compliance.

Suggested Policy Areas. Require the use of company-provided, up-to-date anti-virus software on all computing devices that access the corporate network, including handheld and wireless devices. Inform users that removing or disabling protection is a policy violation. Address remote and mobile Windows users by specifying that they must have up-to-date protection in order to connect to the network. Consider establishing virus protection policies for guest users, such as vendors and consultants, and for protecting Linux, UNIX, and Macintosh operating systems as well.

Weaknesses in software programs are routinely discovered and exploited; therefore, a sound anti-virus policy must address how and when patching will be done, as well as the means and frequency for conducting backups.

The information security practitioner needs to recognize that users with Web-based e-mail accounts can circumvent the carefully constructed layers of protection at the firewall, e-mail gateway, and desktop by browsing to a Web-based e-mail server. Policy against using external e-mail systems is one way to prevent this vector, but it must be backed up with an HTTP content filter and firewall rules to block e-mail traffic from all but approved servers or sources.

Finally, include a section in the policy about virus warnings. Example: "Do not forward virus warnings of any kind to *anyone* other than the *incident handling/response team.* A virus warning that comes from any other source should be ignored."

Education and Awareness

Security policy must be backed up with awareness and education programs that teach users about existing threats, explain how to recognize suspicious activity, and how to protect the organization and their systems from infection. The information security practitioner must provide the user community with safe computing practices to follow, and supply both the tools (e.g., anti-virus software) and techniques (e.g., automatic updates) to protect their systems.

Awareness training must include the social engineering aspects of viruses. The AnnaKournikova and NakedWife viruses, for example, took advantage of human curiosity to propagate; and communications-enabled worms spread via screen savers or attachments from known correspondents whose systems had been infected.

The awareness program should reiterate policy on how to recognize and deal with virus hoaxes. E-mail hoaxes are common and can be as costly in terms of time and money as the real thing. Tell users that if they do forward the "notify everyone you know" warnings to all their colleagues, it can create a strain on mail servers and make them crash — having the same effect as the real thing.

Protection from Malicious Active Code

Protect against potentially malicious scripts by teaching users how to configure their Internet browsers for security by disabling or limiting automatic activation of Java or ActiveX applets. Teach users how to disable Windows Scripting Host and to disable scripting features in e-mail programs — many e-mail programs use the same code as Web browsers to display HTML; therefore, vulnerabilities that affect ActiveX, Java, and JavaScript are often applicable to e-mail as well as Web pages.

System and Application Protection. Consider using alternative applications and operating systems that are less vulnerable to common attacks. The use of the same operating system at the desktop or in servers allows one exploit to compromise an entire enterprise. Similarly, because virus writers often develop and test code on their home computers, corporate use of technologies and applications that are also popular with home users increases the threat to the corporation from malicious code designed to exploit those applications. If trained support staff is available in-house, the organization may decide to run services such as DNS, e-mail, and Web servers on different operating systems or on virtual systems. With this approach, an attack on one operating system will have less chance of affecting the entire network.

Regardless of which operating system or application is used, it is critical to keep them up-to-date with the latest security patches. Worms use known vulnerabilities in the OS or application to take over systems. Frequently, vendors have released patches months in advance of the first exploitation of a weakness. Rather than being in the reactive mode of many system administrators who were caught by the Code Red worm, be proactive about testing and applying patches as soon as possible after receiving notification from the vendor. Use scripts or other tools to harden the operating system and disable all unnecessary services. Worms have taken advantage of default installations of Web server and OS software.

Layered Anti-virus Protection. Because malicious code can enter the enterprise through multiple avenues, it is imperative that protective controls be applied at multiple levels throughout the enterprise. In the time prior to macro viruses, there was little benefit to be gained by using anti-virus controls anywhere but the desktop. However, when macro viruses

became prevalent, placing controls at the file server helped reduce infection. In today's environment of communication-enabled worms and viruses, a thorough protection strategy involves integrated anti-virus solutions at the desktop, file and application servers, groupware servers, and Internet e-mail gateway and firewall; and inspection of all traffic flowing between the external gateway and internal network.

Protect the Desktop. Desktop protection remains a crucial component of an effective protection strategy. The information security practitioner must ensure that the organization has an enterprise license for anti-virus software, along with a procedure to automate installation and updates. Anti-virus software should be part of the standard build for desktops, laptops, and workstations, backed up by policy that makes it a violation to disable or uninstall the real-time scanning. It is prudent to give remote users a license for company-approved anti-virus software to enable them to run it on their end systems, regardless of whether the company owns those nodes.

Because current viruses and worms can spread worldwide in 12 hours or less (and new ones may propagate much faster), the ability to quickly update systems during an outbreak can limit the infection. However, the heavy traffic caused by thousands or millions of users trying to simultaneously update their definition files will hamper the ability to obtain an update from the vendor's site during an outbreak. Instead, the enterprise anti-virus administrator can provide a local site for updating. The anti-virus administrator can download once from the vendor site, allowing the entire network to be updated locally. This approach avoids network congestion and reduces the risk of infection from users who are unable to obtain a timely update from the vendor.

Server Protection. Although infection via macro viruses is no longer widespread, protection for network files and print servers can prevent infection from old or infrequently used files. Regardless of policies or training, there are always some users without up-to-date anti-virus protection — whether from naïveté, deliberately disabling the software, or because of system problems that prevent the anti-virus software from starting. One unprotected system can infect many files on the network server if server-side protection is not installed.

Fortify the Gateway. The speed of infection and the multiple vectors through which malicious code can enter the enterprise provide the impetus to protect the network at the perimeter. Rather than trying to keep current on the list of ports known to be used by malicious programs, configure firewalls to use the default *deny all* approach of closing all ports and only opening those ports that are known to be needed by the business. Virus writers are aware of this approach, so they attack ports that are usually open such as HTTP, e-mail, and FTP. Because e-mail is the current method

of choice for malicious code propagation, the information security practitioner must implement gateway or network-edge protection. This protection is available as anti-virus software for a particular brand of e-mail server, as gateway SMTP systems dedicated to scanning mail before passing the messages to the corporate e-mail servers, or anti-virus and malicious code services provided by an e-mail service provider. To protect against infection via Web and FTP, gateway virus protection is available for multiple platforms. The software can scan both incoming and outgoing FTP traffic, and it scans HTTP traffic for hostile Java, JavaScript, or ActiveX applets.

Protect the Routing Infrastructure. As companies learn to patch their systems, block certain attachments, and deploy malicious code-detection software at the gateway, attackers will turn to other vectors. As mentioned earlier, routers are attractive targets because they are more a part of the network infrastructure than computer systems; and they are often less protected by security policy and monitoring technology than computer systems, enabling intruders to operate with less chance of discovery.

To protect these devices, practice common-sense security: change the default passwords, set up logging to an external log server, use AAA with a remote server, or require access through SSH or VPNs.

Vulnerability Scans. A proactive security program includes running periodic vulnerability scans on systems; results of the scans can alert the information security practitioner to uninstalled patches or security updates, suddenly opened ports, and other vulnerabilities. System administrators can proactively apply patches and other system changes to close identified vulnerabilities before they are exploited by attackers using the same tools. There are a number of commercial and open-source scanning tools, such as SATAN, SAINT, and Nessus.

Handhelds. As IP-enabled handhelds such as PDAs, palmtops, and smart phones become more popular, they will be targeted by attackers. To keep these computing devices from infecting the network, provide a standard anti-virus software package for mobile devices and instruct users on how to download updates and how to run anti-virus software when synching their handheld with their PC.

Personal Firewalls. Personal firewalls offer another layer of protection for users, especially for remote users. Properly configured personal firewalls can monitor both incoming and outgoing traffic, detect intrusions, block ports, and provide application (e-mail, Web, chat) controls to stop malicious code. The firewalls function as an agent on the desktop, intercepting and inspecting all data going into or out of the system. To facilitate enterprise management, the personal firewall software must be centrally managed so that the administrator can push policy to users, limit the ability

of users to configure the software, and check for the presence of correctly configured and active firewalls when the remote user connects to the network. The firewall logging feature should be turned on to log security — relevant events such as scans, probes, viruses detected, and to send the logs to a central server.

Research

> If you know the enemy and know yourself, you need not fear the result of a hundred battles. If you know yourself but not the enemy, for every victory gained you will also suffer a defeat. If you know neither the enemy nor yourself, you will succumb in every battle.

> Author of *The Art of War*

Knowing what direction virus development is taking, and knowing and eliminating potential vulnerabilities before they can be exploited, is one of the most positive steps an organization can take toward defense. Virus creators keep up with the state-of-the-art in antiviral technology and improve their malicious technology to avoid detection. The information security practitioner must do likewise. Monitor hacker and black-hat sites (follow precautions listed earlier) to keep abreast of the threat environment. Visit anti-virus vendor sites: EICAR (European Institute of Computer Anti-virus Researchers), *The Virus Bulletin*, and the Wild List of viruses at www.wildlist.org. Other sources to monitor are the Honeynet Project and SecurityFocus' ARIS (Attack Registry and Intelligence Services) predictor service (fee based). These sites monitor exploits and develop statistical models that can predict attacks.

DETECTION AND RESPONSE

Virus and Vulnerability Notification

Monitor sites such as BugTraq and SecurityFocus that publish vulnerability and malicious code information. Subscribe to mailing lists, alert services, and newsgroups to be notified of security patches. Subscribe to alerts from anti-virus vendors, organizations such as SANS, Carnegie Mellon's CERT, NIPC (National Infrastructure Protection Center), Mitre's CVE (Common Vulnerabilities and Exposures), and BugTraq. Monitor the anti-virus vendor sites and alerts for information about hoaxes as well, and proactively notify end users about hoaxes before they start flooding the corporate e-mail server.

Anti-virus (AV) software vendors rely on customers and rival AV companies for information on the latest threats. Typically, if a corporation thinks that an as-yet unidentified virus is loose on its network, it sends a sample

to the AV vendor to be analyzed. This sample is then passed on to other AV vendors so that all work in concert to identify the virus and develop signature updates. This cooperative effort ensures that end users receive timely protection, regardless of which AV vendor is used.

Virus researchers also spend time visiting underground virus writing sites where some authors choose to post their latest code. This allows AV companies to work to develop methods to detect any new techniques or potential threats before they are released.

Current Methods for Detecting Malicious Code

The propagation rate of malware attacks is rapidly reaching the point of exceeding human ability for meaningful reaction. The Code Red and Nimda worms were virulent indicators of the speed with which simple active worms can spread. By the time humans detected their presence, through firewall probes or monitoring of IP ranges, the worms had spread almost worldwide.

Signature Scanning. Signature scanning, the most common technique for virus detection, relies on pattern-matching methods. This technique searches for an identifiable sequence or string in suspect files or traffic samples and uses this virus fingerprint or *signature* to detect infection. While this method is acceptable for detecting file and macro viruses or scripts that require activation to spread, it is not very effective against worms or polymorphic viruses. This reactive method also allows a new virus a window of opportunity between the initial appearance of the virus and the time it takes for the industry to analyze the threat, determine the virus signature, and rush to deploy updates to detect the signature.

The response time to worm outbreaks is shrinking to a few hours. Worms can spread faster than virus updates can be created. Even faster infection strategies have been postulated, such as the Warhol worm and Flash worms, which theoretically may allow a worm to infect all vulnerable machines in minutes. Firewall and anti-virus development must move in the direction of detecting and automatically responding to new attacks.

Client or Desktop AV to Detect and Remove Viral Code. Client AV programs can detect and often disinfect viruses, and they must provide both on-access and static virus checking. Static file scanning checks a file or file volume for viruses; on-access, real-time virus checking scans files before they are fully opened. Suspect files are treated according to configurable rules — they may be repaired, disinfected, quarantined for later treatment, or deleted.

Anti-virus software generally uses virus signatures to recognize virus threats. Most viruses that arrive via e-mail have been released within the

previous year or more recently; therefore, virus software containing old signatures is essentially useless. It is vital to ensure that virus software is updated on a regular basis — weekly at a minimum for desktops. To ensure that desktop protection is up-to-date, the information security practitioner should provide an automated update mechanism. The client software can be configured to periodically check for new AV signatures and automatically install them on the desktop. Desktop anti-virus software must be able to scan compressed and encoded formats to detect viruses buried in multiple levels of compression.

Because laptops and notebooks are frequently used without being connected to the network, when an unprotected machine attaches to the network, some mechanism needs to be in place to detect the connection and force either the installation or update of anti-virus software, or force the computer to disconnect. Another way to check a laptop system is to run a vulnerability scan each time a remote desktop authenticates to the network in order to ensure it has not already been compromised. Many of the enterprise Code Red infections occurred not through Internet-facing MS Internet Information Services (IIS) servers but through infected notebook computers or systems connecting via VPNs. Once Code Red enters the internal network, it infects unpatched systems running IIS, although those systems were inaccessible from the Internet.

Recently, anti-virus vendors have recommended that companies update their virus software every day instead of weekly. With the arrival of viruses such as Nimda, some customers pull software updates every hour.

Besides detection through technology, user observation is another way to detect worm activity. The "goner" worm disabled personal firewall and anti-virus software; users should recognize this, if through no other means than by missing icons in their Windows system tray, and notify the incident handling team.

Server Detection. Server administrators must regularly review their system and application logs for evidence of viral or Trojan activity, such as new user accounts and new files, (rootkits or root.exe in the scripts directory), and remove these files and accounts. Remove worm files and Trojans using updated virus scanners to detect their presence. Discovery of *warez* directories on FTP servers is proof that systems have been compromised. Performance of real-time anti-virus scanners may impact servers; not all files need to be scanned, but at a minimum critical files should be scanned. Server performance monitoring will also provide evidence of infection, either through reduced performance or denial of service.

File Integrity Checkers. File integrity tools are useful for determining if any files have been modified on a system. These tools help protect systems against computer viruses and do not require updated signature files. When

an integrity checker is installed, it creates a database of checksums for a set of files. The integrity checker can determine if files have been modified by comparing the current checksum to the checksum it recorded when it was last run. If the checksums do not match, then the file has been modified in some manner. Some integrity checkers may be able to identify the virus that modified a file, but others may only alert that a change exists.

Real-Time Content Filtering. To prevent the entry of malicious code into the corporate network, implement content filtering at the gateways for Web, mail, and FTP traffic. Set the filters to block known vulnerable attachments at the gateway. Filter attachments that have been delivery vehicles for malicious code, such as .exe, .com, .vbs, .scr, .shs, .bat, .cmd, .com, .dll, .hlp, .pif, .hta, .js, .lnk, .reg, .vbe, .vbs, .wsf, .wsh, and .wsc. Inform users that if they are trying to receive one of these files for legitimate purposes, they can have the sender rename the extension when they send the attachment. Many worms use double extensions, so block attachments with double extensions (e.g., .doc.vbs or .bmp.exe.) at the gateway or firewall.

At the initial stages of an infection, when new signatures are not available, block attachments or quarantine e-mails that contain certain words in the subject line or text until the anti-virus vendor has a signature update.

E-mail and HTML filtering products can examine file attachments and HTML pages. Objects such as executable files or code can be stripped out before passing them on, or they can be quarantined for later inspection. Deploy software that performs real-time virus detection and cleanup for all SMTP, HTTP, and FTP Internet traffic at the gateway. SMTP protection complements the mail server to scan all inbound and outbound SMTP traffic for viruses.

Set up scanning rules on the gateway SMTP system to optimize scanning of incoming e-mail. Some systems scan attachments only, and others scan both attachments and e-mail text — this distinction is important because some viruses, such as BubbleBoy, can infect without existing as an attachment. Be aware of the capabilities of the system selected. As with desktop software, gateway systems provide options to scan all attachments or only selected attachments. Handling viruses is tunable as well — the attachment can be deleted, repair can be attempted, or it can be logged and forwarded. Files with suspect viruses can be quarantined until new updates are received, and repair can be attempted at that time.

HTTP protection keeps infected files from being downloaded and allows the information security practitioner to set uniform, system-wide security standards for Java and Authenticode. It also affords protection against malicious Java and ActiveX programs for users. FTP protection works to ensure that infected files are not downloaded from unsecured remote sites.

Proactive Detection

Detecting Anomalous Activity: Sandboxing and Heuristics. Sandboxing is a proactive technique that works by monitoring the behavior of certain attachments in real-time, blocking malicious content from running before it can negatively impact a system. It essentially places a barrier in front of the operating system resources and lets the barrier determine which access programs and applications have to operating system resources. Programs are classified as low, medium, or high restricted, and system resources' access controls are assigned accordingly. An anti-virus package is still required to identify and disinfect known malicious code, but the threat is removed regardless of whether the anti-virus system reacts.

Heuristic scanning uses an algorithm to determine whether a file is performing unauthorized activities, such as writing to the system registry or activating its own built-in e-mail program. Both sandboxing and heuristic techniques at the desktop can be useful as the final layer of defense. Both examine the behavior of executed code to attempt to identify potentially harmful actions, and they flag the user for action should such behavior be identified. Because behavior-blocking tools do not need to be updated with signatures, layering traditional anti-virus solutions with these proactive solutions can create an effective approach to block both known and new malicious code. The drawback to both methods is the tendency to generate false positives; to get their work done, users often end up saying *yes* to everything, thus defeating the protection.

Worm Detection: Firewalls and Intrusion Detection Systems (IDSs). Hybrid firewalls (those that combine application proxies with stateful inspection technologies) can be used effectively to repel blended threats such as Code Red and Nimda. Application inspection technology analyzes HTTP and other protocol requests and responses to ensure they adhere to RFC standards.

Worms can also be detected by their excessive scanning activity — network monitoring on the LAN should send alerts to the network operations staff when unusual scanning activity is detected, whether the activity is generated externally or internally. Monitoring the network for normal activity will allow operators to set thresholds and trip alarms when those thresholds are exceeded. A number of machines suddenly scanning all its neighbors should send an alarm in fairly short order.

A network IDS that combines heuristics and signature technologies can provide monitoring staff with the first indication of a worm infection by identifying anomalous network traffic with known worm signatures or unusual traffic patterns. The alert still requires analysis by humans to determine if it is malicious, but such systems can provide early warning of potential infection. Many modern firewalls and IDS systems have the ability

to detect certain types of virus and worm attacks such as Code Red and Nimda, alert network support personnel, and immediately drop the connection. Some intelligent routing and switching equipment also comes with the ability to foil certain types of attacks.

Deploy IDS at the network level to detect malicious code that passes the firewall on allowed ports. The information security practitioner should also consider deploying IDS on subnets that house critical servers and services to detect malicious code activity, such as unusual scanning activity or mailing patterns. Have alerts sent when unusual traffic is logged to or from your e-mail server; the LoveLetter e-mail virus, for example, sent out 100 infected e-mails per minute from one user. Possible responses to these communication-enabled viruses include blocking e-mail with the suspect subject line, automatically (based on thresholds) blocking the victim's outbound mail queue, and contacting both the victim and the sender to notify them of the infection.

Tarpits. Tarpits such as LaBrea are a proactive method used to prevent worms from spreading. A tarpit installed on a network seeks blocks of unused IP addresses and uses them to create virtual machines. When a worm hits one of the virtual machines, LaBrea responds and keeps the worm connected indefinitely, preventing it from continuing to scan and infect other systems.

RESPONSE AND CLEANUP

If it appears that a system or network is under attack by a worm, it is prudent to sever the network connection immediately in order to isolate the local network. If the worm is already loose in the system, this act may limit its spread and may also prevent important data from being sent outside of the local area network. It may be appropriate to take the system offline until the breach has been repaired and any necessary patches installed. Critical servers should have backup systems that can be installed while the infected machine is rebuilt with fresh media.

Worms seldom attack single systems, so the incident response team will need to inspect all systems on the network to determine if they have been affected. With expanding use of extranets for customers and partners, and as Web services proliferate, responding to an intrusion or worm may involve contacting partners or customers who could lose their access to services or be compromised themselves. Such notification should be detailed in escalation procedures and incident response plans.

Incident Response and Disaster Recovery Plans

It is imperative that the information security practitioner create and test a rapid-response plan for malicious code emergencies. Infections will happen

despite defense measures, so be prepared to wipe them out quickly. The recovery plan must include escalation levels, malicious code investigators, and repair teams equipped with the tools and techniques to recover lost data. A consistent, strong backup policy, for both users and systems administrators, is essential for restoring lost or damaged data. Ensure that backup operators or system administrators have backups of all data and software, including operating systems. If the organization is affected by a virus, infected files and programs can be replaced with clean copies. For particularly nasty viruses, worms, and remote-access Trojans, the administrator may have no choice but to reformat and rebuild — this process can be simplified using a disk-imaging program such as GHOST.

SUMMARY

Practice defense-in-depth — deploy firewalls, proxy servers, intrusion detection systems, on-demand and on-access scanners at the network gateway, mail, file and application servers, and on the desktop. Employ proactive techniques such as integrity checkers, vulnerability scans, e-mail filters, behavior blockers, and tarpits to protect against incursions by malicious code. All of these tools and techniques must enforce a security policy and be clearly laid out and explained in procedures. The enterprise is complex, with many operating systems and applications running simultaneously. To address this complexity, protection must be multi-layered — controlling all nodes, data transmission channels, and data storage areas. Expect that new vulnerabilities will emerge at least as fast as old ones are repaired, and that attackers will take advantage of any that are not yet repaired.

To fight malicious code, enterprises must take a holistic approach to protection. Every aspect of the enterprise should be examined for ways to reduce the impact of malicious code and allow the organization to fight infection in a coordinated fashion. Once effective measures are in place, the information security practitioner should maintain vigilance by researching new attack methodologies and devising strategies to deal with them. By doing this, the enterprise can remain relatively virus-free, and the end users can concentrate on the business.

ABOUT THE AUTHORS

Ralph S. Hoefelmeyer, CISSP, began his career as a U.S. Air Force officer and went on to defense work. He has more than 20 years of experience in operations, systems design, analysis, security, software development, and network design. Hoefelmeyer has earned a B.S. and M.S. in computer science and has one patent with several patents pending. He is currently a senior engineer with WorldCom in Colorado Springs, Colorado.

Theresa E. Phillips, CISSP, is a senior engineer with WorldCom. She has five years' experience in information security engineering, architecture, design, and policy development. Prior to that, she held management positions in not-for-profit membership organizations dealing with open systems and quality engineering. Phillips earned a B.S. in social work, which provides her with the background to deal with people and policy issues related to information security.

Domain 5
Cryptography

The Cryptography Domain addresses the principles, means, and methods of disguising information to ensure its integrity, confidentiality, and authenticity. Unlike the other domains, Cryptography does not support the standard of availability.

The professional should fully understand the basic concepts within cryptography, including public and private key algorithms in terms of their applications and uses. Cryptography algorithm construction, key distribution, key management, and methods of attack are also important for the successful candidate to understand. The applications, construction, and use of digital signatures are discussed and compared to the elements of cryptography. The principles of authenticity of electronic transactions and non-repudiation are also included in this domain.

Three New Models for the Application of Cryptography

Jay Heiser, CISSP

Applying encryption is not easy. False confidence placed in improperly applied security mechanisms can leave an organization at greater risk than before the flawed encryption project was started. It is also possible to err in the opposite direction. Overbuilt security systems cost too much money upfront, and the ongoing expense from unneeded maintenance and lost productivity continues forever. To help avoid costly misapplications of security technology, this chapter provides guidance in matching encryption implementations to security requirements. It assumes a basic understanding of cryptological concepts, and is intended for security officers, programmers, network integrators, system managers, Web architects, and other technology decisionmakers involved with the creation of secure systems.

Introduction

The growing reliance on the Internet is increasing the demand for well-informed staff capable of building and managing security architectures. It is not just E-commerce that is generating a demand for encryption expertise. Personal e-mail needs to be protected, and employees demand secure remote access to their offices. Corporations hope to increase their productivity — without increasing risk — by electronically linking themselves to their business partners. Unfortunately, eager technologists have a tendency to purchase and install security products without fully understanding how those products address their security exposures. Because of the high cost of a security failure, requirements analysis and careful planning are crucial to the success of a system that relies on cryptological services. This chapter presents four models, each providing a different understanding of the effective application of encryption technology. Descriptive models like these are devices that isolate salient aspects of the systems being analyzed. By artificially simplifying complex reality, the insight they provide helps match security and application requirements to appropriate encryption-based security architectures.

The first model analyzes how encryption implementations accommodate the needs of the encrypted data's recipient. The relationship between the encrypter and the decrypter has significant ramifications, both for the choice of technology and for the cryptographic services used. The second model describes how encryption applications differ based on their logical network layer. The choice of available encryption services varies from network layer to network layer. Somewhat less obviously, choice of network layer also affects who within the organization controls the encryption process. The third encryption application model is topological. It illustrates concepts usually described with terms such as end-to-end, host-to-host, and link-to-link. It provides an understanding of the scope of protection that can be provided when different devices within the network topology perform encryption. The final model is based on the operational state of data. The number of operational states in which data is cryptographically protected varies, depending on the form of encryption service chosen.

Business Analysis

Before these descriptive models can be successfully applied, the data security requirements must be analyzed and defined. One of the classic disputes within the information security community is over the accuracy of quantitative risk analysis. Neither side disagrees that some form of numeric risk analysis providing an absolute measure of security posture would be desirable, and neither side disputes that choice of security countermeasures would be facilitated by an accounting analysis that could provide return on investment or at least a break-even analysis. The issue of contention is whether it is actually possible to quantify security implementations, given that human behavior can be quite random and very little data is available. Whether or not an individual prefers a quantitative or a qualitative analysis, some form of analysis must be performed to provide guidance on the appropriate resource expenditure for security countermeasures. It is not the purpose of this chapter to introduce the subject of risk management; however, a security architecture can only be optimized when the developer has a clear understanding of the security requirements of the data that requires protection.

The Data Criticality Matrix is helpful in comprehending and prioritizing an organization's information asset security categories. Exhibit 108.1 shows an example analysis for a corporation. This matrix includes five security requirements. The widely used CIA requirements of confidentiality, integrity, and availability are supplemented with two additional requirements: non-repudiation and time. The term "non-repudiation" refers to the ability to prevent the denial of a transaction. If a firm submits a purchase order but then refuses to honor the purchase, claiming no knowledge of the original transaction, then the firm has repudiated it. In addition to privacy services, cryptography may be required to provide non-repudiation services. The models in this chapter illustrate encryption options that include both services. The time requirements for data protection are important both in choosing appropriately strong encryption, and in ensuring that data is never left unprotected while it has value. This particular Data Criticality Matrix presents a simplified view of the lifetime requirement; in some cases, it may be useful to assign a specific lifetime to each of the first four security requirements, instead of assuming that confidentiality, integrity, availability, and non-repudiation all must be supported to the same degree over the same period of time. Note that availability is usually not a service provided by encryption, although encryption applications have the potential to negatively affect availability. Encryption rarely improves availability, but if mission-critical encryption services fail, then availability requirements probably will not be met. (Use of a cryptographically based strong authentication system to prevent denial-of-service attacks is an example of using encryption to increase availability.)

An economic analysis cannot be complete without an understanding of the available resources. Insufficient funds, lack of internal support, or poor staff skills can prevent the successful achievement of any project. While the four models can be used to develop an ideal security architecture, they can also facilitate an understanding of the security ramifications of a resource-constrained project.

Recipient Model

The choice of cryptographic function and implementation is driven by the relationship between the originator and the recipient. The recipient is the party — an individual, multiple individuals, or an organizational entity — consuming data that has cryptological services applied to it. The simplified diagram in Exhibit 108.2

EXHIBIT 108.1 Data Criticality Matrix

	Confidentiality	Integrity	Availability	Non-Repudiation	Lifetime
Public Web page	Low	High	High	Low	NA
Unreleased earnings data	High	High	Medium	Low	2 weeks
Accounts receivable	High	High	Medium	High	5 years
Employee medical records	High	High	Low	Low	80 years

	Personal Encryption	Workgroup Encryption	Transaction Encryption
			Recipient	Data Owner	Co-workers	Strangers
Concern	Privacy	Privacy	Establishment and Maintenance of Trust
Technical Concerns	Speed and Transparency	Speed and Transparency	Interoperability

EXHIBIT 108.2 Recipient model.

presents three possible choices of recipient. In reality, the recipient model is a spectrum, encompassing everything from a well-known recipient to a recipient with no prior relationship to the originator. The recipient model provides guidance when choosing between an open-standard product and a closed, proprietary product, and it provides insight into the specific cryptographic services that will be needed.

Personal encryption is the use of cryptographic services on an individual basis, without the expectation of maintaining cryptographic protection when sharing data. Someone encrypting data for his own personal use has completely different priorities than someone encrypting data for others. In most cases, that someone is using personal encryption to maintain the confidentiality of data that is at risk of being physically accessed — especially on a laptop. In a corporate setting, personal encryption is legitimately used on workstations to provide an additional level of privacy beyond what can be provided by an operating environment's access controls — which can always be circumvented by an administrator. Personal encryption might also be used by corporate employees trying to hide data they are not authorized to have, and criminals concerned about law enforcement searches also use personal encryption. Although individuals might want to use digital signature to provide assurance that they did indeed sign their own documents — especially if they have a high number of them — this use is rare. Increasingly, digital signature is used as an integrity control, even for files originated and stored locally. While few individuals currently use digital signature to protect files on their own workstation or laptop, the increasing proliferation of hostile code could make this use of personal encryption routine. Maintaining the confidentiality of personal information is the usual intent of individual encryption, but the technical concerns remain the same for any use of personal encryption. Individuals encrypting data for themselves place a high priority on speed and ease of use. Laptop users typically encrypt the entire hard drive, using an encryption product transparent to applications and almost transparent to users, requiring only the entry of a password at the start of a session. Standards and interoperability are not important for personal encryption, although use of unproven proprietary encryption algorithms should be avoided.

Workgroup encryption is the use of cryptological services to meet the confidentiality needs of a group of people who know each other personally and share data. As in the case of the individual, the group might be concerned that sensitive data is at risk of inappropriate viewing by system administrators. Encryption can even be used to implement a form of access control — everyone given a password has access to the encrypted data, but nobody else does. If the workgroup shares data but does not have a common server, encryption can help them share that data without having to rely on distributed access controls. The most significant issue with workgroup encryption is managing it. If the data has a long life, it is likely that the membership of the workgroup will change. New members need access to existing data, and members leaving the group may no longer be authorized for access after leaving. Constantly decrypting and reencrypting large amounts of data and then passing out new keys is inefficient. For a short-term project, it is feasible for group members to agree on a common secret key and use it to access sensitive data for the project duration. Groups and data with a longer life might find it easier to use an encryption system built on a session key that can be encrypted in turn with each group member's public key. Whether it is based on secret or public key encryption, workgroup

encryption is similar to personal encryption, having the advantage of not being concerned with open standards or multivendor compatibility. Interoperability is provided by choosing a single product for all group members, either a stand-alone encryption utility, an application with encryption capabilities, or an operating environment with security services. Trust is a function of organizational and group membership and personal relationships. Because all the members of a workgroup are personally acquainted, no special digital efforts need be provided to enhance the level of trust.

Transactional encryption describes the use of cryptological services to protect data between originators and recipients who do not have a personal relationship capable of providing trust. It facilitates electronic transactions between unknown parties; E-commerce and Web storefronts are completely dependent on it. While confidentiality may be important, in many transactions the ability to establish identity and prevent repudiation is even more significant. To accept a transaction, the recipient must have an appropriate level of trust that the purported sender is the actual sender. The recipient must also have an appropriate level of confidence that the sender will not deny having initiated the transaction. Likewise, the sender often requires a level of assurance that the recipient cannot later deny having accepted it. If the value of the transaction is high, some form of non-repudiation service may be necessary. Other cryptographic services that can be provided to increase the level of confidence include time stamp and digital notary service. Authentication mechanisms and non-repudiation controls are all electronic attempts to replace human assurance mechanisms that are impossible, impractical, or easily subverted in a digital world. The technical characteristic distinguishing transactional encryption from workgroup or personal encryption is the significance of interoperability. Because the parties of a transaction often belong to different organizations and may not be controlled by the same authority, proprietary products cannot be used. The parties of the transaction might be using different platforms, and might have different applications to generate and process their transactions. Transactional encryption depends on the use of standards to provide interoperability. Not only must standard encryption algorithms be used, but they must be supported with standard data formats such as PKCS #7 and X.509.

Network Layer Model

The OSI seven-layer reference model is widely used to explain the hierarchical nature of network implementations. Services operating at a specific network layer communicate with corresponding services at the same layer through a network protocol. Services within a network stack communicate with higher- and lower-level services through interprocess communication mechanisms exposed to programmers as APIs. No actual network represents a pure implementation of the OSI seven-layer model, but every network has a hierarchical set of services that are effectively a subset of that model. Encryption services can be provided in any of the seven network layers, each with its own advantages and disadvantages. Use of the seven-layer model to describe existing network protocol stacks that grew up organically is more than a little subjective. Over the years, the mapping of the Internet protocol set into the model has slowly but surely changed. Today, it is accepted that the IP layer maps to the OSI network layer, and the TCP protocol maps to the OSI transport layer, although this understanding of exact correspondence is not universal. Likewise, the assignment of specific encryption protocols and services to specific network layers is somewhat arbitrary. The importance of this model to security practitioners is in understanding of how relative position within the network hierarchy affects the characteristics of cryptographic services. As illustrated in Exhibit 108.3, the higher up within the network hierarchy encryption is applied, the more granular its ability to access objects can be. The lower down encryption is provided, the greater the number of upper-layer services that can transparently take advantage of it. Greater granularity means that upper-layer encryption can offer more cryptographic functions. Services based on digital signature can only be provided in the upper layers. A simplified version of this layered model can be used to analyze a nonnetwork environment. For the purposes of this discussion, stand-alone hosts are considered to have four layers: physical, session, presentation, and application.

The physical layer is the lowest layer, the silicon foundation upon which the entire network stack rests. Actually, providing encryption services at the physical layer is quite rare. In a network environment, several secure LANs have been developed using specialized Ethernet cards that perform encryption. Most of these systems actually operate at the data-link layer. Several specialized systems have been built for the defense and intelligence market that could possibly be considered to operate at the physical layer, but these systems are not found in the commercial market. The only common form of physical network layer encryption is spread spectrum, which scrambles transmissions across a wide range of constantly changing frequencies. Physical layer encryption products have been developed for stand-alone systems to protect the hard drive. The advantage

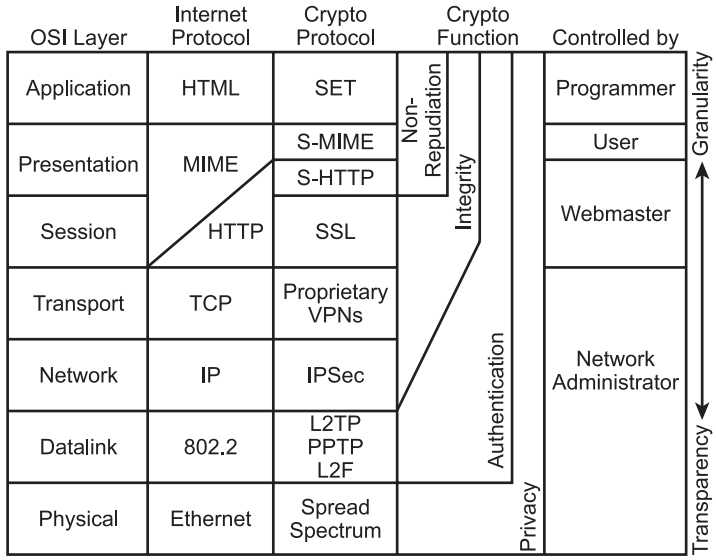

EXHIBIT 108.3 OSI model.

of such a system is that it provides very high performance and is very difficult to circumvent. Furthermore, because it mimics the standard hardware interfaces, it is completely transparent to all system software and applications. Physical layer security is under control of the hardware administrator.

A great deal of development work is being done today at both the data-link and the network layer. Because they provide interoperability between hosts and network elements, and are completely transparent to network-based applications, these two layers are used for the implementation of VPNs. The data-link layer is used to support L2TP, PPTP, and L2F. Although many popular implementations of these link layer security services actually take advantage of the IPSec transport mode, the model still treats them as link layer services because they are providing interfaces at that layer. A major advantage of the link layer is that a single encryption service can support multiple transport protocols. For example, VPNs providing an interface at this layer can support TCP/IP and SPX/IPX traffic simultaneously. Organizations running both Novell and Internet protocols can use a single VPN without having to build and maintain a protocol gateway. The IPSec security protocol resides at the network layer. It is less flexible than the link layer security services, and only supports Internet protocols, but IPSec is still transparent to applications that use TCP or UDP. Whether implemented at the network or the link layer, to be considered a VPN, the interface must be completely transparent to network services, applications, and users. The disadvantage of this complete transparency is a low level of granularity. VPNs can provide identification and authentication either at the host level, or in the case of a remote access client, at the user level. In other words, remote access users can authenticate themselves to whatever host is at the other end of their VPN. Individual files are effectively invisible to a VPN security service, and no transactional services are provided by a VPN. Many proprietary VPN and remote access products are arguably implemented at the transport layer, although no standard defines a security service at this layer. Most transport layer encryption products are actually built as a shim on top of the existing transport layer. However, because they still support the existing transport interface — usually the socket interface — they should be treated as transport layer services. These VPN products are often implemented using protocols operating at higher network layers. Upper-layer security services such as SSH and SOCKS are robust and proven, making them useful mechanisms for VPN implementations. The characteristic that determines if a security service is operating as a true VPN is not the layer at which the encryption service itself runs, but the interface layer at which security services are provided to existing upper-layer applications; whatever is running under the hood is hidden from applications and not relevant to this model. VPNs are under the administrative control of the network administrator.

The session layer is not considered relevant for standard implementations of the Internet protocols; however, the Secure Sockets Layer (SSL) service neatly fits into the definition of a session-layer service. Applications capable of using SSL must be compiled with special SSL versions of the normal socket libraries. Network services compiled with support for SSL, such as S-HTTP, listen on specific ports for connection requests by

compatible clients, such as Web browsers. SSL is still too low in the network stack to provide transactional services. In common with a VPN, it provides session-level privacy, and host-to-user or host-to-host authentication at the session start. SSL does offer a higher level of control granularity than does a VPN. Applications capable of using SSL, such as Web browsers or mail clients, usually have the ability to use it as needed by alternating between connections to standard ports and connections to secured daemons running on SSL ports. This amount of granularity is adequate for electronic commerce applications that do not require digital signature. Note that the HTML designer does have the option of specifying URLs that invoke SSL, providing that person with indirect influence over the use of SSL. Whoever has write access to the Web server is the person who has the final say over which pages are protected with SSL. Sometimes, the user is provided with a choice between SSL-enabled Web pages or unsecured pages, but giving them this option is ultimately the prerogative of the Webmaster. A stand-alone system analogy to a session-layer security service is a security service based on a file system. An encrypting file system is effectively a session-layer service. It requires initial session identification and authentication, and then performs transparently in the background as a normal file system, transparent to applications. An encrypting file system is under the control of the system administrator.

Several commonly-used Internet applications, such as Web browsers and mail clients, provide data representation services, which are presentation-layer services. Presentation-layer services operate at the granularity of an individual file. Presentation-layer file operators are not aware of application-specific data formats, but are aware of more generalized data standards, especially those for text representation. Another example is FTP, which copies individual files while simultaneously providing text conversion such as EBCDIC to ASCII. In a nonnetworked environment, any generic application that operates on files can be considered a presentation-layer service. This includes compression and file encryption utilities. Because it allows access to individual files, the presentation layer is the lowest layer that can provide transactional services, such as integrity verification and non-repudiation. Generic network services that provide digital signature of files, such as PGP, S-MIME, and file system utilities, are not operating at the application level; they are at the presentation level. Presentation services are under control of the end user. Secure HTTP (S-HTTP) is another example of a presentation-layer security service. It was intended to be used both for privacy and the digital signature of individual file objects. Secure HTTP was at one time in competition with SSL as the Web security mechanism of choice. SSL gained critical mass first, and is the only one of the two now being used. If it were available, S-HTTP would be under the control of the Webmaster, so Exhibit 108.3 represents it as being lower in the crypto protocol hierarchy than S-MIME.

Application-layer services have access to the highest level of data granularity. Accessible objects may include application-specific file formats such as word processors or spreadsheets records, or even fields within a database. Application-layer encryption is provided within an application and can only be applied to data compatible with that application. This makes application-layer encryption completely nontransparent, but it also means that application encryption can provide all cryptographic services at any needed granularity. Application-layer encryption services are normally proprietary to a specific application, although standard programming libraries are available. These include CAPI, the Java security libs, and BSAFE. Although it could arguably be considered a session-layer protocol, SET (Secure Electronic Transaction) data formats are quite specific, so it more closely resembles an application-layer protocol. It is intended to provide a complete system for electronic transaction processing, especially for credit card transactions, between merchants and financial institutions. Application-layer encryption is under the control of the programmer. In many cases, the programmer allows the user the option of selectively taking advantage of encryption services, but it is always the programmer's prerogative to make security services mandatory.

Topological Model

The topological model addresses the physical scope of a network cryptological implementation. It highlights the segments of the transmission path over which encryption is applied. Exhibit 108.4 illustrates the six most common spans of network encryption. The top half of the diagram, labeled "a," depicts an individual user on the Internet interacting with organizational servers. This user may be dialed into an ISP, be fully connected through a cable modem or DSL, or may be located within another organization's network. The bottom half of the diagram, labeled "b," depicts a user located at a partner organization or affiliated office. In case "b," the security perimeter on the left side of the diagram is a firewall. In case "a," it is the user's own PC. Note that the endpoints are always vulnerable because encryption services are always limited in their scope.

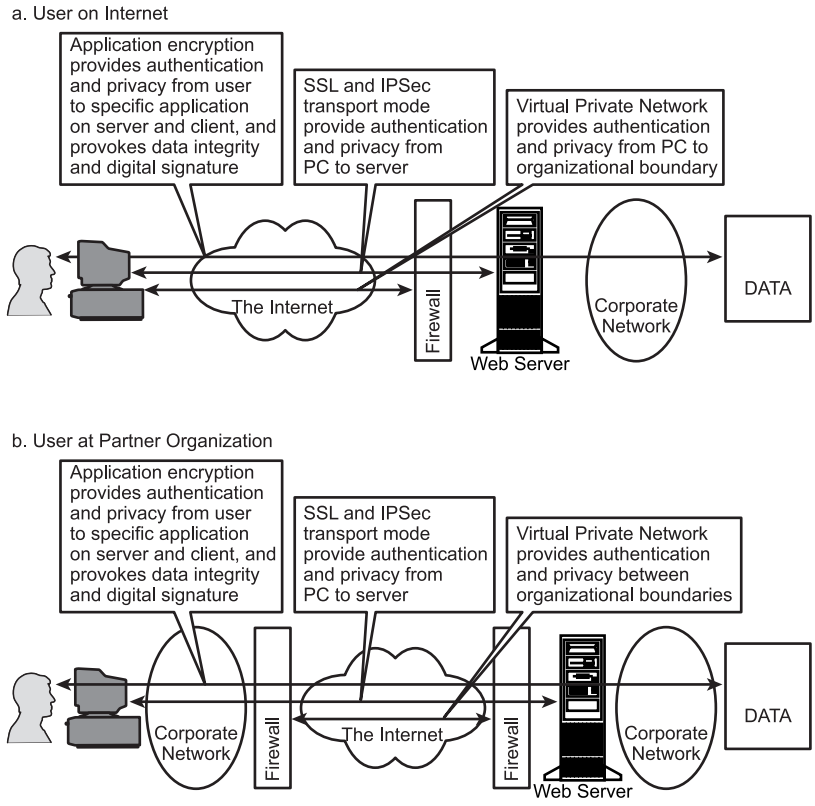

EXHIBIT 108.4 Topological model.

The term "end-to-end encryption" refers to the protection of data from the originating host all the way to the final destination host, with no unprotected transmission points. In a complex environment, end-to-end encryption is usually provided at the presentation or application-layer. The top boxes in both "a" and "b" in Exhibit 18-4 illustrate a client taking advantage of encryption services to protect data directly between the user and the data server. As shown, the data might not be located on the Web server, but might be located on another server located several hops further interior from the firewall and Web server. SSL cannot provide protection beyond the Web server, but application- or presentation-layer encryption can. Full end-to-end protection could still be provided — even in the Web environment illustrated — if both the client and data server have applications supporting the same encryption protocols. This could even take the form of a Java applet. Although the applet would be served by the Web server, it would actually run within the Java virtual machine on the Web browser, providing cryptographic services for data shared between the client and the server, protecting it over all the interior and exterior network segments.

SSL and IPSec transport mode provide authentication and privacy between a workstation and a remote server. This is a sometimes referred to as host-to-host, or node-to-node. The two middle boxes in Exhibit 108.4 represent virtually identical situations. In "b," the outgoing SSL session must transit a firewall, but it is common practice to allow this. On the server side, if the Web server is located inside a firewall, traffic on the port conventionally used by S-HTTP is allowed through the firewall to the IP address of the Web server. The SSL session provides privacy between the Web browser on the client machine and the Web server on the remote host. As in this example, if the Web server uses a back-end database instead of a local datastore, SSL cannot provide protection between the Web server and the database server (hopefully, this connection would be well protected using noncryptographic countermeasures). SSL is somewhat limited in what it can provide, but its convenience makes it the most widely implemented form of network encryption. SSL is easy to implement; virtually all Web servers provide it as a standard capability, and it requires no programming skills. It does not necessarily provide end-to-end protection, but it does protect the transmission segment that is most vulnerable to outside attack.

Another form of host-to-host encryption is the virtual private network (VPN). As shown in both cases "a" and "b" in Exhibit 108.4 at least one of the hosts in a VPN is located on an organizational security boundary. This is usually, but not always, an Internet firewall. Unlike the previous example, where "a" and "b" were functionally identical in terms of security services, in the case of a VPN, "b" is distinct from "a" in that security services are not applied over the entire transmission path. A VPN is used to create an extension of the existing organizational security perimeter beyond that which is physically controlled by the organization. VPNs do not protect transmissions within the security perimeter that they extend. The VPN architecture is probably the more common use of the term "host-to-host." The term implies that cryptographic services are provided between two hosts, at least one of which is not an endpoint. Like SSL, a VPN provides host authentication and privacy. Depending on the implementation, it may or may not include additional integrity services. As shown in case "a," VPN software is often used to support remote access users. In this scenario, the VPN represents only a temporary extension of the security perimeter. Case "b" shows an example of two remotely separated sites that are connected permanently or temporarily using a VPN. In this case, the user side represents a more complex configuration, with the user located on a network not necessarily directly contiguous with the security perimeter. In both "a" and "b," the VPN is only providing services between security perimeters.

Link-to-link encryption is not illustrated. The term refers to the use of encryption to protect a single segment between two physically contiguous nodes. It is usually a hardware device operating at layer two. Such devices are used by financial firms to protect automatic teller machine transactions. Another common form of link-to-link encryption is the secure telephone unit (STU) used by the military. The most common use of link layer encryption services on the Internet is the protection of ATM or Frame Relay circuits using high-speed hardware devices.

Information State Model

It should be clear by now that no encryption architecture provides total protection. When data undergoes transition through processing, copying, or transmission, cryptographic security may be lost. When developing a security architecture, the complete data flow must be taken into account to ensure an appropriate level of protection whenever operations are performed on critical data. As shown in Exhibit 18-5, the number of states in which data is protected varies widely, depending on the choice of encryption service. The table is sorted from top to bottom in increasing order of the number of states in which protection is provided. SSL and VPNs are at the top of the chart because they only protect during one phase: the transmission phase. In contrast, application encryption can be designed to protect data during every state but one. Although systems have been researched, no commercially available product encrypts data while it is being processed. Data undergoing processing is vulnerable in a number of ways, including:

- The human entering or reading the data can remember it or write it down.
- Information on the screen is visible to shoulder surfers.
- Virtual memory can store the cleartext data on the hard drive's swap space.
- If the process crashes, the operating system may store a core dump file containing the cleartext data.

Outside of the processing phase, which can only be addressed through administrative and physical security countermeasures, encryption options are available to protect data wherever necessary.

Several different styles of automated encryption have been developed, relieving users of the responsibility of remembering to protect their data. Some products encrypt an entire hard drive or file system, while others allow configuration of specific directories and encrypt all files placed into them. After users correctly authenticate themselves to such an encryption system, files are automatically decrypted when accessed. The downside of this automated decryption is that whenever authenticated users access a file, the encryption protection is potentially lost. Critical data can be inadvertently stored in cleartext by transmitting it, backing it up, or copying it to another system. Protection can be maintained for an encrypted file system by treating the entire file system as a single object, dumping the raw data to backup storage. Depending on the implementation, it may be impossible to perform incremental backups or restore single files. Products that do not encrypt the directory listing, leaving the names of encrypted files in cleartext, offer more flexibility, but increase the risk that an intruder can gain information about the encrypted data. If the data can be copied without automatically decrypting it, then it can be backed up or transmitted without losing cryptographic protection. Although such data would be safely encrypted on a recipient's system, it probably would not be usable because the recipient would not have a key for it. It would rarely be appropriate for someone automatically encrypting data to share

EXHIBIT 108.5 Information State Model

	Encrypted during Processing	Automatically Encrypted on First Save	Sent Data Encrypted on Originating Host	Automatically Reencrypted after Use	Encrypted when Backed Up	Encrypted during Transmission	Data Encrypted on Receiving Host

VPN						Π	
Encrypting file system that automatically decrypts		Π	Π	Π			
Encryption utility			Π		Π	Π	Π
Encrypting file system without automatic decryption		Π	Π	Π	Π	Π	No key
E-mail encryption			Π	Π	Π	Π	Π
Application with built-in data encryption		Optional	Π	Π	Π	Π	Π

the key with someone else if that key provided access to one's entire personal information store. Automatic encryption is difficult in a workgroup scenario — at best, moving data between personal storage and group storage requires decryption and reencryption with a different key.

File encryption utilities, and this includes compression utilities with an encryption option (beware of proprietary encryption algorithms), are highly flexible, allowing a file or set of files to be encrypted with a unique key and maintaining protection of that data throughout copy and transmission phases. The disadvantage of encrypting a file with a utility is that the data owner must remember to manually encrypt the data, increasing the risk that sensitive information remains unencrypted. Unless the encryption utility has the ability to invoke the appropriate application, a plaintext version of the encrypted data file will have to be stored on disk before encrypted data can be accessed. The user who decrypts it will have to remember to reencrypt it. Even if the encryption utility directly invokes an application, nothing prevents the user from bypassing automated reencryption by saving the data from within the application, leaving a decrypted copy on disk. E-mail encryption services, such as PGP and S-MIME, leave data vulnerable at the ends. Unless the data is created completely within the e-mail application and is never used outside of a mail browser, cleartext can be left on the hard drive. Mail clients that support encryption protect both the message and any attachments. If cryptographic protection is applied to an outgoing message (usually a choice of signature, encryption, or both), and outgoing messages are stored, the stored copy will be encrypted. The recipient's copy will remain encrypted too, as long as it is stored within the mail system. As soon as an attachment is saved to the file system, it is automatically decrypted and stored in cleartext. Encrypting within an application is the most reliable way to prevent inappropriate storage of cleartext data. Depending on the application, the user may have no choice but to always use encryption. When optional encryption has been applied to data, normal practice is to always maintain that encryption until a keyholder explicitly removes it. On a modern windowing workstation, a user can still defeat automated reencryption by copying the data and pasting it into another application, and application encryption is often weakened by the tendency of application vendors to choose easily breakable proprietary encryption algorithms.

Several manufacturers have created complex encryption systems that attempt to provide encryption in every state and facilitate the secure sharing of that data. Analysis of these systems will show that they use combinations of the encryption types listed in the first column of Exhibit 108.5. Such a hybrid solution potentially overcomes the disadvantages of any single encryption type while providing the advantages of several. The Information State Model is useful in analyzing both the utility and the security of such a product.

Putting the Models to Work

The successful use of encryption consists of applying it appropriately so that it provides the anticipated data protection. The models presented in this chapter are tools, helpful in the technical analysis of an encryption implementation. As shown in Exhibit 108.4, good implement choices are made by following a process. Analyzing the information security requirements is the first step. This consists of understanding what data must be protected, and its time and sensitivity requirements for confidentiality, integrity, availability, and nonrepudiation. Once the information security requirements are well documented, technical analysis can take place. Some combination of the four encryption application models should be used to develop potential implementation options. These models overlap, and they may not all be useful in every situation — choose whichever one offers the most useful insight into any particular situation. After technical analysis is complete, a final implementation choice is made by returning to business analysis. Not every implementation option may be economically feasible. The most rigorous encryption solution will probably be the most expensive. The available resources will dictate which of the implementation options are possible. Risk analysis should be applied to those choices to ensure that they are appropriately secure. If insufficient resources are available to adequately offset risk, the conclusion of the analysis should be that it is inappropriate to undertake the project. Fortunately, given the wide range of encryption solutions available for Internet implementations today, most security practitioners should be able to find a solution that meets their information security requirements and fits within their budget.

109

Auditing Cryptography: Assessing System Security

Steve Stanek

After a start-up data security firm applied for a patent for its newly developed encryption algorithm, the company issued a public challenge: it promised to pay $5000 to anyone who could break the algorithm and another $5000 to the person's favorite charity.

William Russell, an Andersen technology risk manager, accepted the challenge. He is now $5000 richer, his charity is waiting for its money, and the data security firm has run out of business because Russell cracked the supposedly uncrackable code. It took him about 60 hours of work, during which time he developed a program to predict the correct encryption key. His program cracked the code after trying 6120 out of a possible 1,208,925,819,614,629,174,706,176 electronic keys. Clearly, it should not have been as easy as that!

Assessing Risk

In the course of performing a security risk assessment, auditors or security professionals may learn that cryptographic systems were used to address business risks. However, sometimes the cryptographic systems themselves are not reviewed or assessed — potentially overlooking an area of business risk to the organization.

Russell believes there is a lesson in this for information technology auditors: when it comes to encryption technology, rely on the tried and true. "You want the company to be using well-known, well-tested algorithms," Russell says. "Never use private encryption. That goes under the assumption that someone can create something that's as good as what's on the market. The reality is that there are only a few hundred people in the world who can do it well. Everyone else is hoping nobody knows their algorithm. That's a bad assumption."

Russell recently worked with a client who asked him to look at one of the company's data systems, which was secured with encryption technology developed in-house. Russell cracked that system's security application in 11 hours. "If it had been a well-known, well-tested algorithm, something like that would not have been at all likely," Russell says.

Encryption's Number-One Problem: Keeping Keys Secret

Security professionals who use cryptography rely on two factors for the security of the information protected by the cryptographic systems: (1) the rigor of the algorithm against attack and (2) the secrecy of the key that is used to encrypt the sensitive information. Because security professionals advocate well-documented and scrutinized algorithms, they assume that the algorithm used by the cryptographic system has been compromised by an attacker; thus the security professional ultimately relies on the protection of the keys used in the algorithm.

The more information encrypted with a key, the greater the harm if that key is compromised. So it stands to reason that keys must be changed from time to time to mitigate the risk of information compromise. The

length of time a key is valid in a crypto-system is referred to as the cryptographic key period and is determined by factors such as the sensitivity of the information, the relative difficulty to "guess" the keys by a known crypto-analysis technique, and the environment in which the crypto-system functions and operates. While changing keys is important, it can be very costly, depending on the type of cryptography used, the storage media of the keying material, and the distribution mechanism of the keying material. It is a business decision on how to effectively balance security risk with cost, performance, and functionality within the business context.

Keys that can be accessed and used by attackers pose a serious security problem, and all aspects of the security program within an enterprise must be considered when addressing this issue. For example, ensure that the keys are not accessible by unauthorized individuals, that appropriate encryption is used to protect the keying material, that audit trails are maintained and protected, and that processes exist to prevent unauthorized modification of the keying material.

While cryptography is a technology subject, effective use of cryptography within a business is not just a technology issue.

Encryption's Number-One Rule

According to Mark Wilson, vice president of engineering at Embedics, a data security software and hardware design firm in Columbia, Maryland, "The No. 1 rule is that encryption needs to be based on standards. You want to follow well-known specifications for algorithms. For public key, you want to use an authenticated key agreement mechanism with associated digital signatures.

"A lot of people are trying new technologies for public key-based schemes. Most of the time they are not using published standards. They're not open to scrutiny. There are also often interoperability problems." Interoperability is important because it allows vendors to create cryptographic products that will seamlessly integrate with other applications. For example, vendors planning to develop cryptographic hardware should follow the RSA PKCS #11 standard for cryptographic hardware. If they do, then their product will work with several applications seamlessly, including Lotus Notes.

Russell and Wilson agree that even if a company is using widely tested and accepted encryption technologies, its data can be exposed to prying eyes. One Andersen client encrypted highly sensitive information using an encryption key, but the key was stored on a database that was not properly secured. Consequently, several individuals could have obtained the encryption key and accessed highly sensitive information without being noticed.

"Encryption is an important component of security, but it must be seen as a part of the whole. Encryption by itself doesn't solve anything, but as part of a system it can give security and confidence," says Russell.

Auditors also need to evaluate network, physical, and application security, and ask what algorithms the company is using and if they are commonly accepted. For example, Wilson says he often encounters companies that use good encryption technology but do not encrypt every dial-up port. Very important, too, is that while cryptography may be an important component of the technology component of security, process (including policies and procedures) and people (including organization, training) also are key factors in successful security within the enterprise. "A lot of times they have a secure encryptor, but the dial-up port is open," Wilson says. "They should look at secure modems for dial-in. The problem comes in the actual outside support for networks that have unsecured modems on them."

Remember to Encrypt E-Mail

Russell says that, in his view, the most common mistake is in e-mail. "Information is sent all the time internally that is sensitive and accessible," he says. "Ideas, contracts, product proposals, client lists, all kinds of stuff goes through e-mail, yet nobody considers it as an important area to secure. Nearly all organizations have underestimated the need to encrypt e-mail."

Most firms are using encryption somewhere within their organization, particularly for secure Web pages. While this protects information at the front end, it does not protect it at the back end, according to Russell. "On the back end, inside the company, somebody could get that information," he says. He suggests asking who should have access to it and how can it be kept out of everyone else's hands.

"Anything you consider sensitive information that you don't want to get into the wrong hands, you should consider encrypting," Russell says. "It must be sensitive and potentially accessible. If a computer is locked in a vault and nobody can get to it, it doesn't need encryption. If that computer is on a network, it becomes vulnerable."

Russell suggests internal auditors ask the following questions when evaluating security applications.

Does the Vendor Have Credibility in Security Circles?

As security awareness has increased, so has the number of security start-ups. Many of them are unqualified, according to Russell. Look for companies that frequent security conferences, such as RSA Security Inc.'s annual conference. Also look for vendors that are recognized in security journals. Although doing this is not foolproof, it will narrow the field of credible vendors. Depending on the criticality of the system and the intended investment, it may be best to solicit the help of a security consultant.

Does the Product Use Well-Known Cryptographic Algorithms?

The marketing of security applications tends to be an alphabet soup of acronyms. For this reason, it is helpful to know which ones really matter. There are essentially three categories of algorithms: asymmetric key, symmetric key, and hashing. Asymmetric key algorithms are normally used for negotiating a key between two parties. Symmetric key algorithms are normally used for traffic encryption. And hashing is used to create a message digest, which is a number computationally related to the message. It is generally used in relationship with an asymmetric key algorithm to create digital signatures. It also should be noted that although these three categories of algorithms are typical of new systems that are being built today, there exist many legacy applications at larger companies using crypto-systems from the 1970s. Because of the high associated costs, many of these companies have not been retrofitted with the "appropriate" form of cryptography.

The following list represents a few of the more popular algorithms that are tried and true:

- *RSA*. Named after Rivest, Shamir, and Adleman who created it, this asymmetric key algorithm is used for digital signatures and key exchanges.
- *Triple DES*. This algorithm uses the Data Encryption Standard three times in succession in order to provide 112-bit encryption. If it uses three keys, then sometimes it is referred to as having 168-bit encryption.
- *RC4*. This is a widely used variable-key-size symmetric key encryption algorithm that was created by RSA. The algorithm should be used with 128-bit encryption.
- *AES*. Advanced Encryption Standard is a new symmetric key algorithm also known as Rijndael. This new standard is intended to replace DES for protecting sensitive information.
- *SHA1*. The Secure Hash Algorithm was developed by the U.S. government. This algorithm is used for creating message digests and may be used to create a digital signature.
- *MD5*. Message Digest 5 was created by RSA, and is used to create message digests. It is frequently used with an asymmetric key algorithm to create a digital signature.

Does the Product Use SSL v3.0?

Secure Sockets Layer v3.0 is a transport-layer security protocol that is responsible for authenticating one or both parties, negotiating a key exchange, selecting an encryption algorithm, and transferring data securely. Although not every application needs to send information to another computer using this protocol, using it avoids some of the possible pitfalls that may go unnoticed in the development of a proprietary protocol.

Does the Company Report and Post Bug Fixes for Security Weaknesses?

No product is ever perfectly secure, but some vendors want you to think they are. When a company posts bug fixes and notices for security weaknesses, this should be considered a strength. This means they are committed to security, regardless of the impression it might give otherwise.

Does the Product Use an Accepted Random Number Generator to Create Keys?

Random number generators are notoriously difficult to implement. When they are implemented incorrectly, their output becomes predictable, negating the randomness required. Regardless of the encryption algorithm used, a sensitive message can be compromised if the key protecting it is predictable. RSA is currently developing a standard to address this issue. It will be called PKCS #14.

Does the Product Allow for Easy Integration of Hardware Tokens to Store Keys?

Whenever keys are stored as a file on a computer, they are accessible. Often the business case will determine the level of effort used to protect the keys, but the best protection for encryption keys is hardware. Smart cards and PCMCIA cards are often used for this purpose. An application should have the ability to utilize these hardware tokens seamlessly.

Has the Product Received a Federal Information Processing Standards (FIPS) 140-1 Verification?

The National Institute of Standards and Technology (NIST) has created a government-approved standard, referred to as FIPS 140-1, for cryptographic modules. NIST created four levels, which correspond to increasing levels of security. Depending on whether the crypto-module is a stand-alone component or one that is embedded in a larger component, and whether the crypto-model is a hardware device or a software implementation, the crypto-module is subjected to varying requirements to achieve specific validation levels. Issues such as tamper detection and response are addressed at Level 3 (that is, the ability for the cryptographic module to sense when it is being tampered with and to take appropriate action to zeroize the cryptographic keying material and sensitive unencrypted information within the module at the time of tamper). Level 4 considers the operating environment and requires that the module appropriately handle cryptographic security when the module is exposed to temperatures and voltages that are outside of the normal operating range of the module. Because FIPS 140-1 validation considered both the design and implementation of cryptographic modules, the following 11 components are scrutinized during the validation:

1. Basic design and documentation
2. Module interfaces
3. Roles and services
4. Finite state machine model
5. Physical security
6. Software security
7. Operating system security
8. Key management
9. Cryptographic algorithms
10. Electromagnetic compatibility (EMC/EMI)
11. Self-test

"Although no checklist will help you to avoid every security weakness, asking these questions could help you to avoid making a potentially bad decision," Russell says.

Message Authentication

James S. Tiller, CISA, CISSP

For centuries, various forms of encryption have provided confidentiality of information and have become integral components of computer communication technology**.** Early encryption techniques were based on shared knowledge between the communication participants. Confidentiality and basic authentication were established by the fact that each participant must know a common secret to encrypt or decrypt the communication, or as with very early encryption technology, the diameter of a stick.

The complexity of communication technology has increased the sophistication of attacks and has intensified the vulnerabilities confronting data. The enhancement of communication technology inherently provides tools for attacking other communications. Therefore, mechanisms are employed to reduce the new vulnerabilities that are introduced by new communication technology. The mechanisms utilized to ensure confidentiality, authentication, and integrity are built on the understanding that encryption alone, or simply applied to the data, will not suffice any longer. The need to ensure that the information is from the purported sender, that it was not changed or viewed in transit, and to provide a process to validate these concerns is, in part, the responsibility of message authentication.

This chapter describes the technology of message authentication, its application in various communication environments, and the security considerations of those types of implementations.

History of Message Authentication

An encrypted message could typically be trusted for several reasons. First and foremost, the validity of the message content was established by the knowledge that the sender had the appropriate shared information to produce the encrypted message. An extension of this type of assumed assurance was also recognized by the possession of the encrypting device. An example is the World War II German Enigma, a diabolically complex encryption machine that used three or four wheels to produce ciphertext as an operator typed in a message. The Enigma was closely guarded; if it fell into the enemy's possession, the process of deciphering any captured encrypted messages would become much less complex. The example of the Enigma demonstrates that possession of a device in combination with the secret code for a specific message provided insurance that the message contents received were genuine and authenticated.

As the growth of communication technology embraced computers, the process of encryption moved away from complex and rare mechanical devices to programs that provided algorithms for encryption. The mechanical algorithm of wheels and electrical conduits was replaced by software that could be loaded onto computers, which are readily available, to provide encryption. As algorithms were developed, many became open to the public for inspection and verification for use as a standard. Once the algorithm was exposed, the power of protection was in the key that was combined with the clear message and fed into the algorithm to produce ciphertext.

Why Authenticate a Message?

The ability of a recipient to trust the content of a message is placed squarely on the trust of the communication medium and the expectation that it came from the correct source. As one would imagine, this example of open communication is not suitable for information exchange and is unacceptable for confidential or any form of valuable data.

There are several types of attacks on communications that range from imposters posing as valid participants replaying or redelivering outdated information, to data modification in transit.

Communication technology has eliminated the basic level of interaction between individuals. For two people talking in a room, it can be assured — to a degree — that the information from one individual has not been altered prior to meeting the listener's ears. It can be also assumed that the person that is seen talking is the originator of the voice that is being heard. This example is basic, assumed, and never questioned — it is trusted. However, the same type of communication over an alternate medium must be closely scrutinized due to the massive numbers of vulnerabilities to which the session is exposed.

Computers have added several layers of complexity to the trusting process and the Internet has introduced some very interesting vulnerabilities. With a theoretically unlimited number of people on a single network, the options of attacks are similarly unlimited. As soon as a message takes advantage of the Internet as a communication medium, all bets are off without layers of protection.

How are senders sure that what they send will be the same when it reaches the intended recipient? How can senders be sure that the recipients are who they claim to be? The same questions hold true for the recipients and the question of initiator identity.

Technology Overview

It is virtually impossible to describe message authentication without discussing encryption. Message authentication is nothing more than a form of cryptography and, in certain implementations, takes advantage of encryption algorithms.

Hash Function

Hash functions are computational functions that take a variable-length input of data and produce a fixed-length result that can be used as a fingerprint to represent the original data. Therefore, if the hashes of two messages are identical, it can be reasonably assumed that the messages are identical as well. However, there are caveats to this assumption, which are discussed later.

Hashing information to produce a fingerprint will allow the integrity of the transmitted data to be verified. To illustrate the process, Alice creates the message "Mary loves basketball," and hashes it to produce a smaller, fixed-length message digest, "a012f7." Alice transmits the original message and the hash to Bob. Bob hashes the message from Alice and compares his result with the hash received with the original message from Alice. If the two hashes match, it can be assumed that the message was not altered in transit. If the message was changed after Alice sent it and before Bob received it, Bob's hash will not match, resulting in discovering the loss of message integrity. This example is further detailed in Exhibit 110.1.

In the example, a message from Alice in cleartext is used as input for a hash function. The result is a message digest that is a much smaller, fixed-length value unique to the original cleartext message. The message digest is attached to the original cleartext message and sent to the recipient, Bob. At this point, the message and the hash value are in the clear and vulnerable to attack. When Bob receives the message, he separates the message from the digest and hashes the message using the same hash function Alice used. Once the hash process is complete, Bob compares his message digest result with the one included with the original message from Alice. If the two match, the message was not modified in transit.

The caveat to the example illustrated is that an attacker using the same hashing algorithm could simply intercept the message and digest, create a new message and corresponding message digest, and forward it on to the original recipient. The type of attack, known as the "man in the middle," described here is the driving reason why message authentication is used as a component in overall message protection techniques.

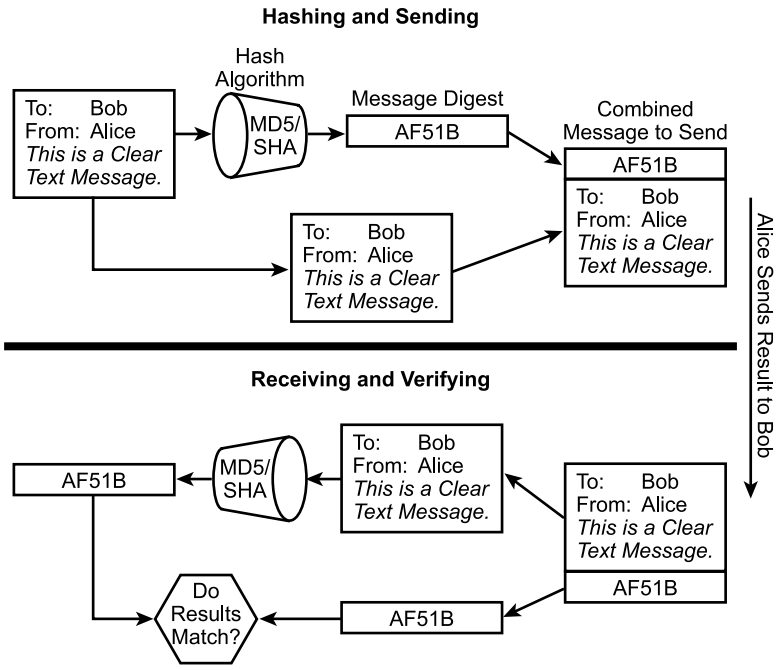

EXHIBIT 110.1 Hash function.

Encryption

Encryption, simply stated, is the conversion of plaintext into unintelligible ciphertext. Typically, this is achieved with the use of a key and an algorithm. The key is combined with the plaintext and computed with a specific algorithm.

There are two primary types of encryption keys: symmetrical and asymmetrical.

Symmetrical

Symmetrical keys, as shown in Exhibit 110.2, are used for both encryption and decryption of the same data. It is necessary for all the communication participants to have the same key to perform the encryption and decryption. This is also referred to as a shared secret.

In the example, Alice creates a message that is input into an encryption algorithm that uses a unique key to convert the clear message into unintelligible ciphertext. The encrypted result is sent to Bob, who has obtained the same key through a mechanism called "out-of-band" messaging. Bob can now decrypt the ciphertext by providing the key and the encrypted data as input for the encryption algorithm. The result is the original plaintext message from Alice.

Asymmetrical

To further accentuate authentication by means of encryption, the technology of public key cryptography, or asymmetrical keys, can be leveraged to provide message authentication and confidentiality.

Alice and Bob each maintain a private and public key pair that is mathematically related. The private key is well protected and is typically passphrase protected. The public key of the pair is provided to anyone who wants it and wishes to send an encrypted message to the owner of the key pair.

An example of public key cryptography, as shown in Exhibit 110.3, is that Alice could encrypt a message with Bob's public key and send the ciphertext to Bob. Because Bob is the only one with the matching private key, he would be the only recipient who could decrypt the message. However, this interaction only provides confidentiality and not authentication because anyone could use Bob's public key to encrypt a message and claim to be Alice.

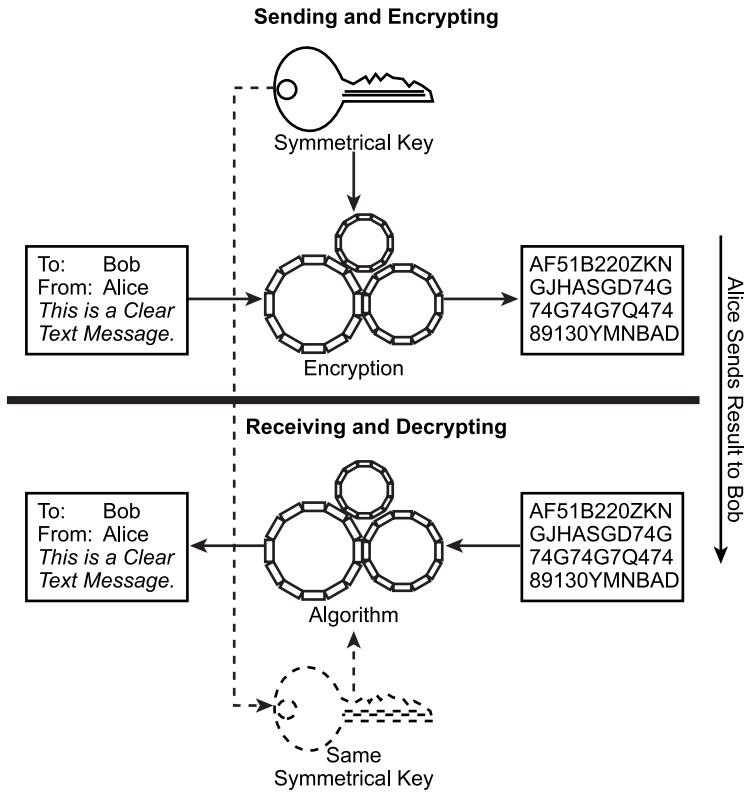

EXHIBIT 110.2 Symmetrical key encryption.

As illustrated in Exhibit 110.3, the encryption process is very similar to normal symmetrical encryption. A message is combined with a key and processed by an algorithm to construct ciphertext. However, the key being used in the encryption cannot be used for decryption. As detailed in the example, Alice encrypts the data with the public key and sends the result to Bob. Bob uses the corresponding private key to decrypt the information.

To provide authentication, Alice can use her private key to encrypt a message digest generated from the original message, then use Bob's public key to encrypt the original cleartext message, and send it with the encrypted message digest. When Bob receives the message, he can use his private key to decrypt the message. The output can then be verified using Alice's public key to decrypt the message authentication that Alice encrypted with her private key. The process of encrypting information with a private key to allow the recipient to authenticate the sender is called digital signature. An example of this process is detailed in Exhibit 110.4.

The illustration conveys a typical application of digital signature. There are several techniques of creating digital signatures; however, the method detailed in the exhibit represents the use of a hash algorithm. Alice generates a message for Bob and creates a message digest with a hash function. Alice then encrypts the message digest with her private key. By encrypting the digest with her private key, Alice reduces the system load created by the processor-intensive encryption algorithm and provides an authenticator. The encrypted message digest is attached to the original cleartext message and encrypted using Bob's public key. The example includes the encrypted digest with the original message for the final encryption, but this is not necessary. The final result is sent to Bob. The entire package is decrypted with Bob's private key — ensuring recipient authentication. The result is the cleartext message and an encrypted digest. Bob decrypts the digest with Alice's public key, which authenticates the sender. The result is the original hash created by Alice that is compared to the hash Bob created using the cleartext message. If the two match, the message content has been authenticated along with the communication participants.

Digital signatures are based on the management of public and private keys and their use in the communication. The process of key management and digital signatures has evolved into certificates. Certificates, simply stated, are public keys digitally signed by a trusted Certificate Authority. This provides comfort in the knowledge

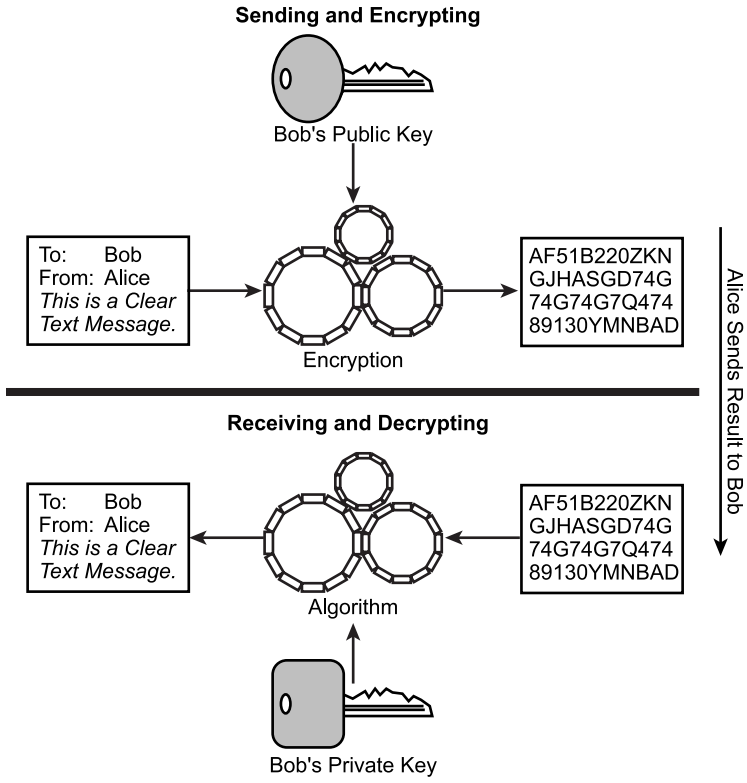

EXHIBIT 110.3 Asymmetrical key encryption.

that the public key being used to establish encrypted communications is owned by the proper person or organization.

Message Authentication Code

Message authentication code (MAC) with DES is the combination of encryption and hashing. As illustrated in Exhibit 110.5, as data is fed into a hashing algorithm, a key is introduced into the process.

MAC is very similar to encryption but the MAC is designed to be irreversible, like a standard hash function. Because of the computational properties of the MAC process, and the inability to reverse the encryption designed into the process, MACs are much less vulnerable to attacks than encryption with the same key length. However, this does not prevent an attacker from forging a new message and MAC.

MAC ensures data integrity like a message digest but adds limited layers of authentication because the recipient would have to have the shared secret to produce the same MAC to validate the message.

The illustration of a message authentication code function appears very similar to symmetrical encryption; however, the process is based on compressing the data into a smaller fixed length that is not designed for decryption. A message is passed into the algorithm, such as DES-CBC, and a symmetrical key is introduced. The result is much like that of a standard message digest, but the key is required to reproduce the digest for verification.

The Need for Authentication

As data is shared across networks — networks that are trusted or not — the opportunities for undesirables to interact with the session are numerous. Of the attacks that communications are vulnerable to, message authentication, in general application, addresses only a portion of the attacks. Message authentication is used as a tool to combine various communication-specific data that can be verified by the valid parties for each

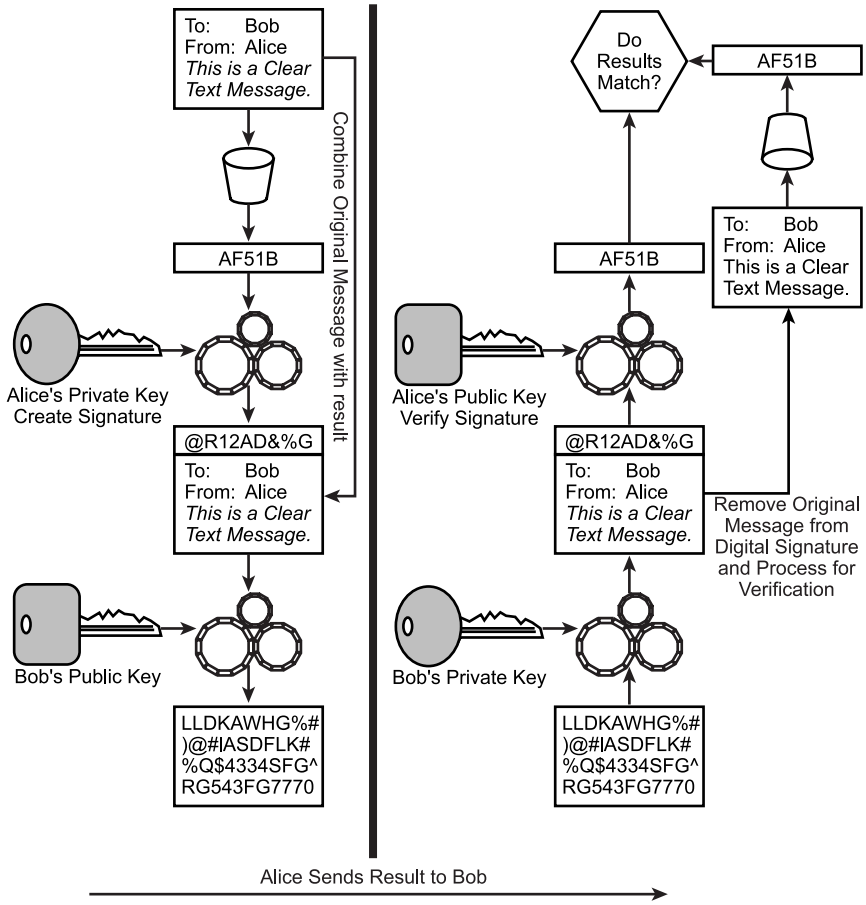

EXHIBIT 110.4 Digital signature with the use of hash functµions.

message received. Message authentication alone is not an appropriate countermeasure; but when combined with unique session values, it can protect against four basic categories of attacks:

1. Masquerading
2. Content modification
3. Sequence manipulation
4. Submission modification

To thwart these vulnerabilities inherent in communications, hash functions can be used to create message digests that contain information for origination authentication and timing of the communications. Typically, time-sensitive random information, or a nonce, is provided during the initialization of the session. The nonce can be input with the data in the hashing process or used as key material to further identify the peer during communications. Also, sequence numbers and time stamps can be generated and hashed for communications that require consistent session interaction — not like that of nontime-sensitive data such as e-mail. The process of authentication, verification through the use of a nonce, and the creation of a key for MAC computations provides an authenticated constant throughout the communication.

Masquerading

The process of masquerading as a valid participant in a network communication is a type of attack. This attack includes the creation of messages from a fraudulent source that appears to come from an authorized origin.

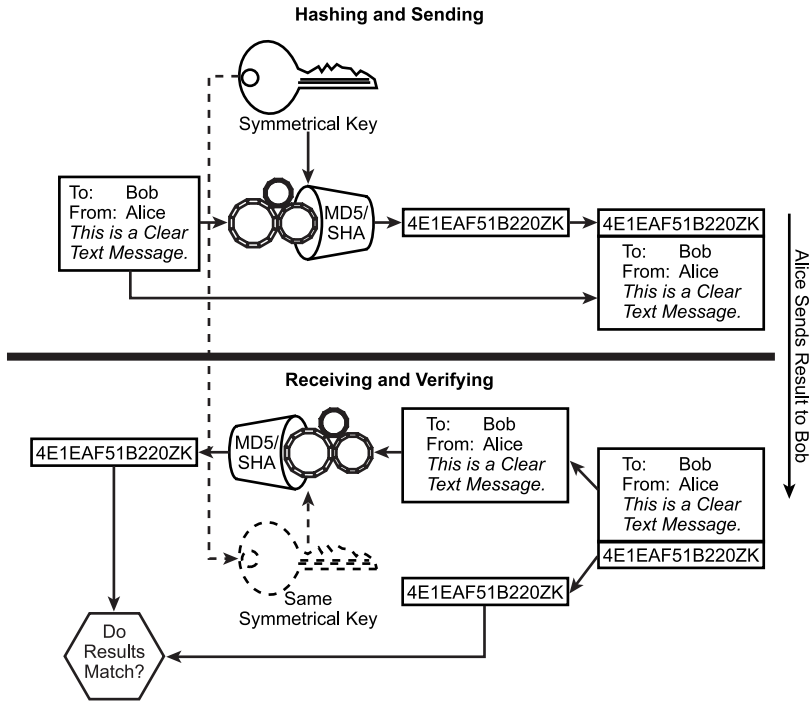

EXHIBIT 110.5 Message authentication code.

Masquerading can also represent the acknowledgment of a message by an attacker in place of the original recipient. False acknowledgment or denial of receipt could complicate non-repudiation issues. The nonce that may have been used in the hash or the creation of a symmetrical key assists in the identification of the remote system or user during the communication. However, to accommodate origin authentication, there must be an agreement on a key prior to communication. This is commonly achieved by a preshared secret or certificate that can be used to authenticate the initial messages and create specific data for protecting the remainder of the communication.

Content Modification

Content modification is when the attacker intercepts a message, changes the content, and then forwards it to the original recipient. This type of attack is quite severe in that it can manifest itself in many ways, depending on the environment.

Sequence Manipulation

Sequence manipulation is the process of inserting, deleting, or reordering datagrams. This type of attack can have several types of effects on the communication process, depending on the type of data and communication standard. The primary result is denial of service. Destruction of data or confusion of the communication can also result.

Submission Modification

Timing modification appears in the form of delay or replay. Both of these attacks can be quite damaging. An example is session establishment. In the event that the protocol is vulnerable to replay, an attacker could use the existence of a valid session establishment to gain unauthorized access.

Message authentication is a procedure to verify that the message received is from the intended source and has not been modified or made susceptible to the previously outlined attacks.

Authentication Foundation

To authenticate a message, an authenticator must be produced that can be used later by the recipient to authenticate the message. An authenticator is a primitive reduction or representation of the primary message to be authenticated. There are three general concepts in producing an authenticator.

Encryption

With encryption, the ciphertext becomes the authenticator. This is related to the trust relationship discussed earlier by assuming the partner has the appropriate secret and has protected it accordingly.

Consider typical encrypted communications: a message sent from Alice to Bob encrypted with a shared secret. If the secret's integrity is maintained, confidentiality is assured by the fact that no unauthorized entities have the shared secret.

Bob can be assured that the message is valid because the key is secret and an attacker without the key would be unable to modify the ciphertext in a manner to make the desired modifications to the original plaintext message.

Message Digest

As briefly described above, hashing is a function that produces a unique fixed-length value that serves as the authenticator for the communication. Hash functions are one-way, in that the creation of the hash is quite simple, but the reverse is infeasible. A well-constructed hash function should be collision resistant. A collision is when two different messages produce the same result or digest. For a function to take a variable length of data and produce a much smaller fixed-length result, it is mathematically feasible to experience collisions. However, a well-defined algorithm with a large result should have a high resistance to collisions.

Hash functions are used to provide message integrity. It can be argued that encryption can provide much of the same integrity. An example is an attacker could not change an encrypted message to modify the resulting cleartext. However, hash functions are much faster than encryption processes and can be utilized to enhance performance while maintaining integrity. Additionally, the message digest can be made public without revealing the original message.

Message Authentication Code

Message authentication code with DES is a function that uses a secret key to produce a unique fixed-length value that serves as the authenticator. This is much like a hash algorithm but provides the added protection by use of a key. The resulting MAC is appended to the original message prior to sending the data. MAC is similar to encryption but cannot be reversed and does not directly provide any authentication process because both parties share the same secret key.

Hash Process

As mentioned, a hash function is a one-way computation that accepts a variable-length input and produces a fixed-length result. The hash function calculates each bit in a message; therefore, if any portion of the original message changes, the resulting hash will be completely different.

Function Overview

A hash function must meet several requirements to be used for message authentication. The function must:

- Be able to accept any size data input
- Produce a fixed-length output
- Be relatively easy to execute, using limited resources
- Make it computationally impractical to derive a message from the digest (one-way property)
- Make it computationally impractical to create a message digest that is equal to a message digest created from different information (collision resistance)

Hash functions accommodate these requirements by a set of basic principles. A message is processed in a sequence of blocks, as shown in Exhibit 110-6. The size of the blocks is determined by the hash function. The function addresses each block one at a time and produces parity for each bit. Addressing each bit provides the message digest with the unique property that dramatic changes will occur if a single bit is modified in the original message.

As detailed in Exhibit 110.6, the message is separated into specific portions. Each portion is XOR with the next portion, resulting in a value the same size of the original portions, not their combined value. As each result is processed, it is combined with the next portion until the entire message has been sent through the function. The final result is a value the size of the original portions that were created and a fixed-length value is obtained.

Message Authentication Codes and Processes

Message authentication code with DES is applying an authentication process with a key. MACs are created using a symmetrical key so the intended recipient or the bearer of the key can only verify the MAC. A plain hash function can be intercepted and replaced or brute-force attacked to determine collisions that can be of use to the attacker. With MACs, the addition of a key complicates the attack due to the secret key used in its computation.

There are four modes of DES that can be utilized:

1. Block cipher-based
2. Hash function-based
3. Stream cipher-based
4. Unconditionally secure

Block Cipher-Based Mode

Block cipher-based message authentication can be derived from block cipher algorithms. A commonly used version is DES-CBC-MAC, which, simply put, is DES encryption based on the Cipher Block Chaining (CBC) mode of block cipher to create a MAC. A very common form of MAC is Data Authentication Algorithm (DAA), which is based on DES. The process uses the CBC mode of operation of DES with a zero initialization vector. As illustrated in Exhibit 110-7, the message is grouped into contiguous blocks of 64 bits; the last group is padded on the right with zeros to attain the 64-bit requirement. Each block is fed into the DES algorithm with a key to produce a 64-bit Data Authentication Code (DAC). The resulting DAC is XOR and the next 64 bits of data is then fed again into the DES algorithm. This process continues until the last block, and returns the final MAC.

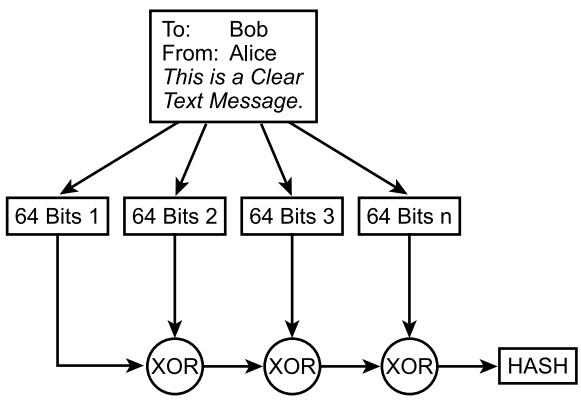

EXHIBIT 110.6 Simple hash function example.

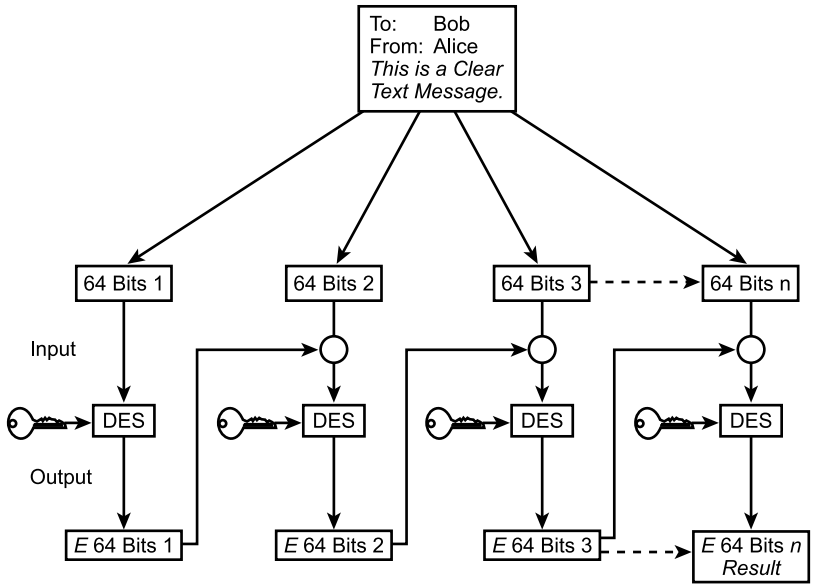

EXHIBIT 110.7 MAC based on DES CBC.

A block cipher is a type of symmetric key encryption algorithm that accepts a fixed block of plaintext to produce ciphertext of the same length — a linear relationship. There are four primary modes of operation on which the block ciphers can be based:

1. *Electronic Code Book (ECB)*. Electronic Code Book mode accepts each block of plaintext and encrypts it independently of previous block cipher results. The weakness in ECB is that identical input blocks will produce identical cipher results of the same length. Interestingly, this is a fundamental encryption flaw that affected the Enigma. For each input, there was a corresponding output of the same length. The "step" of the last wheel in an Enigma could be derived from determinations in ciphertext patterns.
2. *Cipher Block Chaining (CBC)*. With CBC mode, each block result of ciphertext is exclusively OR'ed (XOR) with the previous calculated block, and then encrypted. Any patterns in plaintext will not be transferred to the cipher due to the XOR process with the previous block.
3. *Cipher Feedback (CFB)*. Similar to CBC, CFB executes an XOR between the plaintext and the previous calculated block of data. However, prior to being XORed with the plaintext, the previous block is encrypted. The amount of the previous block to be used (the feedback) can be reduced and not utilized as the entire feedback value. If the full feedback value is used and two cipher blocks are identical, the output of the following operation will be identical. Therefore, any patterns in the message will be revealed.
4. *Output Feedback (OFB)*. Output Feedback is similar to CFB in that the result is encrypted and XORed with the plaintext. However, the creation of the feedback is generated independently of the ciphertext and plaintext processes. A sequence of blocks is encrypted with the previous block, the result is then XORed with the plaintext.

Hash Function-Based Mode

Hash function-based message authentication code (HMAC) uses a key in combination with hash functions to produce a checksum of the message. RFC 2104 defines that HMAC can be used with any iterative cryptographic hash function (e.g., MD5, SHA-1) in combination with a secret shared key. The cryptographic strength of HMAC depends on the properties of the underlying hash function.

The definition of HMAC requires a cryptographic hash function and a secret key. The hash function is where data is hashed by iterating a basic compression function on blocks of data, typically 64 bytes in each

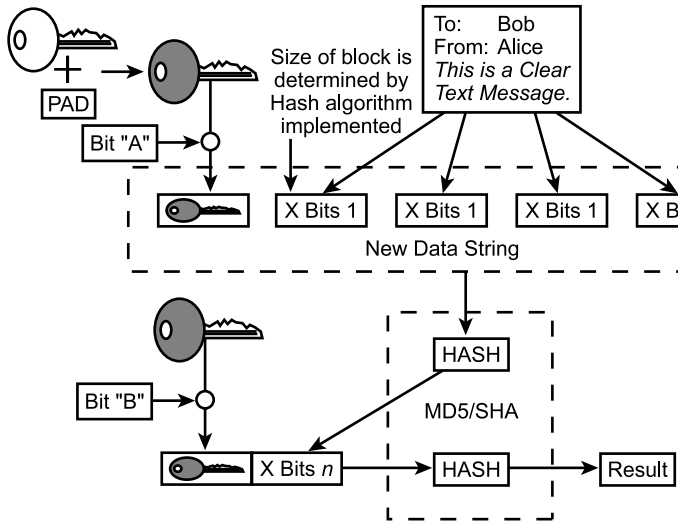

EXHIBIT 110.8 Simple HMAC example.

block. The symmetrical key to be used can be any length up to the block size of the hash function. If the key is longer than the hash block size, the key is hashed and the result is used as the key for the HMAC function.

This process is very similar to the DES-CBC-MAC discussed above; however, the use of the DES algorithm is significantly slower than most hashing functions, such as MD5 and SHA-1.

HMAC is a process of combining existing cryptographic functions and a keyed process. The modularity of the standard toward the type of cryptographic function that can be used in the process has become the point of acceptance and popularity. The standards treat the hash function as a variable that can consist of any hash algorithm. The benefits are that legacy or existing hash implementations can be used in the process and the hash function can be easily replaced without affecting the process. The latter example represents an enormous security advantage. In the event the hash algorithm is compromised, a new one can be immediately implemented.

There are several steps to the production of an HMAC; these are graphically represented in Exhibit 110.8. The first step is to determine the key length requested and compare it to the block size of the hash being implemented. As described above, if the key is longer than the block size it is hashed, the result will match the block size defined by the hash. In the event the key is smaller, it is padded with zeros to accommodate the required block size.

Once the key is defined, it is XOR'ed with a string of predefined bits "A" to create a new key that is combined with the message. The new message is hashed according to the function defined (see Exhibit 110.6). The hash function result is combined with the result of XOR the key with another defined set of bits "B." The new combination of the second key instance and the hash results are hashed again to create the final result.

Stream Cipher-Based Mode

A stream cipher is a symmetric key algorithm that operates on small units of plaintext, typically bits. When data is encrypted with a stream cipher, the transformation of the plaintext into ciphertext is dependent on when the bits were merged during the encryption. The algorithm creates a keystream that is combined with the plaintext. The keystream can be independent of the plaintext and ciphertext (typically referred to as a synchronous cipher), or it can depend on the data and the encryption (typically referred to as self-synchronizing cipher).

Unconditionally Secure Mode

Unconditional stream cipher is based on the theoretical aspects of the properties of a one-time pad. A one-time pad uses a string of random bits to create the keystream that is the same length as the plaintext message.

The keystream is combined with the plaintext to produce the ciphertext. This method of employing a random key is very desirable for communication security because it is considered unbreakable by brute force. Security at this level comes with an equally high price: key management. Each key is the same size and length as the message it was used to encrypt, and each message is encrypted with a new key.

Message Authentication over Encryption

Why use message authentication (e.g., hash functions and message authentication codes) when encryption seems to meet all the requirements provided by message authentication techniques? Following are brief examples and reasoning to support the use of message authentication over encryption.

Speed

Cryptographic hash functions, such as MD5 and SHA-1, execute much faster and use less system resources than typical encryption algorithms. In the event that a message only needs to be authenticated, the process of encrypting the entire message, such as a document or large file, is not entirely logical and consumes valuable system resources.

The reasoning of reducing load on a system holds true for digital signatures. If Alice needs to send a document to Bob that is not necessarily confidential but may contain important instructions, authentication is paramount. However, encrypting the entire document with Alice's private key is simply overkill. Hashing the document will produce a very small rendition of the original message, which then can be encrypted with her private key. The much smaller object encrypts quickly and provides ample authentication and abundant message integrity.

Limited Restrictions

No export restrictions on cryptographic functions are defined. Currently, the laws enforcing import and export restrictions in the international community are complicated and constantly changing. Basically, these laws are to control the level of technology and intellectual property of one country from another. Message authentication releases the communication participants from these restrictions.

Application Issues

There are applications where the same message is broadcast to several destinations. One system is elected as the communication monitor and verifies the message authentication on behalf of the other systems. If there is a violation, the monitoring system alerts the other systems.

Simple Network Management Protocol (SNMP) is an example where command messages can be forged or modified in transit. With the application of MAC, or HMAC, a password can be implemented to act as a key to allow a degree of authentication and message authentication. Each system in the community is configured with a password that can be combined with the data during the hash process and verified upon receipt. Because all the members are configured with the same password, the data can be hashed with the locally configured password and verified. It can also be forged at the destination.

System Operation

In the event that one of a communication pair is overburdened, the process of decryption would be overwhelming. Authentication can be executed in random intervals to ensure authentication with limited resources. Given the hashing process is much less intensive than encryption, periodical hashing and comparisons will consume fewer system cycles.

Code Checksum

Application authentication is achieved by adding the checksum to the program. While the program itself may be open to modification, the checksum can be verified at runtime to ensure that the code is in the original format and should produce the expected results. Otherwise, an attacker could have constructed a malicious activity to surreptitiously operate while the original application was running. It can be argued that if an attacker

can modify the code, the checksum should pose little resistance because it can also be simply regenerated. Given the typically small size of checksums, it is typically published on several Web pages or included in an e-mail. In other words, an attacker would have to modify every existence of the checksum to ensure that the recipient would inadvertently verify the modified application. If encryption was utilized, the program would have to decrypt at each runtime, consuming time and resources. This is very important for systems that provide security functions, such as firewalls, routers, and VPN access gateways.

An example of the need for code protection can be illustrated by the heavy reliance on the Internet for obtaining software, updates, or patches. In early computing, systems patches and software were mailed to the recipient as the result of a direct request, or as a registered system user. As communication technology advanced, Bulletin Board Systems (BBS) could be directly accessed with modems to obtain the necessary data. In both of these examples, a fair amount of trust in the validity of the downloaded code is assumed.

In comparison, the complexity of the Internet is hidden from the user by a simple browser that is used to access the required files. The data presented in a Web page can come from dozens of different sources residing on many different servers throughout the Internet. There are few methods to absolutely guarantee that the file being downloaded is from a trusted source. To add to the complexity, mirrors can be established to provide a wider range of data sources to the Internet community. However, the security of a mirrored site must be questioned. The primary site may have extensive security precautions, but a mirror site may not. An attacker could modify the code on an alternate download location. When the code is finally obtained, a checksum can be validated to ensure that the code obtained is the code the creator intended for receipt.

Utilization of Existing Resources

There is available installed technology designed for DES encryption processes. The use of DEC-CBC-MAC can take advantage of existing technology to increase performance and support the requirements of the communication. The DES encryption standard has been available for quite some time. There are many legacy systems that have hardware designed specifically for DES encryption. As more advanced encryption becomes available and new standards evolve, the older hardware solutions can be utilized to enhance the message authentication process.

Security Considerations

The strength of any message authentication function, such as a MAC or hash, is determined by two primary factors:

1. One-way property
2. Collision resistance

One-way property is the ability of the hash to produce a message digest that cannot be used to determine the original message. This is one of the most significant aspects of message authentication algorithms. If a message authentication algorithm is compromised and a weakness is discovered, the result could have a detrimental effect on various forms of communication.

MD4 is an example of a function's poor one-way property. Within MD4, the data is padded to obtain a length divisible by 512, plus 448. A 64-bit value that defines the original message's length is appended to the padded message. The result is separated into 512-bit blocks and hashed using three distinct rounds of computation. Weaknesses were quickly discovered if the first or last rounds were not processed. However, it was later discovered that without the last round, the original message could be derived. MD4 had several computation flaws that proved the function had limited one-way capabilities.

Collision resistance is the most considered security aspect of message authentication functions. A collision is typically defined as when two different messages have the same hash result. In the event that a hash function has a collision vulnerability, such as MD2, a new message can be generated and used to replace the original in a communication, and the hash will remain valid. The combination of the original hash and the known vulnerability will provide the attacker with enough information to produce an alternative message that will produce the same checksum. An example is the hash algorithm MD2. It was created for 8-bit computers in the late 1980s and uses 16-bit blocks of the message against which to execute the hash. MD2 produces a 16-bit checksum prior to passing through the hash function. If this checksum is omitted, the production of a

collision would be trivial. MD4 was subject to weak collision resistance as well, and it was proven that collisions could be produced in less than a minute on a simple personal computer.

The concept of a collision is a fundamental issue concerning probabilities. Take, for example, a hash function that produces an n-bit digest. If one is looking for a result of x, it can be assumed that one would have to try 2^n input possibilities. This type of brute-force attack is based on a surprising outcome referred to as the "birthday paradox": What is the least number of people in a group that can provide the probability, greater than half, that at least two people will have the same birthday?

If there are 365 days per year, and if the number of people exceeds 365, there will be a successful collision. If the number of people in the group is less than 365, then the number of possibilities is 365^n, where n is the number of people in a group. For those still wondering, the number of people, assuming there is a collision, is 23. This is a very small number; but when calculated against the number of possibilities that any two people's birthdays match, one sees that there are 253 possibilities. This is simply calculated as $n(n-1)/2$, which results in the probability of $P(365, 23) = 0.5073$, or greater than one half.

The birthday paradox states that given a random integer with a constant value between 1 and n, what is the selection of the number of permutations (the number of people required to meet 0.5 probability) that will result in a collision?

Given a fixed-length output that can represent an infinite amount of variation, it is necessary to understand the importance of a robust algorithm. It is also necessary for the algorithm to produce a relatively large result that remains manageable.

However, as certificates and other public key cryptography is utilized, message authentication processes will not be exposed to direct attack. The use of a hash to accommodate a digital signature process is based on the ownership and trust of a private key; the hash, while important, is only a step in a much more complicated process.

Conclusion

Communication technology has provided several avenues for unauthorized interaction with communications requiring the need to address security in ways previously unanalyzed. Message authentication provides a means to thwart various forms of attack and can enhance other aspects of communication security. A message "fingerprint" can be created in several ways, ranging from simple bit parity functions (hash) to utilization of encryption algorithms (DES-CBC-MAC) to complicated hybrids (HMAC). This fingerprint cannot only be used to ensure message integrity, but also given the inherent process of message reduction, it lends itself to authentication and signature processes.

Message authentication is a broad activity that employs several types of technology in various applications to achieve timely, secure communications. The combinations of the application of these technologies are virtually limitless and, as advancements in cryptography, cryptanalysis, and overall communication technology are realized, message authentication will most certainly remain an interesting process.

Fundamentals of Cryptography and Encryption

Ronald A. Gove

This chapter presents an overview of some basic ideas underlying encryption technology. The chapter begins by defining some basic terms and follows with a few historical notes so the reader can appreciate the long tradition that encryption, or secret writing, has had. The chapter then moves into modern cryptography and presents some of the underlying mathematical and technological concepts behind private and public key encryption systems such as DES and RSA. We will provide an extensive discussion of conventional private key encryption prior to introducing the concept of public key cryptography. We do this for both historical reasons (private key did come first) and technical reasons (public key can be considered a partial solution to the key management problem).

SOME BASIC DEFINITIONS

We begin our discussion by defining some terms that will be used throughout the chapter. The first term is *encryption*. In simplest terms, encryption is the process of making information unreadable by unauthorized persons. The process may be manual, mechanical, or electronic, and the core of this chapter is to describe the many ways that the encryption process takes place. Encryption is to be distinguished from message-hiding. Invisible inks, microdots, and the like are the stuff of spy novels and are used in the trade; however, we will not spend any time discussing these techniques for hiding information. Exhibit 19.1 shows a conceptual version of an encryption system. It consists of a sender and a receiver, a message (called the "plain text"), the encrypted message (called the "cipher text"), and an item called a "key." The encryption process, which transforms the plain text into the cipher text, may be thought of as a "black box." It takes inputs (the plain text and key) and produces output (the cipher text). The

messages may be handwritten characters, electromechanical representations as in a Teletype, strings of 1s and 0s as in a computer or computer network, or even analog speech. The black box will be provided with whatever input/output devices it needs to operate; the insides, or cryptographic algorithm will, generally, operate independently of the external representation of the information.

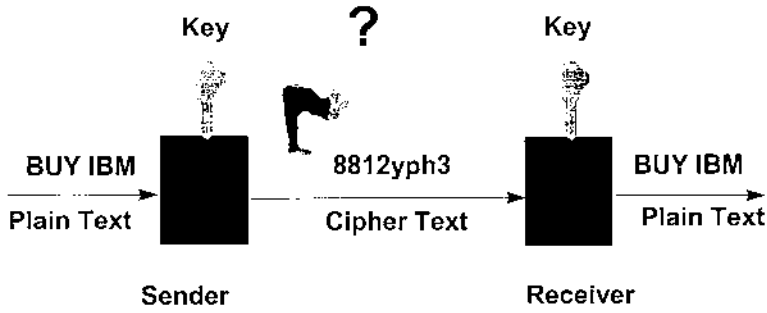

Exhibit 19.1. Conceptual Version of an Encryption System

The *key* is used to select a specific instance of the encryption process embodied in the machine. It is more properly called the "*cryptovariable*." The use of the term "key" is a holdover from earlier times. We will discuss cryptovariables (keys) in more detail in later sections. It is enough at this point to recognize that the cipher text depends on both the plain text and the cryptovariable. Changing either of the inputs will produce a different cipher text. In typical operation, a cryptovariable is inserted prior to encrypting a message and the same key is used for some period of time. This period of time is known as a "cryptoperiod." For reasons having to do with cryptanalysis, the key should be changed on a regular basis. The most important fact about the key is that it embodies the security of the encryption system. By this we mean the system is designed so that complete knowledge of all system details, including specific plain and cipher text messages, is not sufficient to derive the cryptovariable.

It is important that the system be designed in this fashion because the encryption process itself is seldom secret. The details of the data encryption standard (DES), for example, are widely published so that anyone may implement a DES-compliant system. In order to provide the intended secrecy in the cipher text, there has to be some piece of information that is not available to those who are not authorized to receive the message; this piece of information is the cryptovariable, or key.

Inside the black box is an implementation of an algorithm that performs the encryption. Exactly how the algorithm works is the main topic of this chapter, and the details depend on the technology used for the message.

Cryptography is the study of the means to do encryption. Thus cryptographers design encryption systems. Cryptanalysis is the process of figuring out the message without knowledge of the cryptovariable (key), or more generally, figuring out which key was used to encrypt a whole series of messages.

SOME HISTORICAL NOTES

The reader is referred to Kahn[1] for a well-written history of this subject. We note that the first evidence of cryptography occurred over 4000 years ago in Egypt. Almost as soon as writing was invented, we had secret writing. In India, the ancients' version of Dr. Ruth's Guide to Good Sex, the *Kama-Sutra,* places secret writing as 45th in a list of arts women should know. The Arabs in the 7th century AD were the first to write down methods of cryptanalysis. Historians have discovered a text dated about 855 AD that describes cipher alphabets for use in magic.

One of the better known of the ancient methods of encryption is the Caesar Cipher, so called because Julius Caesar used it. The Caesar Cipher is a simple alphabetic substitution. In a Caesar Cipher, each plain text letter is replaced by the letter 3 letters away to the right. For example, the letter A is replaced by D, B by E, and so forth. (See Exhibit 19.2, where the plain-text alphabet is in lower case and the cipher text is in upper case.)

a b c d e f g h i j k l m n o p q r s t u v w x y z

Plain text: Omnia Gallia est divisa in partes tres . . . .

Cipher Text: RPQLD JDOOLD HVW GLYLVD LQ SDUWHV WUHV . . .

Exhibit 19.2. The Caesar Cipher

Caesar's Cipher is a form of a more general algorithm known as monoalphabetic substitution. While Julius Caesar always used an offset of 3, in principal one can use any offset, from one to 25. (An offset of 26 is the original alphabet.) The value of the offset is in fact the cryptovariable for this simplest of all monoalphabetic substitutions. All such ciphers with any offset are now called Caesar Ciphers.

There are many ways to produce alphabetic substitution ciphers. In fact, there are 26! (26 factorial or 26X25X24 . . . X2X1) ways to arrange the 26 letters of the alphabet. All but one of these yields a nonstandard alphabet. Using a different alphabet for each letter according to some well-defined rule can make a more complicated substitution. Such ciphers are called polyalphabetic substitutions.

Cryptography underwent many changes through the centuries often following closely with advances in technology. When we wrote by hand, encryption was purely manual. After the invention of the printing press various mechanical devices appeared such as Leon Batista Alberti's cipher disk in Italy. In the 18th century, Thomas Jefferson invented a ciphering device consisting of a stack of 26 disks each containing the alphabet around the face of the edge. Each disk had the letters arranged in a different order. A positioning bar was attached that allowed the user to align the letters along a row. To use the device, one spelled out the message by moving each disk so that the proper letter lay along the alignment bar. The bar was then rotated a fixed amount (the cryptovariable for that message) and the letters appearing along the new position of the bar were copied off as the cipher text. The receiver could then position the cipher text letters on his "wheel" and rotate the cylinder until the plain text message appeared.

By World War II very complex electromechanical devices were in use by the Allied and Axis forces. The stories of these devices can be found in many books such as Hodges.[2] The need for a full-time, professional cryptographic force was recognized during and after WWII and led to the formation of the National Security Agency by Presidential memorandum signed by Truman. See Bamford[3] for a history of the NSA.

Except for a few hobbyists, cryptography was virtually unknown outside of diplomatic and military circles until the mid-seventies. During this period, as the use of computers, particularly by financial institutions, became more widespread, the need arose for a "public," (non-military or diplomatic) cryptographic system. In 1973 the National Bureau of Standards (now the National Institute of Standards and Technology) issued a request for proposals for a standard cryptographic algorithm. They received no suitable response at that time and reissued the request in 1974. IBM responded to the second request with their Lucifer system, which they had been developing for their own use. This algorithm was evaluated with the help of the NSA and eventually was adopted as the Data Encryption Standard (DES) in 1976. See Federal Information Processing Standard NBS FIPS PUB 46.

The controversy surrounding the selection of DES[4] stimulated academic interest in cryptography and cryptanalysis. This interest led to the discovery of many cryptanalytic techniques and eventually to the concept of public key cryptography. Public key cryptography is a technique that uses

distinct keys for encryption and decryption, only one of which need be secret. We will discuss this technique later in this chapter, as public key cryptography is more understandable once one has a firm understanding of conventional cryptography.

The 20 years since the announcement of DES and the discovery of public key cryptography have seen advances in computer technology and networking that were not even dreamed of in 1975. The Internet has created a demand for instantaneous information exchange in the military, government, and most importantly, private sectors that is without precedent. Our economic base, the functioning of our government, and our military effectiveness are more dependent on automated information systems than any country in the world. However, the very technology that created this dependence is its greatest weakness: the infrastructure is fundamentally vulnerable to attacks from individuals, groups, or nation-states that can easily deny service or compromise the integrity of information. The users of the Internet, especially those with economic interests, have come to realize that effective cryptography is a necessity.

THE BASICS OF MODERN CRYPTOGRAPHY

Since virtually all of modern cryptography is based on the use of digital computers and digital algorithms, we begin with a brief introduction to digital technology and binary arithmetic. All information in a computer is reduced to a representation as 1s and 0s. (Or the "on" and "off" state of an electronic switch.) All of the operations within the computer can be reduced to logical OR, EXCLUSIVE OR, and AND. Arithmetic in the computer (called binary arithmetic) obeys the rules shown in Exhibit 19.3 (represented by "addition" and "multiplication" tables):

⊕	0	1
0	0	1
1	1	0

⊗	0	1
0	0	0
1	0	1

Exhibit 19.3. Binary Arithmetic Rules

The symbol ⊕ is called modulo 2 addition and ⊗ is called modulo 2 multiplication. If we consider the symbol '1' as representing a logical value of TRUE and '0' as the logical value FALSE then ⊕ is equivalent to exclusive OR in logic (XOR) while ⊗ is equivalent to AND. For example, A XOR B is true only if A or B is TRUE but not both. Likewise, A AND B is true only when both A and B are TRUE.

All messages, both plain text and cipher text, may be represented by strings of 1s and 0s. The actual method used to digitize the message is not relevant to an understanding of cryptography so we will not discuss the details here.

We will consider two main classes of cryptographic algorithms:

- Stream Ciphers — which operate on essentially continuous streams of plain text, represented as 1s and 0s
- Block Ciphers — which operate on blocks of plain text of fixed size.

These two divisions overlap in that a block cipher may be operated as a stream cipher. Generally speaking, stream ciphers tend be implemented more in hardware devices, while block ciphers are more suited to implementation in software to execute on a general-purpose computer. Again, these guidelines are not absolute, and there are a variety of operational reasons for choosing one method over another.

STREAM CIPHERS

We illustrate a simple stream cipher in the table below and in Exhibit 19.4. Here the plain text is represented by a sequence of 1s and 0s. (The binary streams are to be read from right to left. That is, the right-most bit is the first bit in the sequence.) A keystream[5] generator produces a "random" stream of 1s and 0s that are added modulo 2, bit by bit, to the plain-text stream to produce the cipher-text stream.

The cryptovariable (key) is shown as entering the keystream generator. We will explain the nature of these cryptovariables later. There are many different mechanisms to implement the keystream generator, and the reader is referred to Schneier[6] for many more examples. In general, we may represent the internal operation as consisting of a finite state machine and a complex function. The finite state machine consists of a system state and a function (called the "next state" function) that cause the system to change state based on certain input.

The complex function operates on the system state to produce the keystream. Exhibit 19.5 shows the encryption operation. The decryption operation is equivalent; just exchange the roles of plain text and cipher text. This works because of the following relationships in modulo two addition: Letting p represent a plain-text bit, k a keystream bit, and c the cipher text bit

$$c = p \oplus k,$$

so, $$c \oplus k = (p \oplus k) \oplus k = p \oplus (k \oplus k) = p \oplus 0 = p,$$

since in binary arithmetic $x \oplus x$ is always 0. $(1 \oplus 1 = 0 \oplus 0 = 0)$.

Plain Text:	1	0	1	1	0	1	1	0	0
	⊙	⓪	⊕	⊕	⊕	⊙	⓪	⓪	⓪
Keystream	1	1	0	1	0	0	0	1	1
Cipher Text	0	1	1	0	0	1	1	1	1

Exhibit 19.4. Stream Cipher

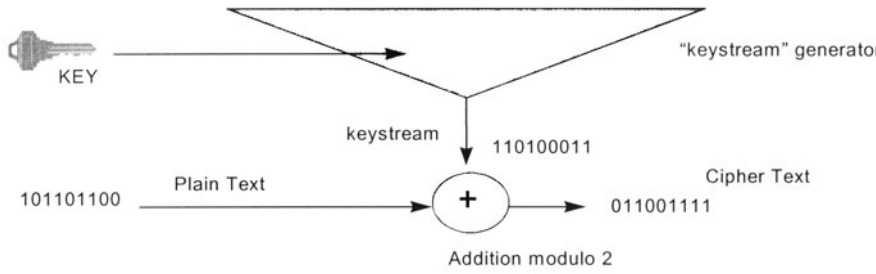

Exhibit 19.5. Stream Ciphers

These concepts are best understood with examples. Exhibit 19.6 shows a simple linear feedback shift register (LFSR). A LFSR is one of the simplest finite state machines and is used as a building block for many stream ciphers (see Schneier's text). In Exhibit 19.6, the four-stage register (shown here filled with 1s) represents the state. During operation, at each tick of the internal clock, the 4 bits shift to the right (the right-most bit is dropped), and the last 2 bits (before the shift) are added (mod 2) and placed in the left-most stage. In general, an LFSR may be of any length, n, and any of the individual stages may be selected for summing and insertion into the left-most stage. The only constraint is that the right-most bit should always be one of the bits selected for the feedback sum. Otherwise, the length is really n – 1, not n. Exhibit 19.6 shows the sequence of system states obtained from the initial value of 1111. In some systems, the initial value of the register is part of the cryptovariable.

Note that if we started the sequence with 0000, then all subsequent states would be 0000. This would not be good for cryptographic applications since the output would be constant. Thus the all-0 state is avoided. Note also that this four-stage register steps through $15 = 2^4 - 1$ distinct

Exhibit 19.6. Simple LFSR

states before repeating. Not all configurations of feedback will produce such a maximal sequence. If we number the stages in Exhibit 19.6 from left to right as 1,2,3,4, and instead of feeding back the sum of stages 3 and 4 we selected 2 and 4, then we would see a very different sequence. This example would produce 2 sequences (we call them cycles) of length 6, one cycle of length 3, and 1 of length 0. For example, starting with 1111 as before will yield:

$$1111 \rightarrow 0111 \rightarrow 0011 \rightarrow 1001 \rightarrow 1100 \rightarrow 1110 \rightarrow 1111$$

It is important to have as many states as possible produced by the internal state machine of the keystream generator. The reason is to avoid repeating the keystream. Once the keystream begins to repeat, the same plain text will produce the same cipher text. This is a cryptographic weakness and should be avoided. While one could select any single stage of the LFSR and use it as the keystream, this is not a good idea. The reason is that the linearity of the sequence of stages allows a simple cryptanalysis. We can avoid the linearity by introducing some more complexity into the system. The objective is to produce a keystream that looks completely random.[7] That is, the keystream will pass as many tests of statistical randomness as one cares to apply. The most important test is that knowledge of the algorithm and knowledge of a sequence of successive keystream bits does not allow a cryptanalyst to predict the next bit in the sequence. The complexity can often be introduced by using some nonlinear polynomial $f(a_1, a_2, \ldots, a_m)$ of a selection of the individual stages of the LFSR. Nonlinear means that some of the terms are multiplied together such as $a_1a_2 + a_3a_4 + \ldots a_{m-1}a_m$. The selection of which register stages are

associated with which inputs to the polynomial can be part of the cryptovariable (key). The reader is encouraged to refer to texts such as Schneier[6] for examples of specific stream-cipher implementations. Another technique for introducing complexity is to use multiple LFSRs and to select output alternately from each based on some pseudorandom process. For example, one might have three LFSRs and create the keystream by selecting bits from one of the two, based on the output of a third.

Some of the features that a cryptographer will design into the algorithm for a stream cipher include:

1. Long periods without a repetition.
2. Functional complexity — each keystream bit should depend on most or all of the cryptovariable bits.
3. Statistically unpredictable — given n successive bits from the keystream it is not possible to predict the n + 1st bit with a probability different from ½.
4. The keystream should be statistically unbiased — there should be as many 0s as 1s, as many 00s as 10s, 01s, and 11s, etc.
5. The keystream should not be linearly related to the cryptovariable.

We also note that in order to send and receive messages encrypted with a stream cipher the sending and receiving systems must satisfy several conditions. First, the sending and receiving equipment must be using identical algorithms for producing the keystream. Second, they must have the same cryptovariable. Third, they must start in the same state; and fourth, they must know where the message begins.

The first condition is trivial to satisfy. The second condition, ensuring that the two machines have the same cryptovariable, is an administrative problem (called key management) that we will discuss in a later section. We can ensure that the two devices start in the same state by several means. One way is to include the initial state as part of the cryptovariable. Another way is to send the initial state to the receiver at the beginning of each message. (This is sometimes called a message indicator, or initial vector.) A third possibility is to design the machines to always default to a specific state. Knowing where the beginning of the message is can be a more difficult problem, and various messaging protocols use different techniques.

BLOCK CIPHERS

A block cipher operates on blocks of text of fixed size. The specific size is often selected to correspond to the word size in the implementing computer, or to some other convenient reference (e.g., 8-bit ASCII text is conveniently processed by block ciphers with lengths that are multiples of 8 bits). Because the block cipher forms a one-to-one correspondence between input and output blocks it is nothing more or less than a permutation. If the blocks

are n bits long, then there are 2^n possible input blocks and 2^n possible output blocks. The relationship between the input and output defines a permutation. There are $(2^n)!$ possible permutations, so theoretically there are $(2^n)!$ possible block cipher systems on n bit blocks.[8]

A simple block cipher on 4-bit blocks is shown in Exhibit 19.7.

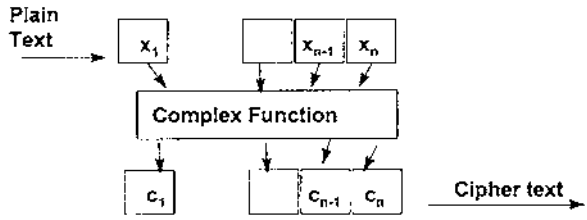

Exhibit 19.7. Block Ciphers

With such a prodigious number of possible block ciphers, one would think it a trivial matter to create one. It is not so easy. First of all, the algorithm has to be easy to describe and implement. Most of the $(2^n)!$ permutations can only be described by listing the entries in a table such as the one in Exhibit 19.8. For a 32-bit block cipher this table would have on the order of $10^{9.6}$ entries, which is quite impractical. Another consideration is that there needs to be a relation between the cryptovariable and the permutation. In most implementations, the cryptovariable selects a specific permutation from a wide class of permutations. Thus one would need as many tables as cryptovariables. We conclude from this that it is not easy to design good block ciphers.

The most well-known block cipher is the Data Encryption Standard, DES. The cryptovariable for DES is 64 bits, 8 of which are parity check bits. Consequently the cryptovariable is effectively 56 bits long. DES operates as follows: a 64-bit plain text block, after going through an initial permutation (which has no cryptographic significance) is split onto left and right halves, L_0 and R_0. These two halves are then processed as follows for i = 0, 1, …, 15

$$L_i = R_{i-1}$$

$$R_i = L_{i-1} + f(R_{i-1}, K_i).$$

The blocks K_i are derived from the cryptovariable. The function f is a very complex function involving several expansions, compressions, and permutations by means of several fixed tables called the S-boxes and

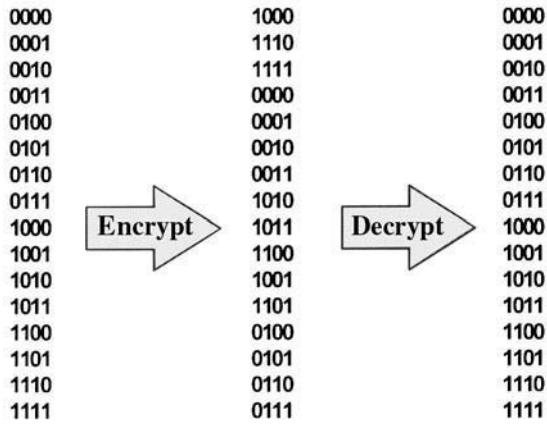

Exhibit 19.8. Simple Block Cipher

P-boxes. The reader is referred to FIPS PUB 46 for a detailed description of the S-boxes and P-boxes.

As was the case with the DES cryptovariable, there has been much discussion about the significance of the S-boxes. Some people have argued that the NSA designed the S-Boxes so as to include a "trap door" that would allow them to decrypt DES-encrypted messages at will. No one has been able to discover such a trap door. More recently it has been stated that the S-boxes were selected to minimize the danger from an attack called differential cryptanalysis.

Because of the widespread belief that the DES cryptovariable is too small, many have suggested that one encrypt a message twice with DES using two different cryptovariables. This "Double DES" is carried out in the following way. Represent the operation of DES encryption on message P and cryptovariable K as C = E(P; K); and the corresponding decryption as P = D(C; K) = D(E(P; K); K). The "Double DES" with cryptovariables K and K′ is

$$C = E(E(P; K); K')$$

Since each cryptovariable is 56 bits long, we have created an effective cryptovariable length of 56 + 56 = 112 bits. However, we shall see in the section on cryptanalysis that there is an attack on double-DES that requires about the same amount of computation as that required to attack a single DES. Thus double DES is really no more secure than single DES.

A third variant is triple DES, which applies the DES algorithm three times with two distinct cryptovariables. Let K and K′ be DES cryptovariables. Then triple DES is

$$C = E(D(E(P; K); K'); K).$$

That is, apply the encrypt function to P using the first cryptovariable, K. Then apply the decrypt function to the result using the second cryptovariable, K′. Since the decrypt function is using a different cryptovariable, the message is not decrypted; it is transformed by a permutation as in any block cipher. The final step is to encrypt once again with the encrypt function using the first key, K. By using the D in the middle, a triple DES implementation can be used to encrypt a single DES message when K = K′:

$$C = E(D(E(P; K); K); K) = E(P; K).$$

Thus, someone using triple DES is still able to communicate securely with persons using single DES. No successful attacks have been reported on triple DES that are any easier than trying all possible pairs of cryptovariables. In the next section we deal with cryptanalysis in more detail.

CRYPTANALYSIS

As we stated in the introduction, cryptography is the science of designing algorithms for encrypting messages. Cryptanalysis is the science (some would say art) of "breaking" the cryptographic systems. In the following we will try to explain just what "breaking" a cryptosystem means, as there are many misconceptions in the press.

There is an obvious analogy between cryptanalysis and cryptography and burglars and locks. As the locksmiths design better locks the burglars develop better ways to pick them. Likewise, as the cryptographer designs better algorithms the cryptanalyst develops new attacks. A typical design methodology would be to have independent design teams and attack teams. The design team proposes algorithms, and the attack teams tries to find weaknesses. In practice, this methodology is used in the academic world. Researchers publish their new algorithms, and the rest of the academic world searches for attacks to be published in subsequent papers. Each cycle provides new papers toward tenure.

Breaking or attacking a cryptosystem means recovering the plain-text message without possession of the particular cryptovariable (or key) used to encrypt that message. More generally, breaking the system means determining the particular cryptovariable (key) that was used. Although it is the message (or the information in the message) that the analyst really wants, possession of the cryptovariable allows the analyst to recover all of the messages that were encrypted in that cryptovariable. Since the cryptoperiod may be days or weeks, the analyst who recovers a cryptovariable will be able to recover many more messages than if he attacks a single message at a time.

Determining the specific details of the algorithm that was used to encrypt the message is generally not considered part of breaking an encryption system. In most cases, e.g., DES, the algorithm is widely known. Even many of the proprietary systems such as RC4 and RC5 have been published. Because it is very difficult to maintain the secrecy of an algorithm it is better to design the algorithm so that knowledge of the algorithm's details is still not sufficient to determine the cryptovariable used for a specific message without trying all possible cryptovariables.

Trying all cryptovariables is called a "brute force" or "exhaustion" attack. It is an attack that will always work as long as one is able to recognize the plain-text message after decryption. That is, in any attack you need to be able to decide when you have succeeded. One also has to be able to find the cryptovariable (and hence the message) in time for it to be of use. For example, in a tactical military environment, to spend one week to recover a message about an attack that will occur before the week is over will not be useful. Last, one has to be able to afford to execute the attack. One may often trade off time and computer power; an attack that may take one year on a PC might take only one day on 365 PCs. If one must have the message within a day for it to be valuable, but one does not have the funds to acquire or run 365 PCs, then one really doesn't have a viable attack.

Often a cryptanalyst might assume that she possesses matched plain and cipher text. This is sometimes possible in real systems because military and diplomatic messages often have stereotyped beginnings. In any case it is not a very restrictive condition and can help the cryptanalyst evaluate the cryptographic strength of an algorithm.

Let us look at a brute force attack on some system. We suppose that the cryptovariable has n binary bits (e.g., DES has n = 56). We suppose that we have a stream cipher and that we have matched plain and cipher text pairs P_i and C_i for I = 1, 2, … . For each possible cryptovariable there is some fixed amount of computation ("work") needed to encrypt a P_i and see if it results in the corresponding C_i. We can convert this work into the total number, W, of basic bit operations in the algorithm such as shifts, mod 2 additions, compares, etc. Suppose for definiteness that W = 1000 or 10^3.

There is a total of 2^n n-bit cryptovariables. For n = 56, 2^{56} is about $10^{16.8}$ or 72,000,000,000,000,000. If we select one of the possible cryptovariables and encrypt P_1 we have a 50:50 chance of getting C_1 since the only choices are 1 and 0. If we do not obtain C_1 we reject the selected cryptovariable as incorrect and test the next cryptovariable. If we do get C_1 then we must test the selected cryptovariable on P_2 and C_2. How many tests do we need to make in order to be sure that we have the correct cryptovariable? The answer is: at least 56. The rationale is that the probability of the wrong cryptovariable successfully matching 56 or more bits is 2^{-56}. Since we potentially have to try 2^{56} cryptovariables the expected number of cryptovariables passing all the

tests is $(2^{56})(2^{-56}) = 1$. With one "survivor" we may correctly assume it is the cryptovariable we want. If we tested only 2^{55} cryptovariables, then we would expect two survivors. (Cryptanalysts call a cryptovariable that passes all of the tests by chance a "non-causal survivor.") If we test a few more than 56, the expected number of non-causal survivors is much less than 1. Thus we can be sure that the cryptovariable that does successfully match the 56 P_i and C_i is the one actually used. In a block cipher, such as DES, testing one block is usually sufficient since a correct block has 64 correct bits.

A natural question is how long does it take to execute a brute force attack (or any other kind of attack for that matter). The answer depends on how much computational power is available to the analyst. And since we want cryptographic systems to be useful for many years we also need to know how much computational power will be available in years hence. Gordan Moore, one of the founders of Intel, once noted that processing speeds seem to double (or costs halved) every 18 months. This is equivalent to a factor of 10 increase in speed per dollar spent about every 5 years. This trend has continued quite accurately for many years and has come to be known as "Moore's law."

Using Moore's law we can make some predictions. We first introduce the idea of a MIPS year (M.Y.). This is the number of instructions a million-instruction-per-second computer can execute in one year. One M.Y. is approximately $10^{13.5}$ instructions. At today's prices, one can get a 50 MIPS PC for about $750. We can then estimate the cost of a MIPS year at about $750/50 or $15, assuming we can run the computer for one year.

Let's look at what this means in two examples. We consider two cryptographic systems. One with a 56-bit cryptovariable (e.g., DES) and the other a 40-bit cryptovariable. Note that 40 bits is the maximum cryptovariable length allowed for export by the U.S. government. We assume that each algorithm requires about 1000 basic instructions to test each cryptovariable. Statistics tells us that, on average, we may expect to locate the correct cryptovariable after testing about ½ of the cryptovariable space.

There are two perspectives: how much does it cost? And how long does it take? The cost may be estimated from:

$$(½)\ (1000N(15))/\text{M.Y.},$$

where N equals the number of cryptovariables (in the examples, either 2^{56} or 2^{40}), and M.Y. = $10^{13.5}$. The elapsed time requires that we make some assumptions as to the speed of processing. If we set K equal to the number of seconds in one year, and R the number of cryptovariables tested per second, we obtain the formula:

$$\text{Time (in years)} = (½)\ (N/KR).$$

The results are displayed in Exhibit 19.9.

YEAR	M.Y. Cost	On 56 bit cryptovariable	On 40 bit cryptovariable
1998	$15	$17 Million	$260
2003	$1.50	$1.7Million	$26
2008	$0.15	$170 thousand	$2.60

Number of cryptovariables tested per second	On 56 bit cryptovariable	On 40 bit cryptovariable
1,000	300 million years	17.5 years
1,000,000	300,000 years	6.2 days
1,000,000,000	300 years	9 minutes
1,000,000,000,000	109 days	0.5 seconds

Exhibit 19.9. Cost and Time for Brute Force Attack

One of the first public demonstrations of the accuracy of these estimates occurred during the summer of 1995. At that time a student at Ecole Polytechnique reported that he had "broken" an encrypted challenge message posted on the Web by Netscape. The message, an electronic transaction, was encrypted using an algorithm with a 40-bit cryptovariable. What the student did was to partition the cryptovariable space across a number of computers to which he had access and set them searching for the correct one. In other words he executed a brute force attack and he successfully recovered the cryptovariable used in the message. His attack ran for about 6 days and processed about 800,000 keys per second. While most analysts did not believe that a 40-bit cryptovariable was immune to a brute force attack, the student's success did cause quite a stir in the press. Additionally the student posted his program on a Web site so that anyone could copy the program and run the attack. At the RSA Data Security Conference, January 1997, it was announced that a Berkeley student using the idle time on a network of 250 computers was able to break the RSA challenge message, encrypted using a 40-bit key, in three and one-half hours.

More recently a brute force attack was completed against a DES message on the RSA Web page. We quote from the press release of the DES Challenge team (found on www.frii.com/~rtv/despr4.htm):

> LOVELAND, COLORADO (June 18, 1997). Tens of thousands of computers, all across the U.S. and Canada, linked together via the Internet in an unprecedented cooperative supercomputing effort to decrypt a message encoded with the government-endorsed Data Encryption Standard (DES).
>
> Responding to a challenge, including a prize of $10,000, offered by RSA Data Security, Inc., the DESCHALL effort successfully decoded RSA's secret message.

> According to Rocke Verser, a contract programmer and consultant who developed the specialized software in his spare time, "Tens of thousands of computers worked cooperatively on the challenge in what is believed to be one of the largest supercomputing efforts ever undertaken outside of government."
>
> Using a technique called "brute-force," computers participating in the challenge simply began trying every possible decryption key. There are over 72 quadrillion keys (72,057,594,037,927,936). At the time the winning key was reported to RSADSI, the DESCHALL effort had searched almost 25% of the total. At its peak over the recent weekend, the DESCHALL effort was testing 7 billion keys per second.
>
> … And this was done with "spare" CPU time, mostly from ordinary PCs, by thousands of users who have never even met each other.

In other words, the DESCHALL worked as follows. Mr. Verser developed a client-server program that would try all possible keys. The clients were available to any and all who wished to participate. Each participant downloaded the client software and set it executing on their PC (or other machine). The client would execute at the lowest priority in the client PC and so did not interfere with the participant's normal activities. Periodically the client would connect to the server over the Internet and would receive another block of cryptovariables to test. With tens of thousands of clients it only took 4 months to hit the correct cryptovariable.

Another RSA Data Security Inc.'s crypto-cracking contest, launched in March 1997, was completed in October 1997. A team of some 4000 programmers from across the globe, calling themselves the "Bovine RC5 Effort," has claimed the $10,000 prize for decoding a message encrypted in 56-bit -RC5 code. The RC5 effort searched through 47 percent of the possible keys before finding the one used to encrypt the message.

RSA Data Security Inc. sponsored the contest to prove its point that 128-bit encryption must become the standard. Under current U.S. policy, software makers can sell only 40-bit key encryption overseas, with some exceptions available for 56-bit algorithms.

A second DES challenge was solved in February 1998 and took 39 days (see Exhibit 19.10). In this challenge, the participants had to test about 90 percent of the keyspace.

This chapter has focused mostly on brute force attacks. There may be, however, other ways to attack an encryption system. These other methods may be loosely grouped as analytic attacks, statistical attacks, and implementation attacks.

Analytic attacks make use of some weakness in the algorithm that enables the attacker to effectively reduce the complexity of the algorithm

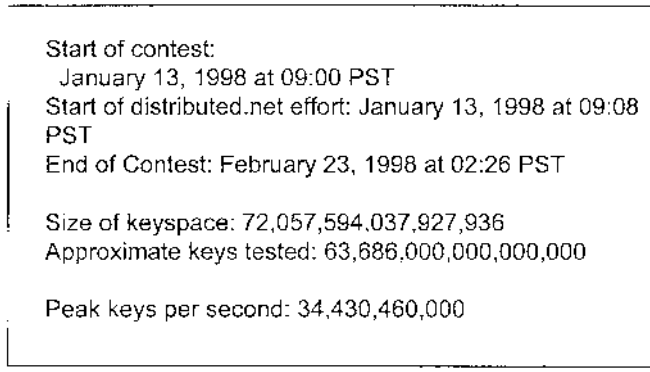

Exhibit 19.10. RSA Project Statistics

through some algebraic manipulation. We will see in the section on public key systems, that the RSA public key algorithm can be attacked by factoring with much less work than brute force. Another example of an analytic attack is the attack on double DES.

Double DES, you recall, may be represented by:

$$C = E(E(P; K); L),$$

where K and L are 56-bit DES keys. We assume that we have matched plain and cipher text pairs C_i, P_i. Begin by noting that if $X = E(P; K)$. Then $D(C; L) = X$. Fix a pair C_1, P_1, and make a table of all 2^{56} values of $D(C_1; L)$ as L ranges through all 2^{56} possible DES keys. Then try each K in succession, computing $E(P_1; K)$ and looking for matches with the values of $D(C_1; L)$ in the table. Each pair K, L for which $E(P_1; K)$ matches $D(C_1; L)$ in the table is a possible choice of the sought-for cryptovariable. Each pair passing the test is then tested against the next plain–cipher pair P_2, C_2.

The chance of a non-causal match (a match given that the pair K, L is not the correct cryptovariable) is about 2^{-64}. Thus of the 2^{112} pairs K, L, about $2^{(112-64)} = 2^{48}$ will match on the first pair P_1, C_1. Trying these on the second block P_2, C_2 and only $2^{(48-64)} = 2^{-16}$ of the non-causal pairs will match. Thus, the probability of the incorrect cryptovariable passing both tests is about $2^{-16} \sim 0$. And the probability of the correct cryptovariable passing both tests is 1.

The total work to complete this attack (called the "meet in the middle" attack) is proportional to $2^{56} + 2^{48} = 2^{56}(1+2^{-8}) \sim 2^{56}$. In other words an attack on double DES has about the same work as trying all possible single DES keys. So there is no real gain in security with double DES.

Statistical attacks make use of some statistical weakness in the design. For example, if there is a slight bias toward 1 or 0 in the keystream, one can sometimes develop an attack with less work than brute force. These attacks are too complex to describe in this short chapter.

The third class of attacks is implementation attacks. Here one attacks the specific implementation of the encryption protocol, not simply the cryptographic engine. A good example of this kind of attack was in the news in late summer 1995. The target was Netscape; and this time the attack was against the 128-bit cryptovariable. Several Berkeley students were able to obtain source code for the Netscape encryption package and were able to determine how the system generated cryptovariables. The random generator was given a seed value that was a function of certain system clock values.

The students discovered that the uncertainty in the time variable that was used to seed the random-number generator was far less than the uncertainty possible in the whole cryptovariable space. By trying all possible seed values they were able to guess the cryptovariable with a few minutes of processing time. In other words, the implementation did not use a randomization process that could, in principle, produce any one of the 2^{128} possible keys. Rather it was selecting from a space more on the order of 2^{20}. The lesson here is that even though one has a very strong encryption algorithm and a large key space, a weak implementation could still lead to a compromise of the system.

KEY (CRYPTOVARIABLE) MANAGEMENT

We have noted in the previous sections that each encryption system requires a key (or cryptovariable) to function and that all of the secrecy in the encryption process is maintained in the key. Moreover, we noted that the sending and receiving party must have the same cryptovariable if they are to be able to communicate. This need translates to a significant logistical problem.

The longer a cryptovariable is used the more likely it is to be compromised. The compromise may occur through a successful attack or, more likely, the cryptovariable may be stolen by or sold to an adversary. Consequently, it is advisable to change the variable frequently. The frequency of change is a management decision based on the perceived strength of the algorithm and the sensitivity of the information being protected.

All communicating parties must have the same cryptovariable. Thus you need to know in advance with whom you plan to exchange messages. If a person needs to maintain privacy among a large number of different persons, then one would need distinct cryptovariables for each possible

communicating pair. In a 1000-person organization, this would amount to almost one million keys.

Next, the keys must be maintained in secrecy. They must be produced in secret, and distributed in secret, and held by the users in a protected area (e.g., a safe) until they are to be used. Finally they must be destroyed after being used.

For centuries, the traditional means of distributing keys was through a trusted courier. A government organization would produce the cryptovariables. And couriers, who have been properly vetted and approved, would distribute the cryptovariables. A rigorous audit trail would be maintained of manufacture, distribution, receipt, and destruction. Careful plans and schedules for using the keys would be developed and distributed.

This is clearly a cumbersome, expensive, and time-consuming process. Moreover the process was and is subject to compromise. Many of history's spies were also guilty of passing cryptovariables (as well as other state secrets) to the enemy.

As our communications systems became more and more dependent on computers and communication networks, the concept of a key distribution center was developed. The key distribution center concept is illustrated in Exhibit 19.11. The operation is as follows: Initially each user, A, B, …, is given (via traditional distribution) a user-unique key that we denote by K_A, K_B, etc. These cryptovariables will change only infrequently, which reduces the key distribution problem to a minimum. The KDC maintains a copy of each user-unique key. When A calls B, the calling protocol first contacts the KDC and tells it that user A is sending a message to user B. The KDC then generates a random "session key," K, i.e., a cryptovariable that will be used only for this communicating session between A and B. The KDC encrypts K in user A's unique cryptovariable, $E(K; K_A)$ and sends this to A. User A decrypts this message obtaining K. The KDC likewise encrypts K in user B's unique cryptovariable, $E(K; K_B)$ and sends this result to B. Now A and B (and no other party) have K, which they use as the cryptovariable for this session.

A session here may be a telephone call or passing a message through a packet switch network; the principles are the same. In practice the complete exchange is done in seconds and is completely transparent to the user.

The KDC certainly simplifies the distribution of cryptovariables. Only the user-unique keys need to be distributed in advance, and only infrequently. The session key only exists for the duration of the message so there is no danger that the key might be stolen and sold to an unauthorized person at some later date. But the KDC must be protected, and one still has

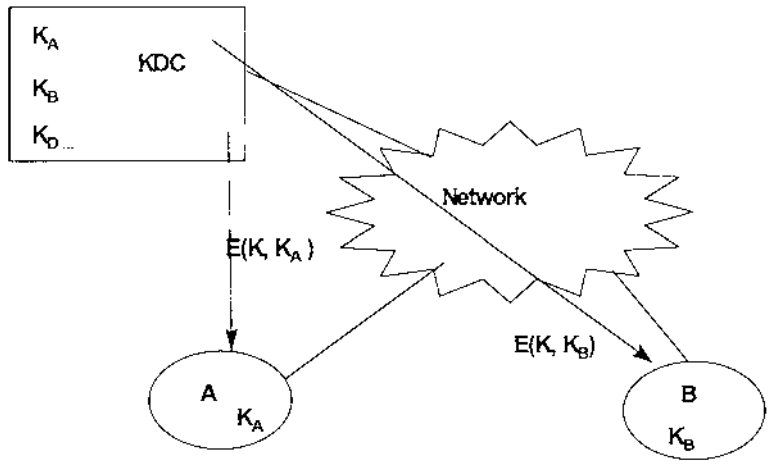

Exhibit 19.11. Key Distribution Center

to know with whom they will be communicating. The KDC will not help if one needs to send an electronic mail message to some new party (i.e., a party unknown to the KDC) for example.

It is clear that cryptovariable (or key) management is difficult and does not provide much in the way of flexibility. Many people have wondered if it would be possible to develop an encryption system that did not require secret keys; a system where one could have a directory of public keys. When you wanted to send an encrypted message to someone, you would look up that person's cryptovariable in a "telephone book," encrypt the message, and send it. And no one intercepting the message would be able to decrypt it except the intended recipient. Can such a system be designed? The answer is yes. It is called public key cryptography.

PUBLIC KEY CRYPTOGRAPHY

The concept of public key cryptography was first discovered and publicly announced by Whitfield Diffie and Martin Hellman (and independently by Ralph Merkle) in 1976. Adm. Bobby Inmann, a former director of the National Security Agency once stated publicly that NSA knew of the idea for many years prior to the publication by Diffie and Hellman.

The public key concept is rather simple (as are most great ideas, once they are explained). We assume that we have two special functions, E and D, that can operate on messages M. (In actual applications large integers will represent the messages, and E and D will be integer functions.) We assume that E and D satisfy the following conditions:

1. $D(E(M)) = M$
2. $E(D(M)) = M$
3. Given E it is not possible to determine D
4. Given D it is not possible to determine E.

The use of the function E in encryption is straightforward. We assume that each person, A, B, C, has pairs of functions E_A, D_A, E_B, D_B, … that satisfy the conditions 1., 2., and 3. given above. Each user X makes their E_X publicly available but keeps their D_X secret and known only to themselves. When A wants to send a message, M, to B, A looks up E_B in the published list and computes $E_B(M)$. By property 2, $D_B(E_B(M) = M$ so B can decrypt the message. From property 3, no person can determine D_B from knowledge of E_B so no one but B can decipher the message.

The functions can also be used to sign messages. Perhaps A wants to send a message M to B and she does not care if anyone else sees the message, but she does want B to know that it really came from her. In this case A computes $D_A(M)$, called a signature, and sends it along with M. When B gets these two messages, he looks up A's function E_A and computes $E_A(D_A(M))$ and obtains M from property 2. If this computed M agrees with the message sent as M, then B is sure that it came from A. Why? Because no one else has or can compute D_A except A and the likelihood of someone producing a fictitious X such that $E_A(X) = M$ is infinitesimally small.

Now suppose A wants to send B a secret message and sign it. Let M be the message. A first computes a "signature" $S = D_A(M)$ and concatenates this to the message M, forming M, S. A then encrypts both the message and the signature, $E_B(M, S)$ and sends it to B. B applies D_B to $E_B(M, S)$ obtaining $D_B(E_B(M, S)) = M, S$. B then computes $E_A(S) = E_A(D_A(M)) = M$ and compares it to the message he decrypted. If both versions of M are the same, he can be assured that A sent the message.

The question the reader should be asking is "Do such functions exist?" The answer is yes, if we relax what we mean by conditions 3 and 4 above. If we only require that it be computationally infeasible to recover D from E (and vice versa) then the functions can be shown to exist. The most well-known example is the RSA algorithm, named for its discoverers, Rivest, Shamir, and Adleman.

A description of RSA requires a small amount of mathematics that we will explain as we proceed. We start with two large prime numbers, p and q. By large we mean they contain hundreds of digits. This is needed in order to meet conditions 3 and 4. A prime number, you recall, is a number that has no divisors except the number itself and 1. (In dealing with integers when we say a divides b we mean that there is no remainder; i.e., $b = ac$ for some integer c.) The numbers 2, 3, 7, 11, 13, 17 are all prime. The number 2 is the only even prime. All other primes must be odd numbers.

We then define a number n as the product of p and q:

$$n = pq$$

We also define a number t as:

$$t = (p - 1)(q - 1)$$

As an example, take p = 3 and q = 7. (These are not large primes, but the mathematics is the same.) Then n = 21 and t = 12. The next step in the construction of RSA is to select a number e that has no common divisors with t. (In this case e and t are said to be relatively prime.) In our numerical example we may take e = 5 since 5 and 12 have no common divisors. Next we must find an integer d such that ed-1 is divisible by t. (This is denoted by ed = 1 mod t.) Since 5*5 – 1 = 25 – 1 = 24 = 2*12 = 2*t, we may take d = 5. (In most examples e and d will not be the same.)

The numbers d, p, and q are kept secret. They are used to create the D function. The numbers e and n are used to create the E function. The number e is usually called the public key and d the secret key. The number n is called the modulus. Once p and q are used to produce n and t, they are no longer needed and may be destroyed, but should never be made public.

To encrypt a message, one first converts the message into a string of integers, m_1, m_2, … all smaller than n. We then compute:

$$c_i = E(m_i) = m_i^e \bmod n$$

This means that we raise m_i to the e^{th} power and then divide by n. The remainder is $c_i = E(m_i)$. In our example, we suppose that the message is m_1 = 9. We compute:

$$c_1 = 9^5 \bmod 21$$

$$= 59049 \bmod 21$$

Because 59049 = 89979*21 + 18, we conclude that c_1 = 18 mod 21.

The decryption, or D function, is defined by:

$$D(c_i) = c_i^d \bmod n$$

In our example,

$$18^d \bmod n$$

$$= 18^5 \bmod 21$$

$$= 1889668 \bmod 21$$

As 1889568 = 889979*21 + 9, we conclude that D(18) = 9, the message we started with.

To demonstrate mathematically that the decryption function always works to decrypt the message (i.e., that properties 1 and 2 above hold) requires a result from number theory called Euler's generalization of Fermat's little theorem. The reader is referred to any book on number theory for a discussion of this result.

The security of RSA depends on the resistance of n to being factored. Since e is made public, anyone who knows the corresponding d can decrypt any message. If one can factor n into its two prime factors, p and q, then one can compute t and then easily find d. Thus it is important to select integers p and q such that it is not likely that someone can factor the product n. In 1983, the best factoring algorithm and the best computers could factor a number of about 71 decimal (235 binary) digits. By 1994, 129 digit (428 bits) numbers were being factored. Current implementations of RSA generate p and q on the order 256 to 1024 bits so that n is about 512 to 2048 bits.

The reader should note that attacking RSA by factoring the modulus n is a form of algebraic attack. The algebraic weakness is that the factors of n lead to a discovery of the "secret key." A brute force attack, by definition, would try all possible values for d. Since d is hundreds of digits long, the work is on the order of 10^{100}, which is a prodigiously large number. Factoring a number, n, takes at most on the order of square root of n operations or about 10^{50} for a 100-digit number. While still a very large number it is a vast improvement over brute force. There are, as we mentioned, factoring algorithms that are much smaller, but still are not feasible to apply to numbers of greater than 500 bits with today's technology, or with the technology of the near future.

As you can see from our examples, using RSA requires a lot of computation. As a result, even with special purpose hardware, RSA is slow; too slow for many applications. The best application for RSA and other public key systems is as key distribution systems.

Suppose A wants to send a message to B using a conventional private key system such as DES. Assuming that B has a DES device, A has to find some way to get a DES cryptovariable to B. She generates such a key, K, through some random process. She then encrypts K using B's public algorithm, $E_B(K)$ and sends it to B along with the encrypted message $E_{DES}(M; K)$. B applies his secret function D_B to $E_B(K)$ and recovers K, which he then uses to decrypt $E_{DES}(M; K)$.

This technique greatly simplifies the whole key management problem. We no longer have to distribute secret keys to everyone. Instead, each person has a public key system that generates the appropriate E and D functions. Each person makes the E public, keeps D secret and we're done. Or are we?

The Man-in-the-Middle

Unfortunately there are no free lunches. If a third party can control the public listing of keys, or E functions, that party can masquerade as both ends of the communication.

We suppose that A and B have posted their E_A and E_B, respectively, on a public bulletin board. Unknown to them, C has replaced E_A and E_B with E_C, his own encryption function. Now when A sends a message to B, A will encrypt it as $E_C(M)$ although he believes he has computed $E_B(M)$. C intercepts the message and computes $D_C(E_C\ (M)) = M$. He then encrypts it with the real E_B and forwards the result to B. B will be able to decrypt the message and is none the wiser. Thus this man in the middle will appear as B to A and as A to B.

The way around this is to provide each public key with an electronically signed signature (a certificate) attesting to the validity of the public key and the claimed owner. The certificates are prepared by an independent third party known as a certificate authority (e.g., VeriSign). The user will provide a public key (E function) and identification to the certificate authority (CA). The CA will then issue a digitally signed token binding the customer's identity to the public key. That is, the CA will produce $D_{CA}(ID_A, E_A)$. A person, B, wishing to send a message to A will obtain A's public key, E_A and the token $D_{CA}(ID_A, E_A)$. Since the CA's public key will be publicized, B computes $E_{CA}(D_{CA}(ID_A, E_A)) = ID_A, E_A$. Thus B, to the extent that he can trust the certification authority, can be assured that he really has the public key belonging to A and not an impostor.

There are several other public key algorithms, but all depend in one way or another on difficult problems in number theory. The exact formulations are not of general interest since an implementation will be quite transparent to the user. The important user issue is the size of the cryptovariable, the speed of the computation, and the robustness of the implementation. However, there is a new implementation that is becoming popular and deserves some explanation.

ELLIPTIC CURVE CRYPTOGRAPHY

A new public key technique based on elliptic curves has recently become popular. To explain this new process requires a brief digression. Recall from the previous section, that the effectiveness of public key algorithms depend on the existence of very difficult problems in mathematics. The security of RSA depends, for example, on the difficulty of factoring large numbers. While factoring small numbers is a simple operation, there are only a few (good) known algorithms or procedures for factoring large integers, and these still take prodigiously long times when factoring numbers that are hundreds of digits long. Another difficult mathematical problem is called

the discrete logarithm problem. Given a number b, the base, and x, the logarithm, one can easily compute b^x or b^x mod N for any N. It turns out to be very difficult to solve the reverse problem for large integers. That is, given a large integer y and a base b, find x so that $b^x = y$ Mod N. The known procedures (algorithms) require about the same level of computation as finding the factors of a large integer. Diffie and Hellman[9] exploited this difficulty to define their public key distribution algorithm.

Diffie and Hellman Key Distribution

Suppose that Sarah and Tanya want to exchange a secret cryptovariable for use in a conventional symmetric encryption system, say a DES encryption device. Sarah and Tanya together select a large prime p and a base b. The numbers p and b are assumed to be public knowledge. Next Sarah chooses a number s and keeps it secret. Tanya chooses a number t and keeps it secret. The numbers s and t must be between 1 and p-1. Sarah and Tanya then compute (respectively):

$$x = b^s \text{ Mod } p \text{ (Sarah)}$$

$$y = b^t \text{ Mod } p \text{ (Tanya)}$$

In the next step of the process Sarah and Tanya exchange the numbers x and y; Tanya sends y to Sarah, and Sarah sends x to Tanya. Now Sarah can compute

$$y^s = b^{ts} \text{ Mod } p$$

And Tanya can compute

$$x^t = b^{st} \text{ Mod } p$$

But,

$$b^{ts} \text{ Mod } p = b^{st} \text{ Mod } p = K$$

which becomes their common key. In order for a third party to recover K, that party must solve the discrete logarithm problem to recover s and t. (To be more precise, solving the discrete logarithm problem is sufficient to recover the key, but it might not be necessary. It is not known if there is another way to find b^{st} given b^s and b^t. It is conjectured that the latter problem is at least as difficult as the discrete logarithm problem.) The important fact regarding the Diffie-Hellman key exchange is that it applies to any mathematical object known as an Abelian group. (See Exhibit 19.12.)

Now we can get into the idea of elliptic curve cryptography, at least at a high level. An elliptic curve is a collection of points in the x-y plane that satisfy an equation of the form

$$y^2 = x^3 + ax + b \text{ . (1)}$$

GROUPS:
A group is a collection of elements, G, together with an operation * (called a "product" or a "sum") that assigns to each pair of elements x, y in G a third element z = x*y. The operation must have an identity element e with e*x = x*e = x for all x in G. Each element must have an inverse with respect to this identity. That is, for each x there is an x' with x*x' = e = x'*x. Last, the operation must be associative. If it is also true that x*y = y*x for all x and y in G, the group is said to be commutative, or Abelian. (In this case the operation is often written as +.

Exhibit 19.12. Definition of Abelian Groups

The elements a and b can be real numbers, imaginary numbers, or elements from a more general mathematical object known as a field. As an example, if we take a = -1 and b = 0. The equation is:

$$y^2 = x^3 - x \ . \ (2)$$

A graph of this curve is shown in Exhibit 19.13. It turns out that the points of this curve (those pairs (x, y) that satisfy the equation 2) can form a group under a certain operation. Given two points P = (x, y) and Q = (x′, y′) on the curve we can define a third point R = (x,″ y″) on the curve called the "sum" of P and Q. Furthermore this operation satisfies all of the requirements for a group. Now that we have a group we may define a Diffie-Hellman key exchange on this group. Indeed, any cryptographic algorithm that may be defined in a general group can be instantiated in the group defined on an elliptic curve. For a given size key, implementing an elliptic curve system seems to be computationally faster than the equivalent RSA. Other than the speed of the implementation there does not appear to be any advantage for using elliptic curves over RSA. RSA Data Security Inc. includes an elliptic curve implementation in their developer's kit (BSAFE) but they strongly recommend that the technique not be used except in special circumstances. Elliptic curve cryptographic algorithms have been

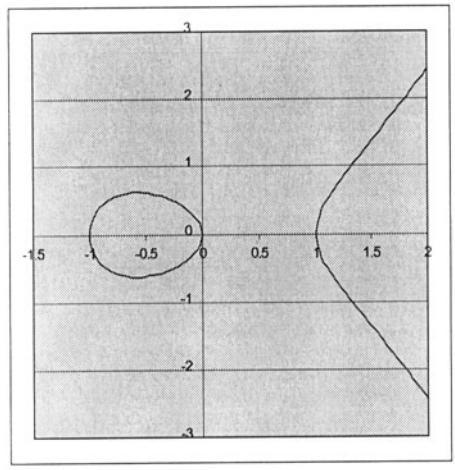

Exhibit 19.13. Graph of Elliptic Curve

subjected to significantly less analysis than the RSA algorithm so it is difficult to state with any confidence that elliptic curves are as secure or more secure than RSA. See Koblitz[10] for a complete discussion.

CONCLUSIONS

This short chapter presented a quick survey of some basic concepts in cryptography. No attempt was made to be comprehensive; the object was to help the reader better understand some of the reports about encryption and "breaking encryption systems" that often appear in the trade press and newspapers. The reader is referred to any of the many fine books that are available for more detail on any of the topics presented.

Notes

1. Kahn, David: *The Codebreakers; The Comprehensive History of Secret Communication from Ancient Times to the Internet*, Scribner, 1996.
2. Hodges, A., *Alan Turing: The Enigma of Intelligence*, Simon and Schuster, 1983.
3. Bamford, J., *The Puzzle Palace*, Houghton Mifflin, 1982.
4. Many thought that NSA had implanted a "trap door" that would allow the government to recover encrypted messages at will. Others argued that the cryptovariable length (56 bits) was too short.
5. The reader is cautioned not to confuse "keystream" with key. The term is used for historical reasons and is not the "key" for the algorithm. It is for this reason that we prefer the term "cryptovariable."
6. Schneier, B., *Applied Cryptography*, John Wiley, 1996.
7. The output cannot be truly random since the receiving system has to be able to produce the identical sequence.

8. For n = 7, $2^n!$ is about 10^{215}. The case n=8 is more than I can calculate. Clearly, there is no lack of possible block ciphers.

Steganography: The Art of Hiding Messages

Mark Edmead, CISSP, SSCP, TICSA

Recently, there has been an increased interest in steganography (also called stego). We have seen this technology mentioned during the investigation of the September 11 attacks, where the media reported that the terrorists used it to hide their attack plans, maps, and activities in chat rooms, bulletin boards, and Web sites. Steganography had been widely used long before these attacks and, as with many other technologies, its use has increased due to the popularity of the Internet.

The word *steganography* comes from the Greek, and it means covered or secret writing. As defined today, it is the technique of embedding information into something else for the sole purpose of hiding that information from the casual observer. Many people know a distant cousin of steganography called watermarking — a method of hiding trademark information in images, music, and software. Watermarking is not considered a true form of steganography. In stego, the information is hidden in the image; watermarking actually adds something to the image (such as the word *Confidential*), and therefore it becomes part of the image. Some people might consider stego to be related to encryption, but they are not the same thing. We use encryption — the technology to translate something from readable form to something unreadable — to protect sensitive or confidential data. In stego, the information is not necessarily encrypted, only hidden from plain view.

One of the main drawbacks of using encryption is that with an encrypted message — although it cannot be read without decrypting it — it is recognized as an encrypted message. If someone captures a network data stream or an e-mail that is encrypted, the mere fact that the data is encrypted might raise suspicion. The person monitoring the traffic may investigate why, and use various tools to try to figure out the message's contents. In other words, encryption provides confidentiality but not secrecy. With steganography, however, the information is hidden; and someone looking at a JPEG image, for instance, would not be able to determine if there was any information within it. So, hidden information could be right in front of our eyes and we would not see it.

In many cases, it might be advantageous to use encryption and stego at the same time. This is because, although we can hide information within another file and it is not visible to the naked eye, someone can still (with a lot of work) determine a method of extracting this information. Once this happens, the hidden or secret information is visible for him to see. One way to circumvent this situation is to combine the two — by first encrypting the data and then using steganography to hide it. This two-step process adds additional security. If someone manages to figure out the steganographic system used, he would not be able to read the data he extracted because it is encrypted.

Hiding the Data

There are several ways to hide data, including data injection and data substitution. In data injection, the secret message is directly embedded in the host medium. The problem with embedding is that it usuallymakes the

EXHIBIT 111.1 Eight-Bit Pixel

1	1	0	0	1	1	0	1

host file larger; therefore, the alteration is easier to detect. In substitution, however, the normal data is replaced or substituted with the secret data. This usually results in very little size change for the host file. However, depending on the type of host file and the amount of hidden data, the substitution method can degrade the quality of the original host file.

In the article "Techniques for Data Hiding," Walter Bender outlines several restrictions to using stego:

- The data that is hidden in the file should not significantly degrade the host file. The hidden data should be as imperceptible as possible.
- The hidden data should be encoded directly into the media and not placed only in the header or in some form of file wrapper. The data should remain consistent across file formats.
- The hidden (embedded) data should be immune to modifications from data manipulations such as filtering or resampling.
- Because the hidden data can degrade or distort the host file, error-correction techniques should be used to minimize this condition.
- The embedded data should still be recoverable even if only portions of the host image are available.

Steganography in Image Files

As outlined earlier, information can be hidden in various formats, including text, images, and sound files. In this chapter, we limit our discussion to hidden information in graphic images. To better understand how information can be stored in images, we need to do a quick review of the image file format. A computer image is an array of points called pixels (which are represented as light intensity). Digital images are stored in either 24- or 8-bit pixel files. In a 24-bit image, there is more room to hide information, but these files are usually very large in size and not the ideal choice for posting them on Web sites or transmitting over the Internet. For example, a 24-bit image that is 1024×768 in size would have a size of about 2 MB. A possible solution to the large file size is image compression. The two forms of image compression to be discussed are lossy and lossless compression. Each one of these methods has a different effect on the hidden information contained within the host file. Lossy compression provides high compression rates, but at the expense of data image integrity loss. This means the image might lose some of its image quality. An example of a lossy compression format is JPEG (Joint Photographic Experts Group). Lossless, as the name implies, does not lose image integrity, and is the favored compression used for steganography. GIF and BMP files are examples of lossless compression formats.

A pixel's makeup is the image's raster data. A common image, for instance, might be 640×480 pixels and use 256 colors (eight bits per pixel).

In an eight-bit image, each pixel is represented by eight bits, as shown in Exhibit 111.1. The four bits to the left are the most-significant bits (MSB), and the four bits to the right are the least-significant bits (LSB). Changes to the MSB will result in a drastic change in the color and the image quality, while changes in the LSB will have minimal impact. The human eye cannot usually detect changes to only one or two bits of the LSB. So if we hide data in any two bits in the LSB, the human eye will not detect it. For instance, if we have a bit pattern of 11001101 and change it to 11001100, they will look the same. This is why the art of steganography uses these LSBs to store the hidden data.

A Practical Example of Steganography at Work

To best demonstrate the power of steganography, Exhibit 111.2 shows the host file before a hidden file has been introduced. Exhibit 111.3 shows the image file we wish to hide. Using a program called Invisible Secrets 3, by NeoByte Solution, Exhibit 111.3 is inserted into Exhibit 111.2. The resulting image file is shown in Exhibit 111.4. Notice that there are no visual differences to the human eye. One significant difference is in the size of the resulting image. The size of the original Exhibit 111.2 is 18 kb. The size of Exhibit 111.3 is 19 kb. The size of the resulting stego-file is 37 kb. If the size of the original file were known, the size of the new file

EXHIBIT 111.2 Unmodified image.

EXHIBIT 111.3 Image to be hidden in Exhibit 111.2.

would be a clear indication that something made the file size larger. In reality, unless we know what the sizes of the files should be, the size of the file would not be the best way to determine if an image is a stego carrier. A practical way to determine if files have been tampered with is to use available software products that can take a snapshot of the images and calculate a hash value. This baseline value can then be periodically checked for changes. If the hash value of the file changes, it means that tampering has occurred.

Practical (and Not So Legal) Uses for Steganography

There are very practical uses for this technology. One use is to store password information on an image file on a hard drive or Web page. In applications where encryption is not appropriate (or legal), stego can be used

EXHIBIT 111.4 Image with Exhibit 111.3 inserted into Exhibit 111.2.

for covert data transmissions. Although this technology has been used mainly for military operations, it is now gaining popularity in the commercial marketplace. As with every technology, there are illegal uses for stego as well. As we discussed earlier, it was reported that terrorists use this technology to hide their attacks plans. Child pornographers have also been known to use stego to illegally hide pictures inside other images.

Defeating Steganography

Steganalysis is the technique of discovering and recovering the hidden message. There are terms in steganography that are closely associated with the same terms in cryptography. For instance, a steganalyst, like his counterpart a cryptanalyst, applies steganalysis in an attempt to detect the existence of hidden information in messages. One important — and crucial — difference between the two is that in cryptography, the goal is not to detect if something has been encrypted. The fact that we can see the encrypted information already tells us that it is. The goal in cryptanalysis is to decode the message. In steganography, the main goal is first to determine if the image has a hidden message and to determine the specific steganography algorithm used to hide the information. There are several known attacks available to the steganalyst: stego-only, known cover, known message, chosen stego, and chosen message. In a stego-only attack, the stego host file is analyzed. A known cover attack is used if both the original (unaltered) media and the stego-infected file are available. A known message attack is used when the hidden message is revealed. A chosen stego attack is performed when the algorithm used is known and the stego host is available. A chosen message attack is performed when a stego-media is generated using a predefined algorithm. The resulting media is then analyzed to determine the patterns generated, and this information is used to compare it to the patterns used in other files. This technique will not extract the hidden message, but it will alert the steganalyst that the image in question does have embedded (and hidden) information.

Another attack method is using dictionary attacks against steganographic systems. This will test to determine if there is a hidden image in the file. All of the stenographic systems used to create stego images use some form of password validation. An attack could be perpetrated on this file to try to guess the password and determine what information had been hidden. Much like cryptographic dictionary attacks, stego dictionary attacks can be performed as well. In most steganographic systems, information is embedded in the header of the image file that contains, among other things, the length of the hidden message. If the size of the image header embedded by the various stego tools is known, this information could be used to verify the correctness of the guessed password.

Protecting yourself against steganography is not easy. If the hidden text is embedded in an image, and you have the original (unaltered) image, a file comparison could be made to see if they are different. This comparison would not be to determine if the size of the image has changed — remember, in many cases the image size does not change. However, the data (and the pixel level) does change. The human eye usually cannot easily detect subtle changes — detection beyond visual observation requires extensive analysis. Several techniques are used to do this. One is the use of stego signatures. This method involves analysis of many different types of untouched images, which are then compared to the stego images. Much like the analysis of viruses using signatures, comparing the stego-free images to the stego-images may make it possible to determine a pattern (signature) of a particular tool used in the creation of the stego-image.

Summary

Steganography can be used to hide information in text, video, sound, and graphic files. There are tools available to detect steganographic content in some image files, but the technology is far from perfect. A dictionary attack against steganographic systems is one way to determine if content is, in fact, hidden in an image.

Variations of steganography have been in use for quite some time. As more and more content is placed on Internet Web sites, the more corporations — as well as individuals — are looking for ways to protect their intellectual properties. Watermarking is a method used to mark documents, and new technologies for the detection of unauthorized use and illegal copying of material are continuously being improved.

An Introduction to Cryptography

Javek Ikbal, CISSP

This chapter presents some basic ideas behind cryptography. This is intended for an audience evaluators, recommenders, and end users of cryptographic algorithms and products rather than implementers. Hence, the mathematical background will be kept to a minimum. Only widely adopted algorithms are described with some mathematical detail. We also present promising technologies and algorithms that information security practitioners might encounter and may have to choose or discard.

The Basics

What Is Cryptography?

Cryptography is the art and science of securing messages so unintended audiences cannot read, understand, or alter that message.

Related Terms and Definitions

A message in its original form is called the plaintext or cleartext. The process of securing that message by hiding its contents is encryption or enciphering. An encrypted message is called ciphertext, and the process of turning the ciphertext back to cleartext is called decryption or deciphering. Cryptography is often shortened to crypto.

Practitioners of cryptography are known as cryptographers. The art and science of breaking encryptions is known as cryptanalysis, which is practiced by cryptanalysts. Cryptography and cryptanalysis are covered in the theoretical and applied branch of mathematics known as cryptology, and practiced by cryptologists.

A cipher or cryptographic algorithm is the mathematical function or formula used to convert cleartext to ciphertext and back. Typically, a pair of algorithms is used to encrypt and decrypt.

An algorithm that depends on keeping the algorithm secret to keep the ciphertext safe is known as a restricted algorithm. Security practitioners should be aware that restricted algorithms are inadequate in the current world. Unfortunately, restricted algorithms are quite popular in some settings. Exhibit 112.1 shows the schematic flow of restricted algorithms. This can be mathematically expressed as $E(M) = C$ and $D(C) = M$, where M is the cleartext message, E is the encryption function, C is the ciphertext, and D is the decryption function.

A major problem with restricted algorithms is that a changing group cannot use it; every time someone leaves, the algorithm has to change. Because of the need to keep it a secret, each group has to build its own algorithms and software to use it.

These shortcomings are overcome by using a variable known as the key or cryptovariable. The range of possible values for the key is called the keyspace. With each group using its own key, a common and well-known algorithm may be shared by any number of groups.

Exhibit 112.1 Encryption and decryption with restricted algorithms.

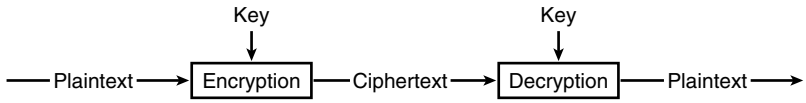

EXHIBIT 112.2 Encryption and decryption with keys.

The mathematical representation now becomes: $E_k(M) = C$ and $D_k(C) = M$, where the subscript k refers to the encryption and decryption key. Some algorithms will utilize different keys for encryption and decryption. Exhibit 112.2 illustrates that the key is an input to the algorithm.

Note that the security of all such algorithms depends on the key and not the algorithm itself. We submit to the information security practitioner that any algorithm that has not been publicly discussed, analyzed, and withstood attacks (i.e., zero restriction) should be presumed insecure and rejected.

A Brief History

Secret writing probably came right after writing was invented. The earliest known instance of cryptography occurred in ancient Egypt 4000 years ago, with the use of hieroglyphics. These were purposefully cryptic; hiding the text was probably not the main purpose — it was intended to impress. In ancient India, government spies communicated using secret codes. Greek literature has examples of cryptography going back to the time of Homer. Julius Caesar used a system of cryptography that shifted each letter three places further through the alphabet (e.g., A shifts to D, Z shifts to C, etc.). Regardless of the amount of shift, all such monoalphabetic substitution ciphers (MSCs) are also known as Caesar ciphers. While extremely easy to decipher if you know how, a Caesar cipher called ROT-13 (N = A, etc.) is still in use today as a trivial method of encryption. Why ROT-13 and not any other ROT-N? By shifting down the middle of the English alphabet, ROT-13 is self-reversing — the same code can be used to encrypt and decrypt. How this works is left as an exercise for the reader. Exhibit 112.3 shows the alphabet and corresponding Caesar cipher and ROT-13.

During the seventh century A.D., the first treatise on cryptanalysis appeared. The technique involves counting the frequency of each ciphertext letter. We know that the letter E occurs the most in English. So if we are trying to decrypt a document written in English where the letter H occurs the most, we can assume that H stands for E. Provided we have a large enough sample of the ciphertext for the frequency count to be statistically significant, this technique is powerful enough to cryptanalyze any MSC and is still in use.

Leon Battista Alberti invented a mechanical device during the 15th century that could perform a polyalphabetic substitution cipher (PSC). A PSC can be considered an improvement of the Caesar cipher because each letter is shifted by a different amount according to a predetermined rule.

The device consisted of two concentric copper disks with the alphabet around the edges. To start enciphering, a letter on the inner disk is lined up with any letter on the outer disk, which is written as the first character of the ciphertext. After a certain number of letters, the disks are rotated and the encryption continues. Because the cipher is changed often, frequency analysis becomes less effective.

The concept of rotating disks and changing ciphers within a message was a major milestone in cryptography.

The public interest in cryptography dramatically increased with the invention of the telegraph. People wanted the speed and convenience of the telegraph without disclosing the message to the operator, and cryptography provided the answer.

English Alphabet	A B C D E F G H I J K L M N O P Q R S T U V W X Y Z
Caesar Cipher (3)	D E F G H I J K L M N O P Q R S T U V W X Y Z A B C
ROT-13	N O P Q R S T U V W X Y Z A B C D E F G H I J K L M

EXHIBIT 112.3 Caesar cipher (Shift-3) and ROT-13.

After World War I, U.S. military organizations poured resources into cryptography. Because of the classified nature of this research, there were no general publications that covered cryptography until the late 1960s; and the public interest went down again.

During this time, computers were also gaining ground in nongovernment areas, especially the financial sector; and the need for a nonmilitary crypto-system was becoming apparent. The organization currently known as the National Institute of Standards and Technology (NIST), then called the National Bureau of Standards (NBS), requested proposals for a standard cryptographic algorithm. IBM responded with Lucifer, a system developed by Horst Feistel and colleagues. After adopting two modifications from the National Security Agency (NSA), this was adopted as the federal Data Encryption Standard (DES) in 1976.[1] NSA's changes caused major controversy, specifically because it suggested DES use 56-bit keys instead of 112-bit keys as originally submitted by IBM.

During the 1970s and 1980s, the NSA also attempted to regulate cryptographic publications but was unsuccessful. However, general interest in cryptography increased as a result. Academic and business interest in cryptography was high, and extensive research led to significant new algorithms and techniques.

Advances in computing power have made 56-bit keys breakable. In 1998, a custom-built machine from the Electronic Frontier Foundation costing $210,000 cracked DES in four and a half days.[2] In January 1999, a distributed network of 100,000 machines cracked DES in 22 hours and 15 minutes.

As a direct result of these DES cracking examples, NIST issued a Request for Proposals to replace DES with a new standard called the Advanced Encryption Standard (AES).[3] On November 26, 2001, NIST selected Rijndael as the AES.

The Alphabet-Soup Players: Alice, Bob, Eve, and Mike

In our discussions of cryptographic protocols, we will use an alphabet soup of names that are participating in (or are trying to break into) a secure message exchange:

- *Alice*, first participant
- *Bob*, second participant
- *Eve*, eavesdropper
- *Mike*, masquerader

Ties to Confidentiality, Integrity, and Authentication

Cryptography is not limited to confidentiality only — it can perform other useful functions.

- *Authentication.* If Alice is buying something from Bob's online store, Bob has to assure Alice that it is indeed Bob's Web site and not Mike's, the masquerader pretending to be Bob. Thus, Alice should be able to authenticate Bob's Web site, or know that a message originated from Bob.
- *Integrity.* If Bob is sending Alice, the personnel manager, a message informing her of a $5000 severance pay for Mike, Mike should not be able to intercept the message in transit and change the amount to $50,000. Cryptography enables the receiver to verify that a message has not been modified in transit.
- *Non-repudiation.* Alice places an order to sell some stocks at $10 per share. Her stockbroker, Bob, executes the order, but then the stock goes up to $18. Now Alice claims she never placed that order. Cryptography (through digital signatures) will enable Bob to prove that Alice did send that message.

Section Summary

- Any message or data in its original form is called plaintext or cleartext.
- The process of hiding or securing the plaintext is called encryption (verb: to encrypt or to encipher).
- When encryption is applied on plaintext, the result is called ciphertext.
- Retrieving the plaintext from the ciphertext is called decryption (verb: to decrypt or to decipher).
- The art and science of encryption and decryption is called cryptography, and its practitioners are cryptographers.
- The art and science of breaking encryption is called cryptanalysis, and its practitioners are cryptanalysts.

- The process and rules (mathematical or otherwise) to encrypt and decrypt are called ciphers or cryptographic algorithms.
- The history of cryptography is over 4000 years old.
- Frequency analysis is an important technique in cryptanalysis.
- Secret cryptographic algorithms should not be trusted by an information security professional.
- Only publicly available and discussed algorithms that have withstood analysis and attacks may be used in a business setting.
- Bottom line: do not use a cryptographic algorithm developed in-house (unless you have internationally renowned experts in that field).

Symmetric Cryptographic Algorithms

Algorithms or ciphers that use the same key to encrypt and decrypt are called symmetric cryptographic algorithms. There are two basic types: stream and block.

Stream Ciphers

This type of cipher takes messages in a stream and operates on individual data elements (characters, bits, or bytes).

Typically, a random-number generator is used to produce a sequence of characters called a key stream. The key stream is then combined with the plaintext via exclusive-OR (XOR) to produce the ciphertext. Exhibit 112.4 illustrates this operation of encrypting the letter Z, the ASCII value of which is represented in binary as 01011010. Note that in an XOR operation involving binary digits, only XORing 0 and 1 yields 1; all other XORs result in 0. Exhibit 112.4 shows how a stream cipher operates.

Before describing the actual workings of a stream cipher, we will examine how shift registers work because they have been the mainstay of electronic cryptography for a long time.

A linear feedback shift register (LFSR) is very simple in principle. For readers not versed in electronics, we present a layman's representation. Imagine a tube that can hold four bits with a window at the right end. Because the tube holds four bits, we will call it a four-bit shift register. We shift all bits in the tube and, as a result, the bit showing through the window changes. Here, shifting involves pushing from the left so the right-most bit falls off; and to keep the number of bits in the tube constant, we place the output of some addition operation as the new left-most bit. In the following example, we will continue with our four-bit LFSR, and the new left-most bit will be the result of adding bits three and four (the feedback) and keeping the right-most bit (note that in binary mathematics, 1+ 1 = 10, with 0 being the right-most bit, and 1+ 0 = 1). For every shift that occurs, we look through the window and note the right-most bit. As a result, we will see the sequence shown in Exhibit 112.5.

Note that after $2^{(N=4)} - 1 = 15$ iterations, we will get a repetition. This is the maximum number of unique sequences (also called period) when dealing with a four-bit LFSR (because we have to exclude 0000, which will always produce a sequence of 0000s). Choosing a different feedback function may have reduced the period, and the longest unique sequence is called the maximal length. The maximal length is important because

1111.-> 0111 -> 0011 -> 0001 -> 1000 -> 0100 -> 0010 -> 1001 -> 1100 -> 0110 -> 1011 -> 0101 -> 1010 -> 1101 -> 1110 -> 1111
Keystream: 111100010011010 (Right-most bit through the window before repetition).

EXHIBIT 112.5 4-bit LFSR output.

repeating key streams mean the same plaintext will produce the same ciphertext, and this will be vulnerable to frequency analysis and other attacks.

To construct a simple stream cipher, take an LFSR (or take many different sizes and different feedback functions). To encrypt each bit of the plaintext, take a bit from the plaintext, XOR it with a bit from the key stream to generate the ciphertext (refer to Exhibit 112.4), and so on.

Of course, other stream ciphers are more complex and involve multiple LFSRs and other techniques.[4] We will discuss RC4 as an example of a stream cipher. First, we will define the term S-box.

An S-box is also known as a substitution box or table and, as the name implies, it is a table or system that provides a substitution scheme. Shift registers are S-boxes; they provide a substitution mechanism.

RC4 uses an output feedback mechanism combined with 256 S-boxes (numbered $S_0 \ldots S_{255}$) and two counters, i and j.

A random byte K is generated through the following steps:

```
i = (i +1) mod 256
j = (j + Si) mod 256
swap (Si, Sj)
t = (Si + Sj) mod 256
K = St
```

Now, K XOR Plaintext = Ciphertext, and K XOR Ciphertext = Plaintext

Block Ciphers

A block cipher requires the accumulation of some amount of data or multiple data elements before ciphering can begin. Encryption and decryption happen on chunks of data, unlike stream ciphers, which operate on each character or bit independently.

DES

The Data Encryption Standard (DES) is over 25 years old; because of its widespread implementation and use, it will probably coexist with the new Advanced Encryption Standard (AES) for a few years.

Despite initial concern about NSA's role in crafting the standard, DES generated huge interest in cryptography; vendors and users alike were eager to adopt the first government-approved encryption standard that was released for public use.

The DES calls for reevaluations of DES every five years. Starting in 1987, the NSA warned that it would not recertify DES because it was likely that it soon would be broken; they proposed secret algorithms available on tamper-proof chips only. Users of DES, including major financial institutions, protested; DES got a new lease on life until 1992. Because no new standards became available in 1992, it lived on to 1998 and then until the end of 2001, when AES became the standard.

DES is a symmetric block cipher that operates in blocks of 64 bits of data at a time, with 64-bit plaintext resulting in 64-bit ciphertext. If the data is not a multiple of 64 bits, then it is padded at the end. The effective key-length is 56 bits with 8 bits of parity. All security rests with the key.

A simple description of DES is as follows:[1]

Take the 64-bit block of message (M).
Rearrange the bits of M (initial permutation, IP).
Break IP down the middle into two 32-bit blocks (L & R).
Shift the key bits, and take a 48-bit portion from the key.
Save the value of R into R_{old}.
Expand R via a permutation to 48 bits.

XOR R with the 48-bit key and transform via eight S-boxes into a new 32-bit chunk.
Now, R takes on the value of the new R XOR-ed with L.
And L takes on the value of R_{old}.
Repeat this process 15 more times (total 16 rounds).
Join L and R.
Reverse the permutation IP (final permutation, FP).

There are some implementations without IP and FP; because they do not match the published standard, they should not be called DES or DES-compliant, although they offer the same degree of security.

Certain DES keys are considered weak, semiweak, or possibly weak: a key is considered weak if it consists of all 1s or all 0s, or if half the keys are 1s and the other half are 0s.[5]

Conspiracy theories involving NSA backdoors and EFFs DES-cracking machine notwithstanding, DES lives on in its original form or a multiple-iteration form popularly known as Triple-DES.

Triple-DES is DES done thrice, typically with two 56-bit keys. In the most popular form, the first key is used to DES-encrypt the message. The second key is used to DES-decrypt the encrypted message. Because this is not the right key, the attempted decryption only scrambles the data even more. The resultant ciphertext is then encrypted again with the first key to yield the final ciphertext. This three-step procedure is called Triple-DES. Sometimes, three keys are used.

Because this follows an Encryption > Decryption > Encryption scheme, it is often known as DES-EDE.

ANSI standard X9.52 describes Triple-DES encryption with keys k_1, k_2, k_3 as:

$$C = E_{k3}(D_{k2}(E_{k1}(M)))$$

where E_k and D_k denote DES encryption and DES decryption, respectively, with the key k. Another variant is DES-EEE, which consists of three consecutive encryptions. There are three keying options defined in ANSI X9.52 for DES-EDE:

The three keys k_1, k_2, and k_3 are different (three keys).
k_1 and k_2 are different, but $k_1 = k_3$ (two keys).
$k_1 = k_2 = k_3$ (one key).

The third option makes Triple-DES backward-compatible with DES and offers no additional security.

AES (Rijndael)

In 1997, NIST issued a Request for Proposals to select a symmetric-key encryption algorithm to be used to protect sensitive (unclassified) federal information. This was to become the Advanced Encryption Standard (AES), the DES replacement. In 1998, NIST announced the acceptance of 15 candidate algorithms and requested the assistance of the cryptographic research community in analyzing the candidates. This analysis included an initial examination of the security and efficiency characteristics for each algorithm.

NIST reviewed the results of this preliminary research and selected MARS, RC6™, Rijndael, Serpent, and Twofish as finalists. After additional review, in October 2000, NIST proposed Rijndael as AES. For research results and rationale for selection, see Reference 5.

Before discussing AES, we will quote the most important answer from the Rijndael FAQ:

> If you're Dutch, Flemish, Indonesian, Surinamer or South African, it's pronounced like you think it should be. Otherwise, you could pronounce it like reign dahl, rain doll, or rhine dahl. We're not picky. As long as you make it sound different from region deal.[6]

Rijndael is a block cipher that can process blocks of 128-, 192-, and 256-bit length using keys 128-, 192-, and 256-bits long. All nine combinations of block and key lengths are possible.[7] The AES standard specifies only 128-bit data blocks and 128-, 192-, and 256-bit key lengths. Our discussions will be confined to AES and not the full scope of Rijndael. Based on the key length, AES may be referred to as AES-128, AES-192, or AES-256. We will present a simple description of Rijndael. For a mathematical treatment, see References 8 and 9.

Rijndael involves an initial XOR of the state and a round key, nine rounds of transformations (or rounds), and a round performed at the end with one step omitted. The input to each round is called the state. Each round consists of four transformations: SubBytes, ShiftRow, MixColumn (omitted from the tenth round), and AddRoundKey.

In the SubBytes transformation, each of the state bytes is independently transformed using a nonlinear S-box.

In the ShiftRow transformation, the state is processed by cyclically shifting the last three rows of the state by different offsets.

In the MixColumn transformation, data from all of the columns of the state are mixed (independently of one another) to produce new columns.

In the AddRoundKey step in the cipher and inverse cipher transformations, a round key is added to the state using an XOR operation. The length of a round key equals the size of the state.

Weaknesses and Attacks

A well-known and frequently used encryption is the stream cipher available with PKZIP. Unfortunately, there is also a well-known attack involving known plaintext against this — if you know part of the plaintext, it is possible to decipher the file.[10] For any serious work, information security professionals should not use PKZIP's encryption.

In 1975, it was theorized that a customized DES cracker would cost $20 million. In 1998, EFF built one for $220,000.[2] With the advances in computing power, the time and money required to crack DES has significantly gone down even more. Although it is still being used, if possible, use AES or Triple-DES.

Section Summary

- Symmetric cryptographic algorithms or ciphers are those that use the same key to encrypt and decrypt.
- Stream ciphers operate one bit at a time.
- Stream ciphers use a key stream generator to continuously produce a key stream that is used to encrypt the message.
- A repeating key stream weakens the encryption and makes it vulnerable to cryptanalysis.
- Shift registers are often used in stream ciphers.
- Block ciphers operate on a block of data at a time.
- DES is the most popular block cipher.
- DES keys are sometimes referred to as 64-bit, but the effective length is 56 bits with 8 parity bits; hence, the actual key length is 56 bits.
- There are known weak DES keys; ensure that those are not used.
- DES itself has been broken and it should be assumed that it is not secure against attack.
- Make plans to migrate away from DES; use Triple-DES or Rijndael instead of DES, if possible.
- Do not use the encryption offered by PKZIP for nontrivial work.

Asymmetric (Public Key) Cryptography

Asymmetric is the term applied in a cryptographic system where one key is used to encrypt and another is used to decrypt.

Background

This concept was invented in 1976 by Whitfield Diffie and Martin Hellman[11] and independently by Ralph Merkle. The basic theory is quite simple: is there a pair of keys so that if one is used to encrypt, the other can be used to decrypt — and given one key, finding the other would be extremely hard?

Luckily for us, the answer is yes, and this is the basis of asymmetric (often called public key) cryptography.

There are many algorithms available, but most of them are either insecure or produce ciphertext that is larger than the plaintext. Of the algorithms that are both secure and efficient, only three can be used for both encryption and digital signatures.[4] Unfortunately, these algorithms are often slower by a factor of 1000 compared to symmetric key encryption.

As a result, hybrid cryptographic systems are popular: Suppose Alice and Bob want to exchange a large message. Alice generates a random session key, encrypts it using asymmetric encryption, and sends it over to Bob, who has the other half of the asymmetric key to decode the session key. Because the session key is small, the overhead to asymmetrically encipher/decipher it is not too large. Now Alice encrypts the message with the

session key and sends it over to Bob. Bob already has the session key and deciphers the message with it. As the large message is enciphered/deciphered using much faster symmetric encryption, the performance is acceptable.

RSA

We will present a discussion of the most popular of the asymmetric algorithms — RSA, named after its inventors, Ron Rivest, Adi Shamir, and Leonard Adleman. Readers are directed to Reference 12 for an extensive treatment. RSA's patent expired in September 2000; and RSA has put the algorithm in the public domain, enabling anyone to implement it at zero cost.

First, a mathematics refresher:

- If an integer P cannot be divided (without remainders) by any number other than itself and 1, then P is called a prime number. Other prime numbers are 2, 3, 5, and 7.
- Two integers are relatively prime if there is no integer greater than one that divides them both (their greatest common divisor is 1). For example, 15 and 16 are relatively prime, but 12 and 14 are not.
- The mod is defined as the remainder. For example, 5 mod 3 = 2 means divide 5 by 3 and the result is the remainder, 2.

Note that RSA depends on the difficulty of factoring large prime numbers. If there is a sudden leap in computer technology or mathematics that changes that, security of such encryption schemes will be broken. Quantum and DNA computing are two fields to watch in this arena.

Here is a step-by-step description of RSA:

1. Find P and Q, two large (e.g., 1024-bit or larger) prime numbers. For our example, we will use P = 11 and Q = 19, which are adequate for this example (and more manageable).
2. Calculate the product PQ, and also the product (P – 1)(Q – 1). So PQ = 209, and (P – 1)(Q – 1) = 180.
3. Choose an odd integer E such that E is less than PQ, and such that E and (P – 1)(Q – 1) are relatively prime. We will pick E = 7.
4. Find the integer D so that (DE – 1) is evenly divisible by (P – 1)(Q – 1). D is called the multiplicative inverse of E. This is easy to do: let us assume that the result of evenly dividing (DE – 1) by (P – 1)(Q – 1) is X, where X is also an integer. So we have X = (DE – 1)/(P – 1)(Q – 1); and solving for D, we get D = (X(P – 1)(Q – 1) + 1)/E. Start with X = 1 and keep increasing its value until D is an integer. For our example, D works out to be 103.
5. The public key is (E and PQ), the private key is D. Destroy P and Q (note that given P and Q, it would be easy to work out E and D; but given only PQ and E, it would be hard to determine D). Give out your public key (E, PQ) and keep D secure and private.
6. To encrypt a message M, we raise M to the *E*th power, divide it by PQ, and the remainder (the mod) is the ciphertext. Note that M must be less than PQ. A mathematical representation will be ciphertext = M^E mod PQ. So if we are encrypting 13 (M = 13), our ciphertext = 13^7 mod 209 = 29.
7. To decrypt, we take the ciphertext, raise it to the *D*th power, and take the mod with PQ. So plaintext = 29^{103} mod 209 = 13.

Compared to DES, RSA is about 100 times slower in software and 1000 times slower in hardware. Because AES is even faster than DES in software, the performance gap will widen in software-only applications.

Elliptic Curve Cryptosystems (ECC)

As we saw, solving RSA depends on a hard math problem: factoring very large numbers. There is another hard math problem: reversing exponentiation (logarithms). For example, it is possible to easily raise 7 to the 4th power and get 2401; but given only 2401, reversing the process and obtaining 7^4 is more difficult (at least as hard as performing large factorizations).

The difficulty in performing discrete logarithms over elliptic curves (not to be confused with an ellipse) is even greater;[13] and for the same key size, it presents a more difficult challenge than RSA (or presents the same difficulty/security with a smaller key size). There is an implementation of ECC that uses the factorization problem, but it offers no practical advantage over RSA.

An elliptic curve has an interesting property: it is possible to define a point on the curve as the sum of two other points on the curve. Following is a high-level discussion of ECC. For details, see Reference 13.

Example: Alice and Bob agree on a nonsecret elliptic curve and a nonsecret fixed curve point F. Alice picks a secret random integer A_k as her secret key and publishes the point $A_P = A_k * F$ as her public key. Bob picks a secret random integer B_k as his secret key and publishes the point $B_P = B_k * F$ as his public key. If Alice wants to send a message to Bob, she can compute $A_k * B_P$ and use the result as the secret key for a symmetric block cipher like AES. To decrypt, Bob can compute the same key by finding $B_k * A_P$, because $B_k * A_P = B_k * (A_k * F) = A_k * (B_k * F) = A_k * B_P$.

ECC has not been subject to the extensive analysis that RSA has and is comparatively new.

Attacks

It is possible to attack RSA by factoring large numbers, or guessing all possible values of $(P - 1)(Q - 1)$ or D. These are computationally infeasible, and users should not worry about them. But there are chosen ciphertext attacks against RSA that involve duping a person to sign a message (provided by the attacker). This can be prevented by signing a hash of the message, or by making minor cosmetic changes to the document by signing it. For a description of attacks against RSA, see Reference 14. Hash functions are described later in this chapter.

Real-World Applications

Cryptography is often a business enabler. Financial institutions encrypt the connection between the user's browser and Web pages that show confidential information such as account balances. Online merchants similarly encrypt the link so customer credit card data cannot be sniffed in transit. Some even use this as a selling point: "Our Web site is protected with the highest encryption available." What they are really saying is that this Web site uses 128-bit Secure Sockets Layer (SSL).

As an aside, there are no known instances of theft of credit card data in transit; but many high-profile stories of customer information theft, including theft of credit card information, are available. The theft was possible because enough safeguards were not in place, and the data was usable because it was in cleartext, that is, not encrypted. Data worth protecting should be protected in all stages, not just in transit.

SSL and TLS

Normal Web traffic is cleartext — your ISP can intercept it easily. SSL provides encryption between the browser and a Web server to provide security and identification. SSL was invented by Netscape[15] and submitted to the Internet Engineering Task Force (IETF). In 1996, IETF began with SSL v3.0 and, in 1999, published TLS v1.0 as a proposed standard.[16] TLS is a term not commonly used, but we will use TLS and SSL interchangeably.

Suppose Alice, running a popular browser, wants to buy a book from Bob's online book store at bobs-books.com, and is worried about entering her credit card information online. (For the record, SSL/TLS can encrypt connections between any two network applications and not Web browsers and servers only.) Bob is aware of this reluctance and wants to allay Alice's fears — he wants to encrypt the connection between Alice's browser and bobsbooks.com. The first thing he has to do is install a digital certificate on his Web server.

A certificate contains information about the owner of the certificate: e-mail address, owner's name, certificate usage, duration of validity, and resource location or distinguished name (DN), which includes the common name (CN, Web site address or e-mail address, depending on the usage), and the certificate ID of the person who certifies (signs) this information. It also contains the public key, and finally a hash to ensure that the certificate has not been tampered with.

Anyone can create a digital certificate with freely available software, but just like a person cannot issue his own passport and expect it to be accepted at a border, browsers will not recognize self-issued certificates. Digital certificate vendors have spent millions to preinstall their certificates into browsers, so Bob has to buy a certificate from a well-known certificate vendor, also known as root certificate authority (CA). There are certificates available with 40- and 128-bit encryptions. Because it usually costs the same amount, Bob should buy a 128-bit certificate and install it on his Web server. As of this writing, there are only two vendors with wide acceptance of certificates: VeriSign and Thawte. Interestingly, VeriSign owns Thawte, but Thawte certificate prices are significantly lower.

So now Alice comes back to the site and is directed toward a URL that begins with https instead of http. That is the browser telling the server that an SSL session should be initiated. In this negotiation phase, the browser also tells the server what encryption schemes it can support. The server will pick the strongest of the supported ciphers and reply back with its own public key and certificate information. The browser will check

if it has been issued by a root CA. If not, it will display a warning to Alice and ask if she still wants to proceed. If the server name does not match the name contained in the certificate, it will also issue a warning.

If the certificate is legitimate, the browser will:

- Generate a random symmetric encryption key
- Encrypt this symmetric key with the server's public key
- Encrypt the URL it wants with the symmetric key
- Send the encrypted key and encrypted URL to the server

The server will:

- Decrypt the symmetric key with its private key
- Decrypt the URL with the symmetric key
- Process the URL
- Encrypt the reply with the symmetric key
- Send the encrypted reply back to the browser

In this case, although encryption is two-way, authentication is one-way only: the server's identity is proven to the client but not vice versa. Mutual authentication is also possible and performed in some cases. In a high-security scenario, a bank could issue certificates to individuals, and no browser would be allowed to connect without those individual certificates identifying the users to the bank's server.

What happens when a browser capable of only 40-bit encryption (older U.S. laws prohibited export of 128-bit browsers) hits a site capable of 128 bits? Typically, the site will step down to 40-bit encryption. But CAs also sell super or step-up certificates that, when encountered with a 40-bit browser, will temporarily enable 128-bit encryption in those browsers. Step-up certificates cost more than regular certificates.

Note that the root certificates embedded in browsers sometimes expire; the last big one was VeriSign's in 1999. At that time, primarily financial institutions urged their users to upgrade their browsers. Finally, there is another protocol called Secure HTTP that provides similar functionality but is very rarely used.

Choosing an Algorithm

What encryption algorithm, with what key size, would an information security professional choose? The correct answer is: it depends; what is being encrypted, who do we need to protect against, and for how long?

If it is stock market data, any encryption scheme that will hold up for 20 minutes is enough; in 20 minutes, the same information will be on a number of free quote services. Your password to the *New York Times* Web site? Assuming you do not use the same password for your e-mail account, SSL is overkill for that server. Credit card transactions, bank accounts, and medical records need the highest possible encryption, both in transit and in storage.

Export and International Use Issues

Until recently, exporting 128-bit Web browsers from the United States was a crime, according to U.S. law. Exporting software or hardware capable of strong encryption is still a crime. Some countries have outlawed the use of encryption, and some other countries require a key escrow if you want to use encryption. Some countries have outlawed use of all but certain approved secret encryption algorithms. We strongly recommend that information security professionals become familiar with the cryptography laws of the land, especially if working in an international setting.[17]

Section Summary

- In asymmetric cryptography, one key is used to encrypt and another is used to decrypt.
- Asymmetric cryptography is often also known as public key cryptography.
- Asymmetric cryptography is up to 1000 times slower than symmetric cryptography.
- RSA is the most popular and well-understood asymmetric cryptographic algorithm.
- RSA's security depends on the difficulty of factoring very large (>1024-bit) numbers.
- Elliptic curve cryptography depends on the difficulty of finding discrete logarithms over elliptic curves.

- Smaller elliptic curve keys offer similar security as comparatively larger RSA keys.
- It is possible to attack RSA through chosen plaintext attacks.
- SSL is commonly used to encrypt information between a browser and a Web server.
- Choosing a cipher and key length depends on what needs to be encrypted, for how long, and against whom.
- There are significant legal implications of using encryption in a multinational setting.

Key Management and Exchange

In symmetric encryption, what happens when one person who knows the keys goes to another company (or to a competitor)? Even with public key algorithms, keeping the private key secret is paramount: without it, all is lost. For attackers, the reverse is true; it is often easier to attack the key storage instead of trying to crack the algorithm. A person who knows the keys can be bribed or kidnapped and tortured to give up the keys, at which time the encryption becomes worthless. Key management describes the problems and solutions to securely generating, exchanging, installing and storing, verifying, and destroying keys.

Generation

Encryption software typically generates its own keys (it is possible to generate keys in one program and use them in another); but because of the implementation, this can introduce weaknesses. For example, DES software that picks a known weak or semiweak key will create a major security issue. It is important to use the largest possible keyspace: a 56-bit DES key can be picked from the 256 ASCII character set, the first 128 of ASCII, or the 26 letters of the alphabet. Guessing the 56-bit DES key (an exhaustive search) involves trying out all 56-bit combinations from the keyspace. Common sense tells us that the exhaustive search of 256 bytes will take much longer than that for 26 bytes. With a large keyspace, the keys must be random enough so as to be not guessable.

Exchange

Alice and Bob are sitting on two separate islands. Alice has a bottle of fine wine, a lock, its key, and an empty chest. Bob has another lock and its key. An islander is willing to transfer items between the islands but will keep anything that he thinks is not secured, so you cannot send a key, an unlocked lock, or a bottle of wine on its own.

How does Alice send the wine to Bob? See the answer at the end of this section.

This is actually a key exchange problem in disguise: how does Alice get a key to Bob without its being compromised by the messenger? For asymmetric encryption, it is easy — the public key can be given out to the whole world. For symmetric encryption, a public key algorithm (like SSL) can be used; or the key may be broken up and each part sent over different channels and combined at the destination.

Answer to our key/wine exchange problem: Alice puts the bottle into the chest and locks it with her lock, keeps her key, and sends the chest to the other island. Bob locks the chest with his lock, and sends it back to Alice. Alice takes her lock off the chest and sends it back to Bob. Bob unlocks the chest with his key and enjoys the wine.

Installation and Storage

How a key is installed and stored is important. If the application does no initial validation before installing a key, an attacker might be able to insert a bad key into the application. After the key is installed, can it be retrieved without any access control? If so, anyone with access to the computer would be able to steal that key.

Change Control

How often a key is changed determines its efficiency. If a key is used for a long time, an attacker might have sufficient samples of ciphertext to be able to cryptanalyze the information. At the same time, each change brings up the exchange problem.

Destruction

A key no longer in use has to be disposed of securely and permanently. In the wrong hands, recorded ciphertext may be decrypted and give an enemy insights into current ciphertext.

Examples and Implementations

PKI

A public key infrastructure (PKI) is the set of systems and software required to use, manage, and control public key cryptography. It has three primary purposes: publish public keys, certify that a public key is tied to an individual or entity, and provide verification as to the continued validity of a public key. As discussed before, a digital certificate is a public key with identifying information for its owner. The certificate authority (CA) "signs" the certificate and verifies that the information provided is correct. Now all entities that trust the CA can trust that the identity provided by a certificate is correct. The CA can revoke the certificate and put it in the certificate revocation list (CRL), at which time it will not be trusted anymore. An extensive set of PKI standards and documentation is available.[18] Large companies run their own CA for intranet/extranet use. In Canada and Hong Kong, large public CAs are operational. But despite the promises of the "year of the PKI," market acceptance and implementation of PKIs are still in the future.

Kerberos

From the comp.protocol.kerberos FAQ:

> Kerberos; also spelled Cerberus. *n.* The watchdog of Hades, whose duty it was to guard the entrance — against whom or what does not clearly appear; it is known to have had three heads.
>
> **— Ambrose Bierce**
>
> *The Enlarged Devil's Dictionary*

Kerberos was developed at MIT in the 1980s and publicly released in 1989. The primary purposes were to prevent cleartext passwords from traversing the network and to ease the log-in process to multiple machines.[19] The current version is 5 — there are known security issues with version 4. The three heads of Kerberos comprise the key distribution center (KDC), the client, and the server that the client wants to access. Kerberos 5 is built into Windows 2000 and later, and will probably result in wider adoption of Kerberos (notwithstanding some compatibility issues of the Microsoft implementation of the protocol[20]).

The KDC runs two services: authentication service (AS) and ticket granting service (TGS). A typical Kerberos session (shown in Exhibit 112.6) proceeds as follows when Alice wants to log on to her e-mail and retrieve it.

1. She will request a ticket granting ticket (TGT) from the KDC, where she already has an account. The KDC has a hash of her password, and she will not have to provide it. (The KDC must be extremely secure to protect all these passwords.)
2. The TGS on the KDC will send Alice a TGT encrypted with her password hash. Without knowing the password, she cannot decrypt the TGT.
3. Alice decrypts the TGT; then, using the TGT, she sends another request to the KDC for a service ticket to access her e-mail server. The service ticket will not be issued without the TGT and will only work for the e-mail server.
4. The KDC grants Alice the service ticket.
5. Alice can access the e-mail server.

Note that both the TGT and the ST have expiration times (default is ten hours); so even if one or both tickets are captured, the exposure is only until the ticket expiration time. All computer system clocks participating in a Kerberos system must be within five minutes of each other and all services that grant access. Finally, the e-mail server must be kerberized (support Kerberos).

Section Summary

- Key management (generating/exchanging/storing/installing/destroying keys) can compromise security.
- Public key cryptography is often the best solution to key distribution issues.

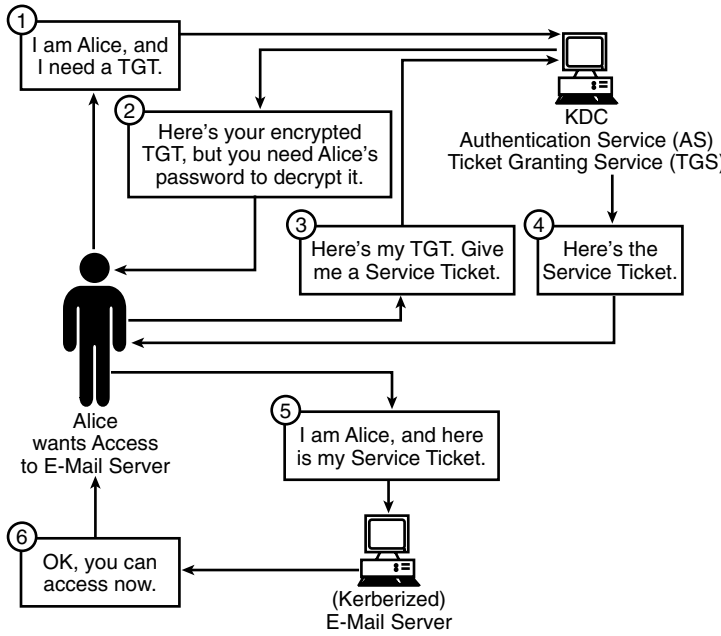

EXHIBIT 112.6 Kerberos in operation.

- A public key infrastructure (PKI) is a system that can manage public keys.
- A certificate authority (CA) is a PKI that can validate public keys.
- Digital certificates are essentially public keys that also include key owner information. The key and information are verified by a CA.
- If an entity trusts a CA, it can also trust digital certificates that the CA signs (authenticates).
- Kerberos is a protocol for eliminating cleartext passwords across networks.
- A ticket granting ticket (TGT) is issued to the user, who will use that to request a service ticket. All tickets expire after a certain time.
- Under Kerberos, tickets are encrypted and cleartext passwords never cross the network.

Hash Functions

A hash function is defined as a process that can take an arbitrary-length message and return a fixed-length value from that message. For practical use, we require further qualities:

- Given a message, it should be easy to find the hash.
- Given the hash, it should be hard to find the message.
- Given the message, it should be hard to find another (specific or random) message that produces the same hash.

Message Digests

A message digest is the product of a one-way hash function applied on a message: it is a fingerprint or a unique summary that can uniquely identify the message.

MD2, MD4, and MD5

Ron Rivest (the R in RSA) designed all of these. All three produce 128-bit hashes. MD4 has been successfully attacked. MD5 has been found weak in certain cases; it is possible to find another random message that will produce the same hash. MD2 is slower, although no known weaknesses exist.

SHA

The secure hash algorithm (SHA) was designed by NIST and NSA, and is used in the digital signature standard, officially known as the Secure Hash Standard (SHS) and is available as FIPS-180-1.[21]

The current SHA produces a 160-bit hash and is also known as SHA-1. There are additional standards undergoing public comments and reviews that will offer 256-, 384-, and 512-bit hashes. The draft standard is available.[16] The proposed standards will offer security matching the level of AES. The draft is available as FIPS-180-2.[22]

Applications of Message Digests

Message digests are useful and should be used to provide message integrity. Suppose Alice wants to pay $2000 to Eve, a contract network administrator. She types an e-mail to Bob, her accountant, to that effect. Before sending the message, Alice computes the message digest (SHA-1 or MD5) of the message and then sends the message followed by the message digest. Eve intercepts the e-mail and changes $2000 to $20,000; but when Bob computes the message digest of the e-mail, it does not match the one from Alice, and he knows that the e-mail has been tampered with.

But how do we ensure that the e-mail to Bob indeed came from Alice, when faking an e-mail source address is notoriously easy? This is where digital signatures come in.

Digital Signatures

Digital signatures were designed to provide the same features of a conventional ("wet") signature. The signature must be non-repudiatable, and it must be nontransferable (cannot be lifted and reused on another document). It must also be irrevocably tied back to the person who owns it.

It is possible to use symmetric encryption to digitally sign documents using an intermediary who shares keys with both parties, but both parties do not have a common key. This is cumbersome and not practical.

Using public key cryptography solves this problem neatly. Alice will encrypt a document with her private key, and Bob will decrypt it with Alice's public key. Because it could have been encrypted with only Alice's private key, Bob can be sure it came from Alice. But there are two issues to watch out for: (1) the rest of the world may also have Alice's public key, so there will be no privacy in the message; and (2) Bob will need a trusted third party (a certificate authority) to vouch for Alice's public key.

In practice, signing a long document may be computationally costly. Typically, first a one-way hash of the document is generated, the hash is signed, and then both the signed hash and the original document are sent. The recipient also creates a hash and compares the decrypted signed hash to the generated one. If both match, then the signature is valid.

Digital Signature Algorithm (DSA)

NIST proposed DSA in 1991 to be used in the Digital Signature Standard and the standard issued in May 1994. In January 2000, it announced the latest version as FIPS PUB 186-2.[23] As the name implies, this is purely a signature standard and cannot be used for encryption or key distribution.

The operation is pretty simple. Alice creates a message digest using SHA-1, uses her private key to sign it, and sends the message and the digest to Bob. Bob also uses SHA-1 to generate the message digest from the message and uses Alice's public key on the received message digest to decrypt it. Then the two message digests are compared. If they match, the signature is valid.

Finally, digital signatures should not be confused with the horribly weakened "electronic signature" law passed in the United States, where a touch-tone phone press could be considered an electronic signature and enjoy legal standing equivalent to an ink signature.

Message Authentication Codes (MACs)

MACs are one-way hash functions that include the key. People with the identical key will be able to verify the hash. MACs provide authentication of files between users and may also provide file integrity to a single user to ensure files have not been altered in a Web site defacement. On a Web server, the MAC of all files could be computed and stored in a table. With only a one-way hash, new values could have been inserted in the table

and the user will not notice. But in a MAC, because the attacker will not know the key, the table values will not match; and an automated process could alert the owner (or automatically replace files from backup).

A one-way hash function can be turned into a MAC by encrypting the hash using a symmetric algorithm and keeping the key secret. A MAC can be turned into a one-way hash function by disclosing the key.

Section Summary

- Hash functions can create a fixed-length digest of arbitrary-length messages.
- One-way hashes are useful: given a hash, finding the message should be very hard.
- Two messages should not generate the same hash.
- MD2, MD4, and MD5 all produce 128-bit hashes.
- SHA-1 produces a 160-bit hash.
- Encrypting a message digest with a private key produces a digital signature.
- Message authentication codes are one-way hashes with the key included.

Other Cryptographic Notes

Steganography

Steganography is a Greek word that means sheltered writing. This is a method that attempts to hide the existence of a message or communication. In February 2001, *USA Today* and various other news organizations reported that terrorists are using steganography to hide their communication in images on the Internet.[24] A University of Michigan study[25] examined this by analyzing two million images downloaded from the Internet and failed to find a single instance.

In its basic form, steganography is simple. For example, every third letter of a memo could hide a message. And it has the added advantage over encryption that it does not arouse suspicion: often, the presence of encryption could set off an investigation; but a message hidden in plain sight would be ignored.

The medium that hides the message is called the cover medium, and it must have parts that can be altered or used without damaging or noticeably changing the cover media. In case of digital cover media, these alterable parts are called redundant bits. These redundant bits or a subset can be replaced with the message we want to hide.

Interestingly, steganography in digital media is very similar to digital watermarking, where a song or an image can be uniquely identified to prevent theft or unauthorized use.

Digital Notary Public

Digital notary service is a logical extension of digital signatures. Without this service, Alice could send a digitally signed offer to Bob to buy a property; but after property values drop the next day, she could claim she lost her private key and call the message a forgery. Digital notaries could be trusted third parties that will also time-stamp Alice's signature and give Bob legal recourse if Alice tries to back out of the deal. There are commercial providers of this type of service.

With time-sensitive offers, this becomes even more important. Time forgery is a difficult if not impossible task with paper documents, and it is easy for an expert to detect. With electronic documents, time forgeries are easy and detection is almost impossible (a system administrator can change the time stamp of an e-mail on the server). One do-it-yourself time-stamping method suggests publishing the one-way hash of the message in a newspaper (as a commercial notice or advertisement). From then on, the date of the message will be time-stamped and available for everyone to verify.

Backdoors and Digital Snake Oil

We will reiterate our warnings about not using in-house cryptographic algorithms or a brand-new encryption technology that has not been publicly reviewed and analyzed. It may promise speed and security or low cost, but remember that only algorithms that withstood documented attacks are worthy of serious use — others should be treated as unproven technology, not ready for prime time.

Also, be careful before using specific software that a government recommends. For example, Russia mandates use of certain approved software for strong encryption. It has been mentioned that the government certifies all such software after behind-the-scenes key escrow. To operate in Russia, a business may not have any choice in this matter, but knowing that the government could compromise the encryption may allow the business to adopt other safeguards.

Hash Algorithms: From Message Digests to Signatures

Keith Pasley, CISSP

There are many information-sharing applications that are in use on modern networks today. Concurrently, there are a growing number of users sharing data of increasing value to both sender and recipient. As the value of data increases among users of information-sharing systems, the risks of unauthorized data modification, user identity theft, fraud, unauthorized access to data, data corruption, and a host of other business-related problems mainly dealing with data integrity and user authentication, are introduced. The issues of integrity and authentication play an important part in the economic systems of human society. Few would do business with companies and organizations that do not prove trustworthy or competent.

For example, the sentence "I owe Alice US$500" has a hash result of "gCWXVcL3fPV8VrJNajm8JKA==," while the sentence "I owe Alice US$5000" has a hash of "DSAyXRTza2bHLH46IPMrSq==." As can be seen, there is a big difference in hash results between the two sentences. If an attacker were trying to misappropriate the $4500 difference, hashing would allow detection.

Why Hash Algorithms Are Needed and the Problems They Solve

- Is the e-mail you received really from who it says it is?
- Can you ensure the credit card details you submit are going to the site you expected?
- Can you be sure the latest anti-virus, firewall, or operating system software upgrade you install is really from the vendor?
- Do you know if the Web link you click on is genuine?
- Does the program hash the password when performing authentication or just passing it in the clear?
- Is there a way to know who you are really dealing with when disclosing your personal details over the Internet?
- Are you really you?
- Has someone modified a Web page or file without authorization?
- Can you verify that your routers are forwarding data only to authorized peer routers?
- Has any of the data been modified in route to its destination?
- Can hash algorithms help answer these questions?

What Are Hash Algorithms?

A hash algorithm is a one-way mathematical function that is used to compress a large block of data into a smaller, fixed-size representation of that data.

To understand the concept of hash functions, it is helpful to review some underlying mathematical structures. One such structure is called a function. When hash functions were first introduced in the 1950s, the goal was to map a message into a smaller message called a message digest. This smaller message was used as a sort of shorthand of the original message. The digest was used originally for detection of random and unintended errors in processing and transmission by data processing equipment

Functions

A function is a mathematical structure that takes one or more variables and outputs a variable. To illustrate how scientists think about functions, one can think of a function in terms of a machine (see Exhibit 113.1). The machine in this illustration has two openings. In this case the input opening is labeled x and the output opening is labeled y. These are considered traditional names for input and output. The following are the basic processing steps of mathematical functions:

1. A number goes in.
2. Something is done to it.
3. The resulting number is the output.

The same thing is done to every number input into the function machine. Step 2 above describes the actual mathematical transformation done to the input value, or hashed value, which yields the resulting output, or hash result. In this illustration, Step 2 can be described as a mathematical rule as follows: x + 3 = y. In the language of mathematics, if x is equal to 1, then y equals 4. Similarly, if x is equal to 2, then y equals 5. In this illustration the function, or mathematical structure, called an algorithm, is: for every number x, add 3 to the number. The result, y, is dependent on what is input, x.

As another example, suppose that, to indicate an internal company product shipment, the number 43738 is exchanged. The hash function, or algorithm, is described as: multiply each number from left to right, and the first digit of any multiplied product above 9 is dropped. The hash function could be illustrated in mathematical notation as: x * the number to the right = y (see Exhibit 113.1).

The input into a hash algorithm can be of variable length, but the output is usually of fixed length and somewhat shorter in length than the original message. The output of a hash function is called a message digest. In the case of the above, the hash input was of arbitrary (and variable) length; but the hash result, or message digest, was of a fixed length of 1 digit, 8. As can be seen, a hash function provides a shorthand representation of the original message. This is also the concept behind error checking (checksums) done on data transmitted across communications links. Checksums provide a nonsecure method to check for message accuracy or message integrity. It is easy to see how the relatively weak mathematical functions described above could be manipulated by an intruder to change the hash output. Such weak algorithms could result in the successful alteration of message content leading to inaccurate messages. If you can understand the concept of what a function is and does, you are on your way to understanding the basic concepts embodied in hash functions. Providing data integrity and authentication for such applications requires reliable, secure hash algorithms.

Secure Hash Algorithms

A hash algorithm was defined earlier as a one-way mathematical function that is used to compress a large block of data into a smaller, fixed size representation of that data. An early application for hashing was in detecting unintentional errors in data processing. However, due to the critical nature of their use in the high-

EXHIBIT 113.1 The Hash Function

4 * 3	12

2 * next number (3)	6
6 * next number (7)	42
Drop the first digit (4) leaves	2
2 * next number (3)	6
6 * next number (8)	48
Drop the first digit (4)	8

security environments of today, hash algorithms must now also be resilient to deliberate and malicious attempts to break secure applications by highly motivated human attackers — more so than by erroneous data processing. The one-way nature of hash algorithms is one of the reasons they are used in public key cryptography. A one-way hash function processes a bit stream in a manner that makes it highly unlikely that the original message can be deduced by the output value. This property of a secure hash algorithm has significance in situations where there is zero tolerance for unauthorized data modification or if the identity of an object needs to be validated with a high assurance of accuracy. Applications such as user authentication and financial transactions are made more trustworthy by the use of hash algorithms.

Hash algorithms are called secure if they have the following properties:

- The hash result should not be predictable. It should be computationally impractical to recover the original message from the message digest (one-way property).
- No two different messages, over which a hash algorithm is applied, will result in the same digest (collision-free property).

Secure hash algorithms are designed so that any change to a message will have a high probability of resulting in a different message digest. As such, the message alteration can be detected by comparing hash results before and after hashing. The receiver can tell that a message has suspect validity by the fact that the message digest computed by the sender does not match the message digest computed by the receiver, assuming both parties are using the same hash algorithm. The most common hash algorithms as of this writing are based on Secure Hash Algorithm-1 (SHA-1) and Message Digest 5 (MD5).

Secure Hash Algorithm

SHA-1, part of the Secure Hash Standard (SHS), was one of the earliest hash algorithms specified for use by the U.S. federal government (see Exhibit 113.2). SHA-1 was developed by NIST and the NSA. SHA-1 was published as a federal government standard in 1995. SHA-1 was an update to the SHA, which was published in 1993.

How SHA-1 Works

Think of SHA-1 as a hash machine that has two openings, input and output. The input value is called the hashed value, and the output is called the hash result. The hashed values are the bit streams that represent an electronic message or other data object. The SHA-1 hash function, or algorithm, transforms the hashed value by performing a mathematical operation on the input data. The length of the message is the same as the number of bits in the message. The SHA-1 algorithm processes blocks of 512 bits in sequence when computing the message digest. SHA-1 produces a 160-bit message digest. SHA-1 has a limitation on input message size of less than 18 quintillion (that is, 2^{64} or 18,446,744,073,709,551,616) bits in length.

SHA-1 has five steps to produce a message digest:

1. Append padding to make message length 64 bits less than a multiple of 512.
2. Append a 64-bit block representing the length of the message before padding out.
3. Initialize message digest buffer with five hexadecimal numbers. These numbers are specified in the FIPS 180-1 publication.
4. The message is processed in 512-bit blocks. This process consists of 80 steps of processing (four rounds of 20 operations), reusing four different hexadecimal constants, and some shifting and adding functions.
5. Output blocks are processed into a 160-bit message digest.

EXHIBIT 113.2 Output Bit Lengths

Hash Algorithm	Output Bit Length
SHA-1	160
SHA-256	256
SHA-384	384
SHA-512	512

MD5

SHA was derived from the secure hash algorithms MD4 and MD5, developed by Professor Ronald L. Rivest of MIT in the early 1990s. As can be expected, SHA and MD5 work in a similar fashion. While SHA-1 yields a 160-bit message digest, MD5 yields a 128-bit message digest. SHA-1, with its longer message digest, is considered more secure than MD5 by modern cryptography experts, due in part to the longer output bit length and resulting increased collision resistance. However, MD5 is still in common use as of this writing.

Keyed Hash (HMAC)

Modern cryptographers have found the hash algorithms discussed above to be insufficient for extensive use in commercial cryptographic systems or in private electronic communications, digital signatures, electronic mail, electronic funds transfer, software distribution, data storage, and other applications that require data integrity assurance, data origin authentication, and the like. The use of asymmetric cryptography and, in some cases, symmetric cryptography, has extended the usefulness of hashing by associating identity with a hash result. The structure used to convey the property of identity (data origin) with a data object's integrity is hashed message authentication code (HMAC), or keyed hash.

For example, how does one know if the message and the message digest have not been tampered with? One way to provide a higher degree of assurance of identity and integrity is by incorporating a cryptographic key into the hash operation. This is the basis of the keyed hash or hashed message authentication code (HMAC). The purpose of a message authentication code (MAC) is to provide verification of the source of a message and integrity of the message without using additional mechanisms. Other goals of HMAC are as follows:

- To use available cryptographic hash functions without modification
- To preserve the original performance of the selected hash without significant degradation
- To use and handle keys in a simple way
- To have a well-understood cryptographic analysis of the strength of the mechanism based on reasonable assumptions about the underlying hash function
- To enable easy replacement of the hash function in case a faster or stronger hash is found or required

To create an HMAC, an asymmetric (public/private) or a symmetric cryptographic key can be appended to a message and then processed through a hash function to derive the HMAC. In mathematical terms, if x = (key + message) and f = SHA-1, then f(x) = HMAC. Any hash function can be used, depending on the protocol defined, to compute the type of message digest called an HMAC. The two most common hash functions are based on MD5 and SHA. The message data and HMAC (message digest of a secret key and message) are sent to the receiver. The receiver processes the message and the HMAC using the shared key and the same hash function as that used by the originator. The receiver compares the results with the HMAC included with the message. If the two results match, then the receiver is assured that the message is authentic and came from a member of the community that shares the key.

Other examples of HMAC usage include challenge–response authentication protocols such as Challenge Handshake Authentication Protocol (CHAP, RFC 1994). CHAP is defined as a peer entity authentication method for Point-to-Point Protocol (PPP), using a randomly generated challenge and requiring a matching response that depends on a cryptographic hash of the challenge and a secret key. Challenge–Response Authentication Mechanism (CRAM, RFC 2195), which specifies an HMAC using MD5, is a mechanism for authenticating Internet Mail Access Protocol (IMAP4) users. Digital signatures, used to authenticate data origin and integrity, employ HMAC functions as part of the "signing" process. A digital signature is created as follows:

1. A message (or some other data object) is input into a hash function (i.e., SHA-1, MD5, etc.).
2. The hash result is encrypted by the private key of the sender.

The result of these two steps yields what is called a *digital signature* of the message or data object. The properties of a cryptographic hash ensure that, if the data object is changed, the digital signature will no longer match it. There is a difference between a digital signature and an HMAC. An HMAC uses a shared secret key (symmetric cryptography) to "sign" the data object, whereas a digital signature is created by using a private key from a private/public key pair (asymmetric cryptography) to sign the data object. The strengths of digital signatures lend themselves to use in high-value applications that require protection against forgery and fraud.

See Exhibit 113.3 for other hash algorithms.

EXHIBIT 113.3 Other Hash Algorithms

Hash Algorithm	Output Bit Length	Country
RIPEMD (160,256,320)	160, 256, 320	Germany, Belgium
HAS-160	160	Korea
Tiger	128,160,192	United Kingdom

How Hash Algorithms Are Used in Modern Cryptographic Systems

In the past, hash algorithms were used for rudimentary data integrity and user authentication; today hash algorithms are incorporated into other protocols — digital signatures, virtual private network (VPN) protocols, software distribution and license control, Web page file modification detection, database file system integrity, and software update integrity verification are just a few. Hash algorithms used in hybrid cryptosystems discussed next.

Transport Layer Security (TLS)

TLS is a network security protocol that is designed to provide data privacy and data integrity between two communicating applications. TLS was derived from the earlier Secure Sockets Layer (SSL) protocol developed by Netscape in the early 1990s. TLS is defined in IETF RFC 2246. TLS and SSL do not interoperate due to differences between the protocols. However, TLS 1.0 does have the ability to drop down to the SSL protocol during initial session negotiations with an SSL client. Deference is given to TLS by developers of most modern security applications. The security features designed into the TLS protocol include hashing.

The TLS protocol is composed of two layers:

1. The Record Protocol provides in-transit data privacy by specifying that symmetric cryptography be used in TLS connections. Connection reliability is accomplished by the Record Protocol through the use of HMACs.
2. TLS Handshake Protocol (really a suite of three subprotocols). The Handshake Protocol is encapsulated within the Record Protocol. The TLS Handshake Protocol handles connection parameter establishment. The Handshake Protocol also provides for peer identity verification in TLS through the use of asymmetric (public/private) cryptography.

There are several uses of keyed hash algorithms (HMAC) within the TLS protocol.

TLS uses HMAC in a conservative fashion. The TLS specification calls for the use of both HMAC MD5 and HMAC SHA-1 during the Handshake Protocol negotiation. Throughout the protocol, two hash algorithms are used to increase the security of various parameters:

- Pseudorandom number function
- Protect record payload data
- Protect symmetric cryptographic keys (used for bulk data encrypt/decrypt)
- Part of the mandatory cipher suite of TLS

If any of the above parameters were not protected by security mechanisms such as HMACs, an attacker could thwart the electronic transaction between two or more parties. The TLS protocol is the basis for most Web-based in-transit security schemes. As can be seen by this example, hash algorithms provide an intrinsic security value to applications that require secure in-transit communication using the TLS protocol.

IPSec

The Internet Protocol Security (IPSec) Protocol was designed as the packet-level security layer included in IPv6. IPv6 is a replacement TCP/IP protocol suite for IPv4. IPSec itself is flexible and modular in design, which allows the protocol to be used in current IPv4 implementations. Unlike the session-level security of TLS, IPSec provides packet-level security. VPN applications such as intranet and remote access use IPSec for communications security.

Two protocols are used in IPSec operations, Authentication Header (AH) and Encapsulating Security Payload (ESP). Among other things, ESP is used to provide data origin authentication and connectionless integrity. Data origin authentication and connectionless integrity are joint services and are offered as an option in the implementation of the ESP. RFC 2406, which defines the ESP used in IPSec, states that either HMAC or one-way hash algorithms may be used in implementations. The authentication algorithms are used to create the integrity check value (ICV) used to authenticate an ESP packet of data. HMACs ensure the rapid detection and rejection of bogus or replayed packets. Also, because the authentication value is passed in the clear, HMACs are mandatory if the data authentication feature of ESP is used. If data authentication is used, the sender computes the integrity check value (ICV) over the ESP packet contents minus the authentication data. After receiving an IPSec data packet, the receiver computes and compares the ICV of the received datagrams. If they are the same, then the datagram is authentic; if not, then the data is not valid, it is discarded, and the event can be logged. MD5 and SHA-1 are the currently supported authentication algorithms.

The AH protocol provides data authentication for as much of the IP header as possible. Portions of the IP header are not authenticated due to changes to the fields that are made as a matter of routing the packet to its destination. The use of HMAC by the ESP has, according to IPSec VPN vendors, negated the need for AH.

Digital Signatures

Digital signatures serve a similar purpose as those of written signatures on paper — to prove the authenticity of a document. Unlike a pen-and-paper signature, a digital signature can also prove that a message has not been modified. HMACs play an important role in providing the property of integrity to electronic documents and transactions. Briefly, the process for creating a digital signature is very much like creating an HMAC. A message is created, and the message and the sender's private key (asymmetric cryptography) serve as inputs to a hash algorithm. The hash result is attached to the message. The sender creates a symmetric session encryption key to optionally encrypt the document. The sender then encrypts the session key with the sender's private key, reencrypts it with the receiver's public key to ensure that only the receiver can decrypt the session key, and attaches the signed session key to the document. The sender then sends the digital envelope (keyed hash value, encrypted session key, and the encrypted message) to the intended receiver. The receiver performs the entire process in reverse order. If the results match when the receiver decrypts the document and combines the sender's public key with the document through the specified hash algorithm, the receiver is assured that (1) the message came from the original sender and (2) the message has not been altered. The first case is due to use of the sender's private key as part of the hashed value. In asymmetric cryptography, a mathematical relationship exists between the public and private keys such that either can encrypt and decrypt; but the same key cannot both encrypt and decrypt the same item. The private key is known only to its owner. As such, only the owner of the private key could have used it to develop the HMAC.

Other Applications

HMACs are useful when there is a need to validate software that is downloaded from download sites. HMACs are used in logging onto various operating systems, including UNIX. When the user enters a password, the password is usually run through a hash algorithm; and the hashed result is compared to a user database or password file.

An interesting use of hash algorithms to prevent software piracy is in the Windows XP registration process. SHA-1 is used to develop the installation ID used to register the software with Microsoft.

During installation of Windows XP, the computer hardware is identified, reduced to binary representation, and hashed using MD5. The hardware hash is an eight-byte value that is created by running ten different pieces of information from the PC's hardware components through the MD5 algorithm. This means that the resultant hash value cannot be backward-calculated to determine the original values. Further, only a portion of the resulting hash value is used in the hardware hash to ensure complete anonymity.

Unauthorized file modification such as Web page defacement, system file modification, virus signature update, signing XML documents, and signing database keys are all applications for which various forms of hashing can increase security levels.

Problems with Hash Algorithms

Flaws have been discovered in various hash algorithms. One such basic flaw is called the birthday attack.

Birthday Attack

This attack's name comes from the world of probability theory out of any random group of 23 people, it is probable that at least two share a birthday. Finding two numbers that have the same hash result is known as the birthday attack. If hash function f maps into message digests of length 60 bits, then an attacker can find a collision using only 230 inputs ($2^{f/2}$). Differential cryptanalysis has proven to be effective against one round of MD5. (There are four rounds of transformation defined in the MD5 algorithm.) When choosing a hash algorithm, speed of operation is often a priority. For example, in asymmetric (public/private) cryptography, a message may be hashed into a message digest as a data integrity enhancement. However, if the message is large, it can take some time to compute a hash result. In consideration of this, a review of speed benchmarks would give a basis for choosing one algorithm over another. Of course, implementation in hardware is usually faster than in a software-based algorithm.

Looking to the Future

SHA-256, -384, and -512

In the summer of 2001, NIST published for public comment a proposed update to the Secure Hash Standard (SHS) used by the U.S. government. Although SHA-1 appears to be still part of SHS, the update includes the recommendation to use hash algorithms with longer hash results. Longer hash results increase the work factor needed to break cryptographic hashing. This update of the Secure Hash Standard coincides with another NIST update — selection of the Rijndael symmetric cryptography algorithm for U.S. government use for encrypting data. According to NIST, it is thought that the cryptographic strength of Rijndael requires the higher strength of the new SHS algorithms. The new SHS algorithms feature similar functions but different structures. Newer and more secure algorithms, such as SHA-256, -384, and –512, may be integrated into the IPSec specification in the future to complement the Advanced Encryption Standard (AES), Rijndael. In May 2002, NIST announced that the Rijndael algorithm had been selected as the AES standard, FIPS 197.

Summary

Hash algorithms have existed in many forms at least since the 1950s. As a result of the increased value of data interactions and the increased motivation of attackers seeking to exploit electronic communications, the requirements for hash algorithms have changed. At one time, hashing was used to detect inadvertent errors generated by data processing equipment and poor communication lines. Now, secure hash algorithms are used to associate source of origin with data integrity, thus tightening the bonds of data and originator of data. So-called HMACs facilitate this bonding through the use of public/private cryptography. Protocols such as TLS and IPSec use HMACs extensively. Over time, weaknesses in algorithms have been discovered and hash algorithms have improved in reliability and speed. The present digital economy finds that hash algorithms are useful for creating message digests and digital signatures.

A Look at the Advanced Encryption Standard (AES)

Ben Rothke, CISSP

In the early 1970s, the Data Encryption Standard (DES) became a Federal Information Processing Standard[1,2] (FIPS). This happened with little fanfare and even less public notice. In fact, in the late 1960s and early 1970s, the notion of the general public having an influence on U.S. cryptographic policy was utterly absurd. It should be noted that in the days before personal computers were ubiquitous, the force of a FIPS was immense, given the purchasing power of the U.S. government. Nowadays, the power of a FIPS has a much lesser effect on the profitability of computer companies given the strength of the consumer market.

Jump to the late 1990s and the situation is poles apart. The proposed successor to DES, the Advanced Encryption Standard (AES), was publicized not only in the *Federal Register* and academic journals, but also in consumer computing magazines and the mainstream media.[3]

The entire AES selection process was, in essence, a global town hall event. This was evident from submissions from cryptographers from around the world. The AES process was completely open to public scrutiny and comment. This is important because, when it comes to the design of effective encryption algorithms, history has shown time and time again that secure encryption algorithms cannot be designed, tested, and verified in a vacuum. In fact, if a software vendor decides to use a proprietary encryption algorithm, that immediately makes the security and efficacy of the algorithm suspect.[4] Prudent consumers of cryptography will *never* use a proprietary algorithm.

This notion is based on what is known as Kerckhoff's assumption.[5] This assumption states the security of a cryptosystem should rest entirely in the secrecy of the key and not in the secrecy of the algorithm. History has shown, and unfortunately, that some software vendors still choose to ignore the fact that completely open-source encryption algorithms are the only way to design a truly world-class encryption algorithm.

The AES Process

In January 1997, the National Institute of Standards and Technology (NIST, a branch within the Commerce Department) commenced the AES process.[6] A replacement for DES was needed due to the ever-growing frailty of DES. Not that any significant architectural breaches were found in DES; rather, Moore's law had caught up with it. By 1998, it was possible to build a DES-cracking device for a reasonable sum of money.

The significance of the availability of a DES-cracking device to an adversary cannot be understated because DES is the world's most widely used, general-purpose cryptosystem. For the details of this cracking of DES,[7] see *Cracking DES: Secrets of Encryption Research, Wiretap Politics and Chip Design* by the Electronic Frontier Foundation (1998, O'Reilly & Assoc.).

DES was reengineered and put back into working order via the use of Triple-DES. Triple-DES takes the input data and encrypts it three times. Triple-DES (an official standard in use as ANSI X9.52-1998[8]) is resilient against brute-force attacks, and from a security perspective, it is adequate. So why not simply use Triple-DES

as the new AES? This is not feasible because DES was designed to be implemented in hardware and is therefore not efficient in software implementations. Triple-DES is three times slower than DES; and although DES is fast enough, Triple-DES is far too slow. One of the criteria for AES is that it must be efficient when implemented in software, and the underlying architecture of Triple-DES makes it unsuitable as an AES candidate.

The AES specification called for a symmetric algorithm (same key for encryption and decryption) using block encryption of 128 bits in size, with supporting key sizes of 128, 192, and 256 bits. The algorithm was required to be royalty-free for use worldwide and offer security of a sufficient level to protect data for 30 years. Additionally, it must be easy to implement in hardware as well as software, and in restricted environments (i.e., smart cards, DSP, cell phones, FPGA, custom ASIC, satellites, etc.).

AES will be used for securing sensitive but unclassified material by U.S. government agencies.[9] As a likely outcome, all indications make it likely that it will, in due course, become the *de facto* encryption standard for commercial transactions in the private sector as well.

In August 1998, NIST selected 15 preliminary AES candidates at the first AES Candidate Conference in California. At that point, the 15 AES candidates were given much stronger scrutiny and analysis within the global cryptography community. Also involved with the process was the National Security Agency (NSA).

This is not the place to detail the input of the NSA into the AES selection process, but it is obvious that NIST learned its lesson from the development of DES. An initial complaint against DES was that IBM kept its design principles secret at the request of the U.S. government. This, in turn, led to speculation that there was some sort of trapdoor within DES that would provide the U.S. intelligence community with complete access to all encrypted data. Nonetheless, when the DES design principles were finally made public in 1992,[10] such speculation was refuted.

The AES Candidates

The 15 AES candidates chosen at the first AES conference are listed in Exhibit 114.1.

A second AES Candidate Conference was held in Rome in March 1999 to present analyses of the first-round candidate algorithms. After this period of public scrutiny, in August 1999, NIST selected five algorithms for more extensive analysis (see Exhibit 114.2).

In October 2000, after more than 18 months of testing and analysis, NIST announced that the Rijndael algorithm had been selected as the AES candidate. It is interesting to note that only days after NIST's announcement selecting Rijndael, advertisements were already springing up stating support for the new standard.

In February 2001, NIST made available a Draft AES FIPS[11] for public review and comment, which concluded on May 29, 2001.

This was followed by a 90-day comment period from June through August 2001. In August 2002, NIST announced the approval of Federal Information Processing Standards (FIPS) 180-2, Secure Hash Standard, which contains the specifications for the Secure Hash Algorithm (SHA-1, SHA-256, SHA-384, and SHA-512).

DES Is Dead

It is clear that not only is 56-bit DES ineffective, it is dead. From 1998 on, it is hoped that no organization has implemented 56-bit DES in any type of high-security or mission-critical system. If such is the case, it should be immediately retrofitted with Triple-DES or another secure public algorithm.

Although DES was accepted as an ANSI standard in 1981 (ANSI X3.92) and later incorporated into several American Banking Association Financial Services (X9) standards, it has since been replaced by Triple-DES.

Replacing a cryptographic algorithm is a relatively straightforward endeavor because encryption algorithms are, in general, completely interchangeable. Most hardware implementations allow plug-ins and replacements of different algorithms. The greatest difficulty is in the logistics of replacing the software for companies with tens or hundreds of thousands of disparate devices. Also, for those organizations that have remote sites, satellites, etc., this point is ever more germane.

AES implementations have already emerged in many commercial software security products as an optional algorithm (in addition to Triple-DES and others). Software implementations have always come before hardware products due to the inherent time it takes to design and update hardware. It is generally easier to upgrade software than to perform a hardware replacement or upgrade, and many vendors have already incorporated AES into their latest designs.

EXHIBIT 114.1 AES Candidates Chosen at the First AES Conference

Algorithm	Submitted by	Overview[a]
CAST-256	Entrust Technologies, Canada	A 48-round unbalanced Feistel cipher using the same round functions as CAST-128, which use + — XOR rotates and 4 fixed 6-bit S-boxes; with a key schedule.
Crypton	Future Systems, Inc., Korea	A 12-round iterative cipher with a round function using & | XOR rotates and 2 fixed 8-bit S-boxes; with various key lengths supported, derived from the previous SQUARE cipher.
DEAL	Richard Outerbridge (UK) and Lars Knudsen (Norway)	A rather different proposal, a 6- to 8-round Feistel cipher which uses the existing DES as the round function. Thus a lot of existing analysis can be leveraged, but at a cost in speed.
DFC	Centre National pour la Recherche Scientifique, France	An 8-round Feistel cipher design based on a decorrelation technique and using + x and a permutation in the round function; with a 4-round key schedule.
E2	Nippon Telegraph and Telephone Corporation, Japan	A 12-round Feistel cipher, using a nonlinear function comprised of substitution using a single fixed 8-bit S-box, a permutation, XOR mixing operations, and a byte rotation.
FROG	TecApro International, South Africa	An 8-round cipher, with each round performing four basic operations (with XOR, substitution using a single fixed 8-bit S-box, and table value replacement) on each byte of its input.
HPC	Rich Schroeppel, United States	An 8-round Feistel cipher, which modifies 8 internal 64-bit variables as well as the data using + — x & | XOR rotates and a lookup table.
LOKI97	Lawrie Brown, Josef Pieprzyk, and Jennifer Seberry, Australia	A 16-round Feistel cipher using a complex round function f with two S-P layers with fixed 11-bit and 13-bit S-boxes, a permutation, and + XOR combinations; and with a 256-bit key schedule using 48 rounds of an unbalanced Feistel network using the same complex round function f.
Magenta	Deutsche Telekom, Germany	A 6- to 8-round Feistel cipher, with a round function that uses a large number of substitutions using a single fixed S-box (based on exponentiation on $GF(2^8)$), that is combined together with key bits using XOR.
MARS	IBM, United States	An 8+16+8-round unbalanced Feistel cipher with four distinct phases: key addition and 8 rounds of unkeyed forward mixing, 8 rounds of keyed forwards transformation, 8 rounds of keyed backwards transformation, and 8 rounds of unkeyed backwards mixing and keyed subtraction. The rounds use + — x rotates XOR and two fixed 8-bit S-boxes.
RC6	RSA Laboratories, United States	A 20-round iterative cipher, developed from RC5 (and fully parameterized), which uses a number of 32-bit operations (+ — x XOR rotates) to mix data in each round.
Rijndael	Joan Daemen and Vincent Rijmen, Belgium	A 10- to 14-round iterative cipher, using byte substitution, row shifting, column mixing, and key addition, as well as an initial and final round of key addition, derived from the previous SQUARE cipher.
SAFER+	Cylink Corp., United States	An 8- to 16-round iterative cipher, derived from the earlier SAFER cipher. SAFER+ uses + x XOR and two fixed 8-bit S-boxes.
SERPENT	Ross Anderson (U.K.), Eli Biham (Israel), and Lars Knudsen (Norway)	A 32-round Feistel cipher, with key mixing using XOR and rotates, substitutions using 8 key-dependent 4-bit S-boxes, and a linear transformation in each round.
Twofish	Bruce Schneier et al., United States	A 16-round Feistel cipher using four key-dependent 8-bit S-boxes, matrix transforms, rotations, and based in part on the Blowfish cipher.

[a]From http://www.adfa.edu.au/~lpb/papers/unz99.html.

EXHIBIT 114.2 Five Algorithms Selected by NIST

Algorithm	Main Strength	Main Weaknesses
MARS	High security margin	Complex implementation
RC6	Very simple	Lower security margin as it used operations specific to 32-bit processors
Rijndael	Simple elegant design	Insufficient rounds
Serpent	High security margin	Complex design and analysis, poor performance
Twofish	Reasonable performance, high security margin	Complex design

For those organizations already running Triple-DES, there are not many compelling reasons (except for compatibility) to immediately use AES. It is likely that the speed at which companies upgrade to AES will increase as more products ship in AES-enabled mode.

Rijndael

Rijndael, the AES candidate, was developed by Dr. Joan Daemen of Proton World International and Dr. Vincent Rijmen, a postdoctoral researcher in the electrical engineering department of Katholieke Universiteit of the Netherlands.[12] Drs. Daemen and Rijmen are well-known and respected in the cryptography community. Rijndael has its roots in the SQUARE cipher,[13] also designed by Daemen and Rijmen.

The details on Rijndael are specified in its original AES proposal.[14] From a technical perspective,[15] Rijndael is a substitution-linear transformation network (i.e., non-Feistel[16,17]) with multiple rounds, depending on the key size. Rijndael's key length and block size is either 128, 192, or 256 bits. It does not support arbitrary sizes, and its key and block size must be one of the three lengths.

Rijndael uses a single S-box that acts on a byte input in order to give a byte output. For implementation purposes, it can be regarded as a lookup table of 256 bytes. Rijndael is defined by the equation

$$S(x) = M\ (1/x) + b$$

over the field $GF(2^8)$, where M is a matrix and b is a constant.

A data block to be processed under Rijndael is partitioned into an array of bytes and each of the cipher operations is byte oriented. Rijndael's ten rounds each perform four operations. In the first layer, an 8×8 S-box (S-boxes used as nonlinear components) is applied to each byte. The second and third layers are linear mixing layers, in which the rows of the array are shifted and the columns are mixed. In the fourth layer, subkey bytes are XORed into each byte of the array. In the last round, the column mixing is omitted.[18]

Why Did NIST Select the Rijndael Algorithm?

According to the NIST,[19] Rijndael was selected due to its combination of security, performance, efficiency, ease of implementation, and flexibility.[20] Specifically, NIST felt that Rijndael was appropriate for the following reasons:

- Good performance in both hardware and software across a wide range of computing environments
- Good performance in both feedback and nonfeedback modes
- Key setup time is excellent
- Key agility is good
- Very low memory requirements
- Easy to defend against power and timing attacks (this defense can be provided without significantly impacting performance).

Problems with Rijndael

Although the general consensus is that Rijndael is a fundamentally first-rate algorithm, it is not without opposing views.[21] One issue was with its underlying architecture; some opined that its internal mathematics were simple, almost to the point of being rudimentary. If Rijndael were written down as a mathematical formula, it would look much simpler than any other AES candidate. Another critique was that Rijndael avoids any kind of obfuscation technique to hide its encryption mechanism from adversaries.[22] Finally, it was pointed out that encryption and decryption use different S-boxes, as opposed to DES which uses the same S-boxes for both operations. This means that an implementation of Rijndael that both encrypts and decrypts is twice as large as an implementation that only does one operation, which may be inconvenient on constrained devices.

The Rijndael team defended its design by pointing out that the simpler mathematics made Rijndael easier to implement in embedded hardware. The team also argued that obfuscation was not needed. This, in turn, led to speculation that the Rijndael team avoided obfuscation to evade scrutiny from Hitachi, which had expressed its intentions to seek legal action against anyone threatening its U.S.-held patents. Hitachi claimed to hold exclusive patents on several encryption obfuscation techniques, and had not been forthcoming about whether it would consider licensing those techniques to any outside party.[23] In fact, in early 2000, Hitachi issued patent claims against four of the AES candidates (MARS, RC6, Serpent, and Twofish).

Can AES Be Cracked?

Although a public-DES cracker has been built[24] as detailed in *Cracking DES: Secrets of Encryption Research, Wiretap Politics and Chip Design*, there still exists the question of whether an AES-cracking device can be built?

It should be noted that after nearly 30 years of research, no easy attack against DES has been discovered. The only feasible attack against DES is a brute-force exhaustive search of the entire keyspace. Had the original keyspace of DES been increased, it is unlikely that the AES process would have been undertaken.

DES-cracking machines were built that could recover a DES key after a number of hours by trying all possible key values. Although an AES cracking machine could also be built, the time that would be required to extricate a single key would be overwhelming.

As an example, although the entire DES keyspace can feasibly be cracked in less than 48 hours, this is not the case with AES. If a special-purpose chip, such as a field-programmable gate array[25] (FPGA), could perform a billion AES decryptions per second, and the cracking host had a billion chips running in parallel, it would still require an infeasible amount of time to recover the key. Even if it was assumed that one could build a machine that could recover a DES key in a second (i.e., try 2^{55} keys per second), it would take that machine over 140 trillion years to crack a 128-bit AES key.

Given the impenetrability of AES (at least with current computing and mathematical capabilities), it appears that AES will fulfill its requirement of being secure until 2030. But then again, a similar thought was assumed for DES when it was first designed.

Finally, should quantum computing transform itself from the laboratory to the realm of practical application, it could potentially undermine the security afforded by AES and other cryptosystems.

The Impact of AES

The two main bodies to put AES into production will be the U.S. government and financial services companies. For both entities, the rollout of AES will likely be quite different.

For the U.S. government sector, after AES is confirmed as a FIPS, all government agencies will be required to use AES for secure (but unclassified) systems. Because the government has implemented DES and Triple-DES in tens of thousands of systems, the time and cost constraints for the upgrade to AES will be huge.

AES will require a tremendous investment of time and resources to replace DES, Triple-DES, and other encryption schemes in the current government infrastructure. A compounding factor that can potentially slow down the acceptance of AES is the fact that because Triple-DES is fundamentally secure (its main caveat is its speed), there is no compelling security urgency to replace it. Although AES may be required, it may be easier for government agencies to apply for a waiver for AES as opposed to actually implementing it.[26] With the

budget and time constraints of interchanging AES, its transition will occur over time, with economics having a large part in it.

The financial services community also has a huge investment in Triple-DES. Because there is currently no specific mandate for AES use in the financial services community, and given the preponderance of Triple-DES, it is doubtful that any of the banking standards bodies will require AES use.

While the use of single DES (also standardized as X9.23-1995, Encryption of Wholesale Financial Messages) is being withdrawn by the X9 committee (see X9 TG-25-1999); this nonetheless allows continued use of DES until another algorithm is implemented.

But although the main advantages of AES are its efficiency and performance for both hardware and software implementations, it may find a difficult time being implemented in large-scale nongovernmental sites, given the economic constraints of upgrading it, combined with the usefulness of Triple-DES. Either way, it will likely be a number of years before there is widespread use of the algorithm.

Notes

1. FIPS 46-3, see http://csrc.nist.gov/publications/fips/fips46-3/fips46-3.pdf. Reaffirmed for the final time on October 25, 1999.
2. Under the Information Technology Management Reform Act (Public Law 104-106), the Secretary of Commerce approves standards and guidelines that are developed by the National Institute of Standards and Technology (NIST) for federal computer systems. These standards and guidelines are issued by NIST as Federal Information Processing Standards (FIPS) for use governmentwide. NIST develops FIPS when there are compelling federal government requirements, such as for security and interoperability, and there are no acceptable industry standards or solutions.
3. While IBM and the U.S. government essentially designed DES between them in what was billed as a public process, it attracted very little public interest at the time.
4. See B. Schneier, Security in the Real World: How to Evaluate Security Technology, *Computer Security Journal,* 15(4), 1999; and B. Rothke, Free Lunch, *Information Security Magazine,* Feb. 1999, www.infosecuritymag.com.
5. There are actually six assumptions. Dutch cryptographer Auguste Kerckhoff wrote *La Cryptographie Militare* (Military Cryptography) in 1883. His work set forth six highly desirable elements for encryption systems:
   a. A cipher should be unbreakable. If it cannot be theoretically proven to be unbreakable, it should at least be unbreakable in practice.
   b. If one's adversary knows the method of encipherment, this should not prevent one from continuing to use the cipher.
   c. It should be possible to memorize the key without having to write it down, and it should be easy to change to a different key.
   d. Messages, after being enciphered, should be in a form that can be sent by telegraph.
   e. If a cipher machine, code book, or the like is involved, any such items required should be portable and usable by one person without assistance.
   f. Enciphering or deciphering messages in the system should not cause mental strain, and should not require following a long and complicated procedure.
6. http://csrc.nist.gov/encryption/aes/pre-round1/aes_9701.txt.
7. Details are also available at www.eff.org/descracker.html.
8. The X9.52 standard defines triple-DES encryption with keys k_1, k_2 *and* k_3; k_3 as: $C = E_{k3} (D_{k2} (E_{k1} (M)))$ where E_k and D_k denote DES encryption and DES decryption, respectively, with the key k.
9. It should be noted that AES (like DES) will only be used to protect sensitive but unclassified data. Classified data is protected by separate, confidential algorithms.
10. Dan Coppersmith, The Data Encryption Standard and Its Strength Against Attacks, IBM Report RC18613.
11. http://csrc.nist.gov/encryption/aes/draftfips/fr-AES-200102.html.
12. For a quick technical overview of Rijnadel, see http://www.baltimore.com/devzone/aes/tech_overview.html.
13. www.esat.kuleuven.ac.be/~rijmen/square/index.html.
14. Available at www.esat.kuleuven.ac.be/~rijmen/rijndael/rijndaeldocV2.zip.

15. http://csrc.nist.gov/encryption/aes/round2/r2report.pdf.
16. Feistel ciphers are block ciphers in which the input is split in half. Feistel ciphers are provably invertible. Decryption is the algorithm in reverse, with subkeys used in the opposite order.
17. Of the four other AES finalists, MARS uses an extended Feistel network; RC6 and Twofish use a standard Feistel network; and Serpent uses a single substitution-permutation network.
18. Known as the key schedule, the Rijndael key (which is from 128 to 256 bits) is fed into the key schedule. This key schedule is used to generate the sub-keys, which are the keys used for each round. Each sub-key is as long as the block being enciphered, and thus, if 128 bits long, is made up of 16 bytes. A good explanation of the Rijndael key schedule can be found at http://home.ecn.ab.ca/~jsavard/crypto/co040801.htm.
19. http://csrc.nist.gov/encryption/aes.
20. As clarified in the report by NIST (*Report on the Development of the Advanced Encryption Standard)*, the fact that NIST rejected MARS, RC6, Serpent, and Twofish does not mean that they were inadequate for independent use. Rather, the sum of all benefits dictated that Rijndael was the best candidate for the AES. The report concludes that "all five algorithms appear to have adequate security for the AES."
21. Improved Cryptanalysis of Rijndael, N. Ferguson, J. Kelsey, et al., www.counterpane.com/rijndael.html.
22. Contrast this with Twofish; see *The Twofish Team's Final Comments on AES Selection*, www.counterpane.com/twofish-final.html.
23. www.planetit.com/techcenters/docs/security/qa/PIT20001106S0015.
24. It is an acceptable assumption to believe that the NSA has had this capability for a long time.
25. An FPGA is an integrated circuit that can be programmed in the field after manufacture. They are heavily used by engineers in the design of specialized integrated circuits that can later be produced in large quantities for distribution to computer manufacturers and end users.
26. Similar to those government agencies that applied for waivers to get out of the requirement for C2 (*Orange Book*) certification.

Introduction to Encryption

Jay Heiser

THROUGHOUT RECORDED HISTORY, NEW FORMS OF COMMUNICATION HAVE BEEN PARALLELED BY DEVELOPMENTS IN CRYPTOGRAPHY, THE PRACTICE OF SECURING COMMUNICATIONS. Secret writing appeared soon after the development of writing itself — an Egyptian example from 1900 BC is known. During the Renaissance, the significance of the nation state and growth in diplomacy created a requirement for secret communication systems to support diplomatic missions located throughout Europe and the world. The high volume of encrypted messages, vulnerable to interception through slow and careless human couriers, encouraged the first organized attempts to systematically break secret communications. Several hundred years later, the widespread use of the telegraph, and especially the use of radio in World War I, forced the development of efficient and robust encryption techniques to protect the high volume of sensitive communications vulnerable to enemy surveillance. At the start of World War II, highly complex machines, such as the German Enigma, were routinely used to encipher communications. Despite the sophistication of these devices, commensurate developments in cryptanalysis, the systematic technique of determining the plain text content of an encrypted message, provided the Allies with regular access to highly sensitive German and Japanese communications.

The ubiquity of computers — and especially the growth of the Internet — has created a universal demand for secure high-volume, high-speed communications. Governments, businesses of all sizes, and even private individuals now have a routine need for protected Internet communications. Privacy is just one of the necessary services that cryptography is providing for E-commerce implementations. The burgeoning virtual world of online transactions has also created a demand for virtual trust mechanisms. Cryptological techniques, especially those associated with public key technology, enable highly secure identification mechanisms, digital

signature, digital notary services, and a variety of trusted electronic transaction types to replace paper and human mechanisms.

HOW ENCRYPTION FAILS

Encryption has a history of dismal failures. Like any other human device, it can always be circumvented by humans; it is not a universal panacea to security problems. Having an understanding of how encryption implementations are attacked and how they fail is crucial in being able to successfully apply encryption.

CRYPTOGRAPHIC ATTACKS

Brute-force attack is the sequential testing of each possible key until the correct one is found. On average, the correct key will be found once half of the total key space has been tried. The only defense against a brute-force attack is to make the key space so huge that such an attack is *computationally infeasible* (i.e., theoretically possible, but not practical given the current cost/performance ratio of computers). As processing power has increased, the limits of computational infeasibility have been reduced, encouraging the use of longer keys. A 128-bit key space is an awesomely large number of keys — contemporary computing resources could not compute 2^{128} keys before the sun burned out.

Cryptanalysis is the systematic mathematical attempt to discover weaknesses in either cryptographic implementation or practice, and to use these weaknesses to decrypt messages. The idea of cryptanalytic attack is fascinating, and in some circumstances, the successes can be quite dramatic. In reality, more systems are breached through human failure. Several of the more common forms of cryptanalytic attack are described below.

A **ciphertext-only attack** is based purely on intercepted ciphertext. It is the most difficult because there are so few clues as to what has been encrypted, forcing the cryptanalyst to search for patterns within the ciphertext. The more ciphertext available for any given encryption key, the easier it is to find patterns facilitating cryptanalysis. To reduce the amount of ciphertext associated with specific keys, virtual private networks, which can exchange huge amounts of encrypted data, automatically change them regularly.

A **known plaintext attack** is based on knowledge of at least part of the plaintext message, which can furnish valuable clues in cracking the entire text. It is not unusual for an interceptor to be aware of some of a message's plaintext. The name of the sender or recipient, geographical names, standard headers and footers, and other context-dependent text may be assumed as part of many documents and messages. A **reasonable guess attack** is similar to a known plaintext attack.

Password cracking tools are a common example of reasonable guess techniques. Called a **dictionary attack**, they attempt to crack passwords by starting with words known to be common passwords. If that fails, they then attempt to try all of the words in a dictionary list supplied by the operator. Such automated attacks are effectively brute-force attacks on a limited subset of keys. L0phtcrack not only uses a dictionary attack but also exploits weaknesses in NT's password hashing implementation that were discovered through cryptanalysis, making it a highly efficient password guesser.

COMPROMISE OF KEY

In practice, most encryption failures are due to human weakness and sloppy practices. The human password used to access a security domain or crypto subsystem is often poorly chosen and easily guessable. Password guessing can be extraordinarily fruitful, but stolen passwords are also quite common. Theft may be accomplished through physical examination of an office; passwords are often stuck on the monitor or glued underneath the keyboard. Social engineering is the use of deception to elicit private information. A typical social engineering password theft involves the attacker phoning the victim, explaining that they are with the help desk and need the user's password to resolve a problem.

Passwords can also be stolen using a sniffer to capture them as they traverse the network. Older services, such as FTP and Telnet, send the user password and login across the network in plaintext. Automated attack tools that sniff Telnet and FTP passwords and save them are commonly found in compromised UNIX systems. NT passwords are hashed in a very weak fashion, and the L0phtcrack utility includes a function to collect crackable password hashes by sniffing login sessions.

If a system is compromised, there might be several passwords available on it for theft. Windows 95 and 98 systems use a very weak encryption method that is very easy to crack. Software that requires a password entry often leaves copies of the unencrypted passwords on the hard drive, either in temporary files or swap space, making them easy to find. Private keys are typically 1024 bits long, but are protected online by encrypting them with a human password that is usually easy to remember (or else it would be written down). Recent studies have shown that identifying an encrypted public key on a hard drive is relatively straightforward, because it has such a high level of entropy (high randomness) relative to other data. If a system with a private key on the hard drive is compromised, it must be assumed that a motivated attacker will be able to locate and decrypt the private key and would then be able to masquerade as the key holder.

Even if a workstation is not physically compromised, remote attacks are not difficult. If the system has an exploitable remote control application on it — either a legitimate one like PCAnywhere that might be poorly configured, or an overtly hostile backdoor application such as NetBus — then an attacker can capture the legitimate user's password. Once the attacker has a user's password, if the private key is accessible through software, the remote control attacker can create a message or document and sign it with the victim's private key, effectively appropriating their identity. A virus named Caligula is designed to steal encrypted keys from infected systems using PGP Mail, copying them back out to a site on the Internet where potential attackers can download them and attempt to decrypt them. Because software-based keys are so easily compromised, they should only be used for relatively low assurance applications, like routine business and personal mail. Legal and commercial transactions should be signed with a key stored in a protected and removable hardware device.

CREATING RELIABLE ENCRYPTION IS DIFFICULT

As should be clear from the wide variety of attacks, creating and using encryption is fraught with danger. Unsuccessful cryptosystems typically fail in one of four areas.

Algorithm Development

Modern encryption techniques derive their strength from having so many possible keys that a brute-force attack is infeasible. The key space (i.e., the potential population of keys) is a function of key size. A robust encryption implementation should not be breakable by exploiting weaknesses in the algorithm, which is the complex formula of transpositions and substitutions used to perform the data transformation. When designing algorithms, cryptologists assume that not only the algorithm, but even the encryption engine source code will be known to anyone attempting to break encrypted data. This represents a radical change from pre-computing era cryptography, in which the mechanics of the encryption engines were jealously guarded. The success of the American forces over the Japanese at the battle of Midway was facilitated by knowledge of the Japanese naval deployment, allowing American aviators to attack the larger Japanese fleet at the maximum possible range. American cryptanalysts had reverse-engineered the Japanese encryption machines, making it feasible to break their enciphered transmissions.

Suitable encryption algorithms are notoriously difficult to create. Even the best developers have had spectacular failures. History has shown that the creation and thorough testing of new encryption algorithms requires a team of highly qualified cryptologists. Experience has also shown that proprietary encryption techniques, which are common on PCs, usually fail

when subjected to rigorous attack. At best, only a few thousand specialists can claim suitable expertise in the esoteric world of cryptology. Meanwhile, millions of Internet users need access to strong cryptologic technology. The only safe choice for the layperson is to choose encryption products based on standard algorithms that are widely recognized by experts as being appropriately resistant to cryptanalytic attack.

> Even worse, it doesn't do any good to have a bunch of random people examine the code; the only way to tell good cryptography from bad cryptography is to have it examined by experts. Analyzing cryptography is hard, and there are very few people in the world who can do it competently. Before an algorithm can really be considered secure, it needs to be examined by many experts over the course of years.
>
> — Bruce Schneier, CRYPTO-GRAM, September 15, 1999

Implementation

Creation of a robust encryption algorithm is just the first challenge in the development of an encryption product. The algorithm must be carefully implemented in hardware or software so that it performs correctly and is practical to use. Even when an algorithm is correctly implemented, the overall system security posture may be weakened by some other factor. Key generation is a weak spot. If an attacker discovers a pattern in key generation, it effectively reduces the total population of possible keys and greatly reduces the strength of the implementation. A recent example was the failure of one of the original implementations of Netscape's SSL, which used a predictable time-based technique for random number generation. When subjected to statistical analysis, few man-made devices can provide sufficiently random output.

Deployment

Lack of necessary encryption, due to a delayed or cancelled program, can cause as much damage as the use of a flawed system. For a cryptosystem to be successful, the chosen products must be provided to everyone who will be expected to use them.

Operation

Experience constantly demonstrates that people are the biggest concern, not technology. A successful encryption project requires clearly stated goals, which are formally referred to as policies, and clearly delineated user instructions or procedures. Highly sophisticated encryption projects, such as public key infrastructures, require detailed operational documents such as practice statements. Using encryption to meet organizational goals requires constant administrative vigilance over infrastructure and use of keys. Encryption technology will fail without user cooperation.

> It turns out that the threat model commonly used by cryptosystem designers was wrong: most frauds were not caused by cryptanalysis or other technical attacks, but by implementation errors and management failures. This suggests that a paradigm shift is overdue in computer security; we look at some of the alternatives, and see some signs that this shift may be getting under way.

> A United Kingdom-based study of failure modes
> of encryption in banking applications

TYPES OF ENCRYPTION

Two basic types of encryption are used: symmetric and asymmetric. The traditional form is symmetric, in which a single secret key is used for both encryption and decryption. Asymmetric encryption uses a pair of mathematically related keys, commonly called the private key and the public key. It is not computationally feasible to derive the matching private key using the encrypted data and the public key. Public key encryption is the enabler for a wide variety of electronic transactions and is crucial for the implementation of E-commerce.

Symmetric Encryption

A symmetric algorithm is one that uses the same key for encryption and decryption. Symmetric algorithms are fast and relatively simple to implement. The primary disadvantage in using secret key encryption is actually keeping the key secret. In multi-party transactions, some secure mechanism is necessary in order to share or distribute the key so that only the appropriate parties have access to the secret key. Exhibit 17-1 lists the most common symmetric algorithms, all of which have proven acceptably resistant to cyryptanalytic attack in their current implementation.

Asymmetric (Public Key) Encryption

The concept of public key encryption represented a revolution in the applicability of computer-based security in 1976 when it was introduced in a journal article by Whitfield Diffie and Martin Hellman. This was quickly followed in 1978 with a practical implementation. Developed by Ron Rivest, Adi Shamir, and Len Adelman, their "RSA" scheme is still the only public key encryption algorithm in widespread use. Public key encryption uses one simple but powerful concept to enable an extraordinary variety of online trusted transactions: one party can verify that a second party holds a specific secret without having to know what that secret is. It is impossible to imagine what E-commerce would be without it. Many transaction types would be impossible or hopelessly difficult. Unlike secret key encryption, asymmetric encryption uses two keys, either one of which can be used to decrypt ciphertext encrypted with the corresponding key. In practice, one

Exhibit 17-1. Common symmetric algorithms.

Algorithm	Developer	Key Size (bits)	Characteristics
DES	IBM under U.S. government contract	56	Adopted as a U.S. federal standard in 1976 Most widely implemented encryption algorithm Increasing concern over resistance to brute-force attack
3DES	3 sequential applications of DES	112	Slow
IDEA	Developed in Switzerland by Xuejia Lai and James Massey	128	Published in 1991 Widely used in PGP Must be licensed for commercial use
Blowfish	Bruce Schneier	Up to 448	Published in 1993 Fast, compact, and flexible

key is referred to as the secret key, and is carefully protected by its owner, while the matching public key can be freely distributed. Data encrypted with the public key can only be decrypted by the holder of the private key. Likewise, if ciphertext can be successfully decrypted using the public key, it is proof that whoever encrypted the message used a specific private key.

Like symmetric algorithms, public key encryption implementations do not rely on the obscurity of their algorithm, but use key lengths that are so long that a brute-force attack is impossible. Asymmetric encryption keys are based on prime numbers, which limits the population of numbers that can be used as keys. To make it impractical for an attacker to derive the private key, even when ciphertext and the public key are known, RSA key length of 1024 bits has become the standard practice. This is roughly equivalent to an 80-bit symmetric key in resistance to a brute-force attack. Not only does public key encryption require a much longer key than symmetric encryption, it is also exponentially slower. It is so time-consuming that it is usually not practical to encrypt an entire data object. Instead, a one-time session key is randomly generated and used to encrypt the object with an efficient secret key algorithm. The asymmetric algorithm and the recipient's public key are then used to encrypt the session key so that it can only be decrypted with the recipient's private key.

Only a few asymmetric algorithms are in common use today. The Whitfield-Diffie algorithm is used for secure key exchange, and the digital signature algorithm (DSA) is used only for digital signature. Only two algorithms are currently used for encryption; RSA is by far the most widespread. *Elliptic curve* is a newer form of public key encryption that uses smaller key lengths

and is less computationally intensive. This makes it ideal for smart cards, which have relatively slow processors. Because it is newer, and based on unproven mathematical concepts, elliptic curve encryption is sometimes considered riskier than RSA encryption. It is important to understand that RSA encryption, while apparently remaining unbroken in 20 years of use, has not been mathematically proven secure either. It is based on the intuitive belief that the process of factoring very large numbers cannot be simplified. Minor improvements in factoring, such as a technique called Quadratic Sieve, encouraged the increase in typical RSA key length from 512 to 1024 bits. A mathematical or technological breakthrough in factoring is unlikely, but it would quickly obsolete systems based on RSA technology.

Additional Cryptography Types

A hash algorithm is a one-way cryptographic function. When applied to a data object, it outputs a fixed-size output, often called a message digest. It is conceptually similar to a checksum, but is much more difficult to corrupt. To provide a tamper-proof fingerprint of a data object, it must be impossible to derive any information about the original object from its message digest. If the original data is altered and the hash algorithm is reapplied, the new message digest must provide no clue as to what the change in the data was. In other words, even a 1-bit change in the data must result in a dramatically different hash value.

The most widely used secure hash algorithm is MD5, published by Ron Rivest in 1992. Some authorities expect it to be obsolete shortly, suggesting that developments in computational speed might already have rendered it inadequate. SHA-1 outputs a longer hash than MD5. The U.S. federal government is promulgating SHA-1, and it is becoming increasingly common in commercial applications.

Steganography is the practice of hiding data. This differs from encryption, which makes intercepted data unusable, but does not attempt to conceal its presence. While most forms of security do not protect data by hiding it, the mere fact that someone has taken the trouble to encrypt it indicates that the data is probably valuable. The owner may prefer not to advertise the fact that sensitive data even exists. Traditional forms of steganography include invisible ink and microdots; cryptographic steganography uses data transformation routines to hide information within some other digital data.

Multimedia objects, such as bitmaps and audio or video files, are the traditional hiding places, although a steganographic file system was recently announced. Multimedia files are relatively large compared to textual documents, and quite a few bits can be changed without making differences that are discernable to human senses. As an example, this chapter can easily be secreted within a true color photograph suitable as a 1024×768 screen

background. The desired storage object must be both large enough and complex enough to allow the data object to be hidden within it without making detectable changes to the appearance or sound of the object. This is an implementation issue; a secure steganography utility must evaluate the suitability of a storage object before allowing the transformation to occur. An object containing data secreted within it will have a different hash value than the original, but current implementations of steganography do not allow a direct human comparison between the original and modified file to show any detectible visual or audio changes.

While there are legitimate applications for cryptographic steganography, it is certainly a concern for corporations trying to control the outflow of proprietary data and for computer forensic investigators. Research is being conducted on techniques to identify the existence of steganographically hidden data, based on the hypotheses that specific steganography utilities leave characteristic patterns, or fingerprints. Most steganography utilities also provide an encryption option, so finding the hidden data does not mean that its confidentiality is immediately violated.

Digital watermarking is a communication security mechanism used to identify the source of a bitmap. It is most often used to protect intellectual property rights by allowing the owner of a multimedia object to prove that they were the original owners or creators of the object. Watermarking is similar to digital steganographic techniques in that the coded data is hidden in the least significant bits of some larger object.

CRYPTOGRAPHIC SERVICES

The most obvious use of encryption is to provide privacy, or confidentiality. Privacy can be applied in several contexts, depending on the specific protection needs of the data. Messages can be encrypted to provide protection from sniffing while being transmitted over a LAN or over the Internet. Encryption can also be used to protect the confidentiality of stored data that might be physically accessed by unauthorized parties.

Identification is accomplished in one of three ways, sometimes referred to as (1) something you know, (2) something you have, and (3) something you are. "Something you are" refers to biometric mechanisms, which are beyond the scope of this chapter, but the other two identification mechanisms are facilitated through encryption.

Passwords and passphrases are examples of "something you know" and they are normally protected cryptographically. The best practice is not to actually store phrases or passwords themselves, but to store their hash values. Each hash value has the same length, so they provide no clue as to the content or characteristics of the passphrase. The hash values can be further obfuscated through use of a *salt* value. On UNIX systems, for example,

the first two letters of the user name are used as salt as part of the DE-based hash routine. The result is that different logins that happen to have the same password will be associated with different hash values, which greatly complicates brute-force attacks.

Encryption keys can also serve as "something you have." This can be done with either symmetric or asymmetric algorithms. If two people share a secret key, and one of them encrypts a known value, they can recognize the other as being the only one who can provide the same encrypted result. In practice, public key-based identification systems scale much better, and are becoming increasingly common. Identification keys are stored on magnetic media or within a smart card. Usually, they are encrypted themselves and must be unlocked by the entry of a PIN, password, or passphrase by their owner before they can be accessed.

Integrity is provided by hashing a document to create a message digest. The integrity of the object can be verified by deriving the hash sum again, and comparing that value to the original. This simple application of a cryptographic hash algorithm is useful only when the hash value is protected from change. In a transaction in which an object is transmitted from one party to another, simply tacking a message digest onto the end of the object is insufficient — the recipient would have no assurance that the original document had not been modified and a matching new message digest included.

Authorship and Integrity assurance is provided cryptographically by digital signature. To digitally sign a document using RSA encryption, a hash value of the original document is calculated, which the signer then encrypts with their private key. The digital signature can be verified by decrypting the signature value with the signer's public key, and comparing the result to the hash value of the object. If the values do not match, the original object is no longer intact or the public and private keys do not match; in either case, the validation fails. Even if proof of authorship is not a requirement, digital signature is a practical integrity assurance mechanism because it protects the message digest by encrypting it with the signer's public key.

Digital signature provides a high level of assurance that a specific private key was used to sign a document, but it cannot provide any assurance that the purported owner of that private key actually performed the signature operation. The appropriate level of trust for any particular digitally signed object is provided through organizational procedures that are based on formal written policy. Any organization using digital signature must determine what level of systemic rigor is necessary when signing and verifying objects. Because the signature itself can only prove which key was used to sign the document, but not who actually wielded that key,

signature keys must be protected by authentication mechanisms. It is useless to verify a digital signature without having an acceptable level of trust that the public key actually belongs to the purported sender. Manual sharing of public keys is one way to be certain of their origin, but it is not practical for more than a few dozen correspondents. A third-party authentication service is the only practical way to support the trust needs of even a moderately sized organization, let alone the entire Internet.

A digital certificate provides third-party verification of the identity of a key holder. It takes the form of the keyholder's public key signed by the private key of a Certificate Authority (CA). This powerful concept makes it feasible to verify a digitally signed object sent by an unknown correspondent. The CA vouches for the identity of the certificate holder, and anyone with a trusted copy of the CA's public key can validate an individual's digital certificate. Once the authenticity of a certificate has been confirmed, the public key it contains can be used to validate the digital signature on an object from the certificate holder. E-mail applications that support digital signature and public key-based encryption typically include the sender's digital certificate whenever sending a message with a signed or encrypted object, making it easy for the sender to verify the message contents.

A Certificate Revocation List (CRL) is periodically published by some CAs to increase the level of trust associated with their certificates. Although digital certificates include an expiration date, it is often desirable to be able to cancel a certificate before it has expired. If a private key is compromised, a user account is cancelled, or a certificate holder is provided with a replacement certificate, then the original certificate is obsolete. Listing it on a CRL allows the CA to notify verifiers that the certificate issuer no longer considers it a valid certificate. CRLs increase the implementation and administration costs of a CA. Clients must access the revocation list over a network during verification, which increases the time required to validate a signature. Verification is impossible if the network or revocation list server is unavailable. Although their use can significantly increase the level of assurance provided by digital certificates, revocation implementations are rare.

It is not always practical to provide a digital certificate with every signed object, and high-assurance CAs need a CRL server. Directory service is a distributed database optimized for reading that can make both CRLs and certificates available on a wide area network (WAN) or the Internet. Most directory services are based on the X.500 standard and use the extensible format X.509 to store digital certificates.

Public key infrastructure (PKI) refers to the total system installed by an organization to support the distribution and use of digital certificates. A PKI encompasses both infrastructure and organizational process. Examples of organizational control mechanisms include certificate policies (CP)

specifying the exact levels of assurance necessary for specific types of information, and practice statements specifying the mechanisms and procedures that will provide it. A PKI can provide any arbitrary level of assurance, based on the rigor of the authentication mechanisms and practices. The more effort an organization uses to verify a certificate applicant's identity, and the more secure the mechanisms used to protect that certificate holder's private key, the more trust that can be placed in an object signed by that certificate holder. Higher trust exacts a higher cost, so PKIs typically define a hierarchy of certificate trust levels allowing an optimal tradeoff between efficiency and assurance.

Transactional Roles (Witnessing)

Commerce and law rely on a variety of transactions. Over thousands of years of civilization, conventions have been devised to provide the parties to these transactions with acceptable levels of assurance. The same transactions are desirable in the digital realm, but mechanisms requiring that a human mark a specific piece of paper need virtual replacements. Fortunately, trust can be increased using witnessing services that are enabled through public key encryption.

Nonrepudiation describes protection against the disavowal of a transaction by its initiator. Digital signature provides nonrepudiation by making it impossible for the owner of a private key to deny that his key was used to sign a specific object. The key holder can still claim that his private key had been stolen — the level of trust appropriate for any electronically signed document is dependent on the certificate policy. For example, a weak certificate policy may not require any authentication during the certificate request, making it relatively easy to steal someone's identity by obtaining a certificate in his or her name. A CP that requires a more robust vetting process before issuing a certificate, with private keys that can only be accessed through strong authentication mechanisms (such as biometrics), decreases the potential that a signer will repudiate a document.

A digital notary is a trusted third party that provides document signature authentication. The originator digitally signs a document and then registers it with a digital notary, who also signs it and then forwards it the final recipient. The recipient of a digitally notarized document verifies the signature of the notary, not the originator. A digital notary can follow much more stringent practices than is practical for an individual, and might also offer some form of monetary guarantee for documents that it notarizes. The slight inconvenience and cost of utilizing a digital notary allows a document originator to provide a higher level of assurance than they would be able to without using a trusted third party.

Timestamping is a transactional service that can be offered along with notarization, or it might be offered by an automated timestamp service

that is both lower cost and lower assurance than a full notarization service. A timestamp service is a trusted third party guaranteeing the accuracy of their timestamps. Witnessing is desirable for digital object time verification because computer clocks are untrustworthy and easily manipulated through both hardware and software. Like a digitally notarized document, a timestamped document is digitally signed with the private key of the verification service and then forwarded to the recipient. Applications suitable for timestamping include employee or consultant digital time cards, performance data for service level agreements, telemetry or test data registration, and proposal submission.

Key exchange is a process in which two parties agree on a secret key known only to themselves. Some form of key exchange protocol is required in many forms of secure network connectivity, such as the initiation of a virtual private network connection. The Whitfield-Diffie algorithm is an especially convenient key exchange technique because it allows two parties to securely agree on a secret session key without having any prior relationship or need for a certificate infrastructure.

Key Recovery

Clashes between civil libertarians and the U.S. federal government have generated negative publicity on the subject of key escrow. Security practitioners should not let this political debate distract them from understanding that organizations have a legitimate need to protect their own data. Just as employers routinely keep extra keys to employee offices, desks, and safes, they are justified in their concern over digital keys. Very few organizations can afford to allow a single individual to exercise sole control over valuable corporate information. Key recovery is never required for data transmission keys because lost data can be immediately resent. However, if someone with the only key to stored encrypted data resigns is unavailable, or loses his key, then the organization loses that data permanently. Key recovery describes the ability to decrypt data without the permission or assistance of its owner. Organizations that use encryption to protect the privacy of stored data must understand the risk of key loss; and if key loss is unacceptable, their encryption policy should mandate key recovery or backup capabilities.

PUTTING IT INTO PRACTICE

Exhibit 17-2 provides an example process using both secret and public key cryptography to digitally sign and encrypt a message. Contemporary public key-based systems, such as e-mail and file encryption products, are complex hybrids using symmetric algorithms for privacy and the RSA public key algorithm to securely exchange keys. A hashing algorithm and the RSA public key algorithm provide digital signature. Starting in this case

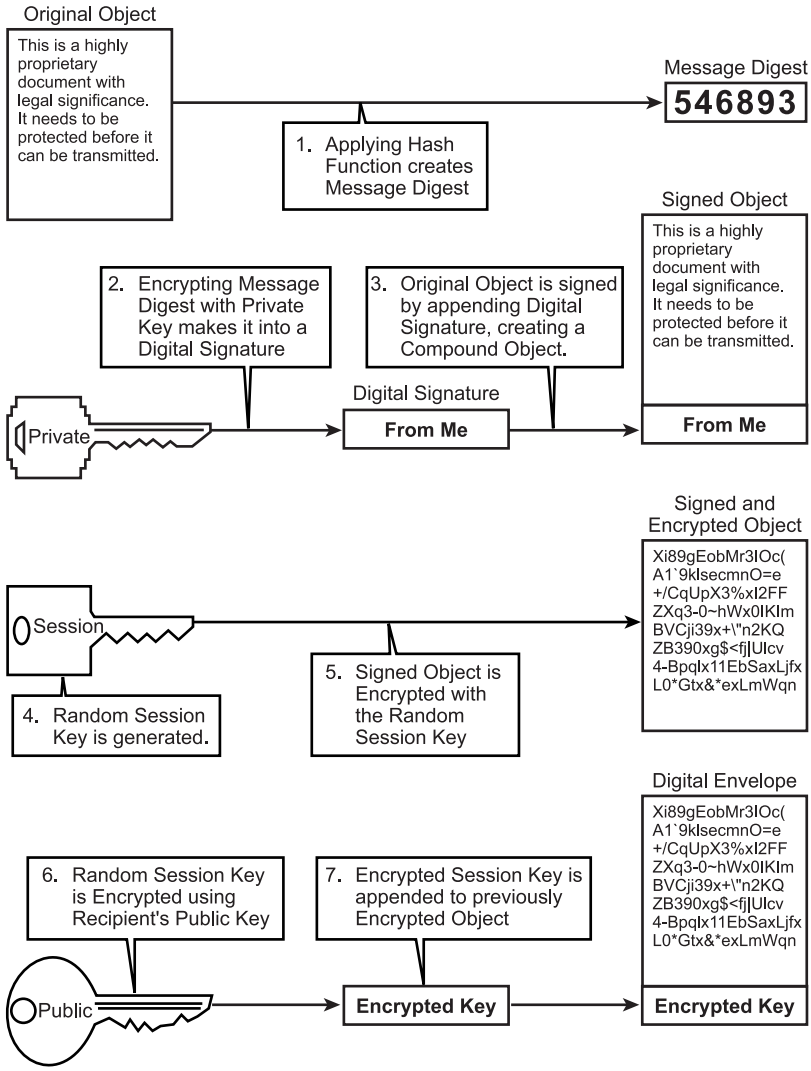

Exhibit 17-2. Using public key encryption to protect an object.

with a text file, the first step is to apply a cryptographic hash function to create a message digest (1). To protect this message digest from manipulation, and to turn it into a digital signature, it is encrypted with the private key of the signer (2). The signer's public key is highly sensitive stored information, and it must be protected with some sort of authentication mechanism. At a minimum, the key owner must enter a password to access the key. (While this is the most common protective mechanism for private

keys, it is by far the weakest link in this entire multi-step process). After creating the digital signature, it is concatenated onto the original file, creating a signed object (3). In practice, a compound object like this normally has additional fields, such as information on the hash algorithm used, and possibly the digital certificate of the signer. At this point, the original object has been turned into a digitally signed object, suitable for transmission. This is effectively an unsealed digital envelope. If privacy is required, the original object and the digital signature must be encrypted.

Although it would be possible to encrypt the signed object using a public key algorithm, this would be extremely slow, and it would limit the potential distribution of the encrypted object. To increase efficiency and provide destination flexibility, the object is encrypted using a secret key algorithm. First, a one-time random session key is generated (4). The signed object is encrypted with a symmetric algorithm, using this session key as the secret key (5). Then the session key, which is relatively small, is encrypted using the public key of the recipient (6). In systems based on RSA algorithms, users normally have two pairs of public and private keys: one pair is used for digital signature and the other is used for session key encryption. If the object is going to be sent to multiple recipients, copies of the session key will be encrypted with each of their public keys. If the message is meant to be stored, one of the keys could be associated with a key recovery system or it might be encrypted for the supervisor of the signer. All of the encrypted copies of the session key are appended onto the encrypted object, effectively creating a sealed digital envelope. Again, in practice, this compound object is in a standardized format that includes information on the encryption algorithms, and mapping information between encrypted session keys and some sort of user identifier is included. A digital envelope standard from RSA called PKCS #7 is widely used. It can serve as either an unsealed (signed but not encrypted) or sealed (signed and encrypted) digital envelope.

The processes are reversed by the recipient. As shown in Exhibit 17-3, the encrypted session key must be decrypted using the recipient's private key (2) (which should be stored in encrypted form and accessed with a password). The decrypted session key is used to decrypt the data portion of the digital envelope (3), providing a new object consisting of the original data and a digital signature. Verification of the digital signature is a three-step process. First, a message digest is derived by performing a hash function on the original data object (5). Then the digital signature is decrypted using the signer's public key. If the decrypted digital signature does not have the same value as the computed hash value, then either the original object has been changed, or the public key used to verify the signature does not match the private key used to sign the object.

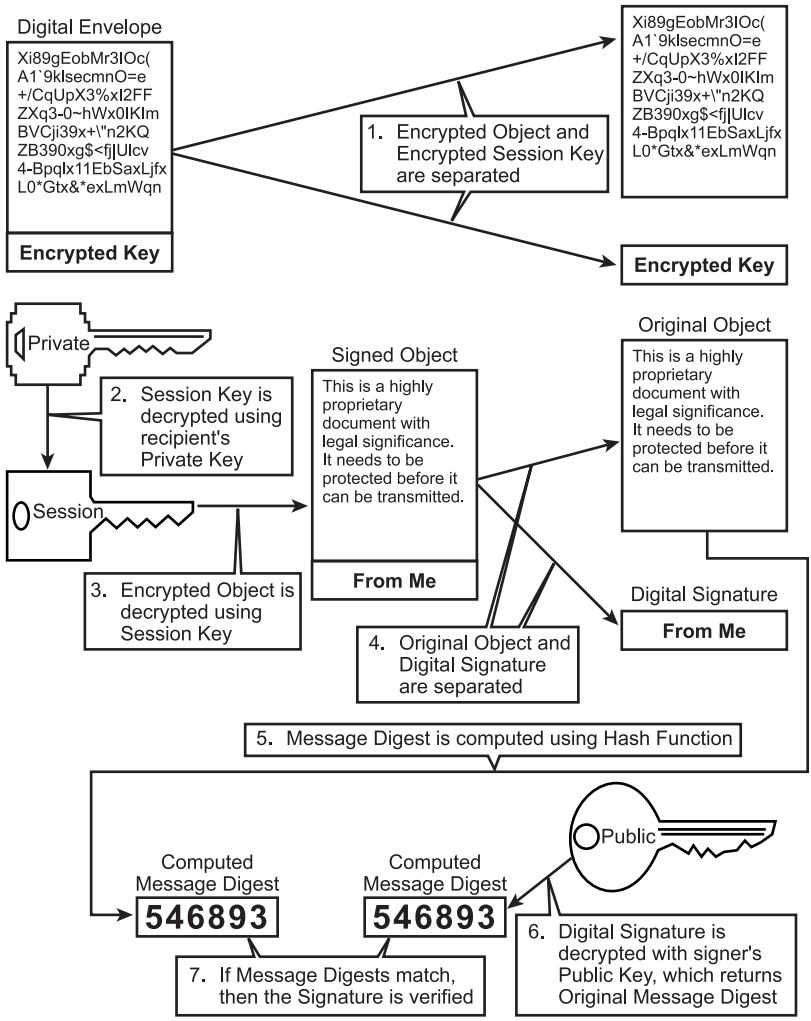

Exhibit 17-3. Decrypting and verifying a signed object.

CONCLUSION

This chapter is just a brief introduction to a fascinating and complex subject. Familiarity with encryption concepts has become mandatory for those seeking a career involving Internet technology (see Exhibit 17-4). Many online and printed resources are available to provide more detailed information on encryption technology and application. The "Annotated Bibliography" contains suggestions for readers interested in a more in-depth approach to this subject.

Principles and Applications of Cryptographic Key Management

William Hugh Murray, CISSP

Introduction

The least appreciated of the (five) inventions that characterize modern cryptography is automated key management. This powerful mechanism enables us to overcome the lack of rigor and discipline that leads to the inevitable compromise of crypto systems. By permitting us to change keys frequently and safely, it overcomes the fundamental limitations of the algorithms that we use. It enables us to compensate for such human limitations as the inability to remember or transcribe long random numbers.

This chapter attempts to tell the information security professional the minimum that he needs to know about key management. It must presume that the professional already understands modern cryptography. This chapter defines key management, enumerates its fundamental principles, and describes its use. It will make recommendations on the key choices that confront the user and manager.

Context

First a little context. Cryptography is the use of secret codes to hide data and to authenticate its origin and content. Although public codes could be used to authenticate content, secret codes are necessary to authenticate origin. This use of cryptography emerged only in the latter half of the 20th century and has been surprising to all but a few.

Of all security mechanisms, cryptography is the one most suited to open and hostile environments, environments where control is otherwise limited, environments like the modern, open, flat, broadcast, packet-switched, heterogeneous networks.

It is broadly applicable. In the presence of cheap computing power, its uses are limited only by our imaginations. Given that most of the power of our computers goes unused, we could, if we wished, use secret codes by default, converting into public codes only for use. Indeed, modern distributed computing systems and applications would be impossible without it.

It is portable; the necessary software to encode or decode the information can be distributed at or near the time of use in the same package and channel. Within minor limits, it is composable; we can put together different functions and algorithms without losing any strength. One can put together mechanisms in such a way as to emulate any environmental or media-based control that we have ever had.

Not only is cryptography effective, it is efficient. That is to say, it is usually the cheapest way to achieve a specified degree of protection. The cost of cryptography is low. Not only is it low in absolute terms, it is low

in terms of the security value it delivers. It is low compared to the value of the data it protects. It is low compared to the alternative ways of achieving the same degree of security by such alternative means as custody, supervision, or automated access control.

Its low cost is the result in part of the low cost of the modern computer, and it is falling with the cost of that computing. The cost of a single cryptographic operation today is one ten thousandth of what it was as recently as 20 years ago and can be expected to continue to fall.

Another way of looking at it is that its relative strength is rising when cost is held constant; the cost to the user is falling relative to the cost to the attacker. As we will see, automated key management is one mechanism that permits us to trade the increasing power of computing for increased security.

Modern cryptography is arbitrarily strong; that is, it is as strong as we need it to be. If one knows what data he wishes to protect, for how long, and from whom, then it is possible to use modern cryptography to achieve the desired protection. There are limitations; if one wanted to encrypt tens of gigabytes of data for centuries, it is hard to know how to achieve that. However, this is a theoretical rather than a practical problem. In practice, there are no such applications or problems.

Cryptography is significantly stronger than other security mechanisms. Almost never will cryptography be the weak link in the security chain. However, in practice its strength is limited by the other links in the chain, for example, key management. As it is not efficient to make one link in a chain significantly stronger than another, so it is not necessary for cryptography to be more than a few hundred times stronger than the other mechanisms on which the safety of the data depends.

The cryptography component of a security solution is robust and resilient, not likely to break. While history suggests that advances in technology may lower the cost of attack against a particular cryptographic mechanism, it also suggests that the cost does not drop suddenly or precipitously. It is very unlikely to collapse. Given the relative effectiveness and efficiency of cryptography relative to other security measures, changes in the cost of attack against cryptography are unlikely to put security at risk. The impact is obvious, and there is sufficient opportunity to compensate.

Changes in technology reduce the cost to both the user of cryptography and the attacker. Because the attacker enjoys economies of scale, historically, advances such as the computer have favored him first and the user second. However, that probably changed forever when both the scale and the cost of the computer fell to within the discretion of an individual. Further advances in technology are likely to favor the cryptographer.

As we will see, as the cost of attack falls, the user will spend a little money to compensate. However, it is in the nature of cryptography that as his costs rise linearly, the costs to the attacker rise exponentially. For example, the cost of attack against the Data Encryption Standard (DES) has fallen to roughly a million MIPS years. Although this is still adequate for most applications, some users have begun to use Triple DES-112. This may quadruple their cost but double the cost of a brute-force attack.

One way of looking at cryptography is that it changes the problem of maintaining the secrecy of the message to one of maintaining the secrecy of the keys. How we do that is called *key management.*

Key Management Defined

Key management can be defined as the generation, recording, transcription, distribution, installation, storage, change, disposition, and control of cryptographic keys. History suggests that key management is very important. It suggests that each of these steps is an opportunity to compromise the cryptographic system. Further, it suggests that attacks against keys and key management are far more likely and efficient than attacks against algorithms.

Key management is not obvious or intuitive. It is very easy to get it wrong. For example, students found that a recent release of Netscape's SSL (Secure Sockets Layer) implementation chose the key from a recognizable subspace of the total keyspace. Although the total space would have been prohibitively expensive to exhaust, the subspace was quite easy. Key management provides all kinds of opportunities for these kinds of errors.

As a consequence, key management must be rigorous and disciplined. History tells us that this is extremely difficult to accomplish. The most productive cryptanalytic attacks in history, such as ULTRA, have exploited poor key management. Modern automated key management attempts to use the computer to provide the necessary rigor and discipline. Moreover, it can be used to compensate for the inherent limitations in the algorithms we use.

Key Management Functions

This section addresses the functions that define key management in more detail. It identifies the issues around each of these functions that the manager needs to be aware of.

Key Generation

Key generation is the selection of the number that is going to be used to tailor an encryption mechanism to a particular use. The use may be a sender and receiver pair, a domain, an application, a device, or a data object. The key must be chosen in such a way that it is not predictable and that knowledge of it is not leaked in the process.

It is necessary but not sufficient that the key be randomly chosen. In an early implementation of the SSL protocol, Netscape chose the key in such a manner that it would, perforce, be chosen from a small subset of the total set of possible keys. Thus, an otherwise secure algorithm and secure protocol was weakened to the strength of a toy. Students, having examined how the keys were chosen, found that they could find the keys chosen by examining a very small set of possible keys.

In addition to choosing keys randomly, it is also important that the chosen key not be disclosed at the time of the selection. Although a key may be stored securely after its generation, it may be vulnerable to disclosure at the time of its generation when it may appear in the clear. Alternatively, information that is used in the generation of the key may be recorded at the time it is collected, thus making the key more predictable than might otherwise be concluded by the size of the keyspace. For example, some key-generation routines, requiring random numbers, ask the user for noisy data. They may ask the user to run his hands over the key board. While knowledge of the result of this action might not enable an attacker to predict the key, it might dramatically reduce the set of keys that the attacker must search.

Distribution

Key distribution is the process of getting a key from the point of its generation to the point of its intended use. This problem is more difficult in symmetric key algorithms, where it is necessary to protect the key from disclosure in the process. This step must be performed in a channel separate from the one that the traffic moves in.

During the World War II, the Germans used a different key each day in their Enigma Machine but distributed the keys in advance. In at least one instance, the table of future keys, recorded on water-soluble paper, was captured from a sinking submarine.

Installation

Key installation is the process of getting the key into the storage of the device or process that is going to use it. Traditionally this step has involved some manual operations. Such operations might result in leakage of information about the key, error in its transcription, or it might be so cumbersome as to discourage its use.

The German Enigma Machine had two mechanisms for installing keys. One was a set of three (later four) rotors. The other was a set of plug wires. In one instance, the British succeeded in inserting a listening device in a code room in Vichy, France. The clicking of the rotors leaked information about the delta between key n and key n + 1.

The plugging of the wires was so cumbersome and error prone as to discourage its routine use. The British found that the assumption that today's plug setting was the same as yesterday's was usually valid.

Storage

Keys may be protected by the integrity of the storage mechanism itself. For example, the mechanism may be designed so that once the key is installed, it cannot be observed from outside the encryption machine itself. Indeed, some key-storage devices are designed to self-destruct when subjected to forces that might disclose the key or that are evidence that the key device is being tampered with.

Alternatively, the key may be stored in an encrypted form so that knowledge of the stored form does not disclose information about the behavior of the device under the key.

Visual observation of the Enigma Machine was sufficient to disclose the rotor setting and might disclose some information about the plug-board setting.

Change

Key change is ending the use of one key and beginning that of another. This is determined by convention or protocol. Traditionally, the time at which information about the key was most likely to leak was at key-change time. Thus, there was value to key stability. On the other hand, the longer the key is in use, the more traffic that is encrypted under it, the higher the probability that it will be discovered and the more traffic that will be compromised. Thus, there is value to changing the key.

The Germans changed the key every day but used it for all of the traffic in an entire theatre of operations for that day. Thus, the compromise of the key resulted in the compromise of a large quantity of traffic and a large amount of information or intelligence.

Control

Control of the key is the ability to exercise a directing or restraining influence over its content or use. For example, selecting which key from a set of keys is to be used for a particular application or party is part of key control. Ensuring that a key that is intended for encrypting keys cannot be used for data is part of key control. This is such a subtle concept that its existence is often overlooked. On the other hand, it is usually essential to the proper functioning of a system.

The inventors of modern key management believe that this concept of key control and the mechanism that they invented for it, which they call the *control vector*, is one of their biggest contributions.

Disposal

Keys must be disposed of in such a way as to resist disclosure. This was more of a problem when keys were used for a long time and when they were distributed in persistent storage media than it is now. For example, Enigma keys for submarines were distributed in books with the keys for the future. In at least one instance, such a book was captured.

Modern Key Management

Modern key management was invented by an IBM team in the 1970s.[1] It was described in the *IBM Systems Journal*[2] at the same time as the publication of the Data Encryption Standard (DES). However, although the DES has inspired great notice, comment, and research, key management has not gotten the recognition it deserves. While commentators were complaining about the length of the DES key, IBM was treating it as a solved problem; they always knew how they would compensate for fixed key length and believed that they had told the world.

Modern key management is fully automated; manual steps are neither required nor permitted. Users do not select, communicate, or transcribe keys. Not only would such steps require the user to know the key and permit him to disclose it, accidentally or deliberately, they would also be very prone to error.

Modern key management permits and facilitates frequent key changes. For example, most modern systems provide that a different key will be used for each object, e.g., file, session, message, or transaction, to be encrypted. These keys are generated at the time of the application of encryption to the object and specifically for that object. Its life is no longer than the life of the object itself. The most obvious example is a session key. It is created at the time of the session, exchanged under a key-encrypting key, and automatically discarded at the end of the session. (Because of the persistence of TCP sessions, even this may result in too much traffic under a single key. The IBM proposal for secure-IP is to run two channels [TCP sessions], one for data and one for keys. The data key might change many times per session.)

One can compare the idea of changing the key for each object or method with the practices used during World War II. The Germans used the same key across all traffic for a service or theater for an entire day. Since the British were recording all traffic, the discovery of one key resulted in the recovery of a large amount of traffic.

Manual systems of key management were always in a difficult bind; the more frequently one changed the key, the greater the opportunity for error and compromise. On the other hand, the more data encrypted under a single key, the easier the attack against that key and the more data that might be compromised with that key. To change or not to change? How to decide?

Automating the system changes the balance. It permits frequent secure key changes that raise the cost of attack to the cryptanalyst. The more keys that are used for a given amount of data, the higher the cost of attack (the more keys to be found), and the lower the value of success (the less data for each key). As the number of keys increases, the cost of attack approaches infinity and the value of success approaches zero. The cost of changing keys increases the cost of encryption linearly, but it increases the cost of attack exponentially. All other things being equal, changing keys increases the effective key length of an algorithm.

Because many algorithms employ a fixed-length key, and one can almost always find the key in use by exhausting the finite set of keys, and because the falling cost and increasing speed of computers is always lowering the cost and elapsed time for such an attack, the finite length of the key might be a serious limitation on the effectiveness of the algorithm. In the world of the Internet, in which thousands of computers have been used simultaneously to find one key, it is at least conceivable that one might find the key within its useful life. Automatic key change compensates for this limit.

A recent challenge key[3] was found using more than 10,000 computers for months at the rate of billions of keys per second. The value of success was only $10,000. By definition, the life of a challenge key is equal to the duration of the attack. Automated key management enables us to keep the life of most keys to minutes to days rather than days to months.

However, modern key management has other advantages in addition to greater effective key length and shorter life. It can be used to ensure the involvement of multiple people in sensitive duties. For example, the Visa master key is stored in San Francisco inside a box called the BBN SafeKeyper. It was created inside that box and no one knows what it is. Beneficial use of the key requires possession of the box and its three physical keys. Because it is at least conceivable that the box could be destroyed, it has exported information about the key. Five trustees share that information in such a way that any three of them, using another SafeKeyper box, could reconstruct the key.

Key management can also be used to reduce the risk associated with a lost or damaged key. Although in a communication application there is no need to worry about lost keys, in a file encryption application, a lost key might be the equivalent of loss of the data. Key management can protect against that. For example, one of my colleagues has information about one of my keys that would enable him to recover it if anything should happen to me. In this case he can recover the key all by himself. Because a copy of a key halves its security, the implementation that we are using permits me to compensate by specifying how many people must participate in recovering the key.

Key management may be a stand-alone computer application or it can be integrated into another application. IBM markets a product that banks can use to manage keys across banks and applications. The Netscape Navigator and Lotus Notes have key management built in.

Key management must provide for the protection of keys in storage and during exchange. Smart cards may be used to accomplish this. For example, if one wishes to exchange a key with another, one can put it in a smart card and mail it. It would be useless to anyone who took it from the mail.

Principles of Key Management

A number of principles guide the use and implementation of key management. These are necessary, but may not be sufficient, for safe implementation. That is, even implementations that adhere to these principles may be weak, but all implementations that do not adhere to these principles are weak.

First, *Key* management must be fully automated. There may not be any manual operations. This principle is necessary both for discipline and for the secrecy of the keys.

Second, *No* key may ever appear in the clear outside a cryptographic device. This principle is necessary for the secrecy of the keys. It also resists known plain-text attacks against keys.

Keys must be randomly chosen from the entire keyspace. If there is any pattern to the manner in which keys are chosen, this pattern can be exploited by an attacker to reduce his work. If the keys are drawn in such a way that all possible keys do not have an equal opportunity to be drawn, then the work of the attacker is reduced. For example, if keys are chosen so as to correspond to natural language words, then only keys that have such a correspondence, rather than the whole space, must be searched.

Key-encrypting keys must be separate from data keys. Keys that are used to encrypt other keys must not be used to encrypt data, and vice versa. Nothing that has ever appeared in the clear may be encrypted under a key-encrypting key. If keys are truly randomly chosen and are never used to encrypt anything that has appeared in the clear, then they are not vulnerable to an exhaustive or brute-force attack. In order to understand this, it is necessary to understand how a brute-force attack works.

In a brute-force attack, one tries keys one after another until one finds the key in use. The problem that the attacker has is that he must be able to recognize the correct key when he tries it. There are two ways to do this, corresponding clear- and cipher-text attacks, and cipher-text-only attacks. In the former, the attacker keeps trying keys on the cipher text until he finds the one that produces the expected clear text.

At a minimum, the attacker must have a copy of the algorithm and a copy of the cryptogram. In modern cryptography, the algorithm is assumed to be public. Encrypted keys will sometimes appear in the environment, and encrypted data, cipher text, is expected to appear there.

For the first attack, the attacker must have corresponding clear and cipher text. In historical cryptography, when keys were used widely or for an extended period of time, the attacker could get corresponding clear and cipher text by duping the cryptographer into encrypting a message that he already knew. In modern cryptography, where a key is used only once and then discarded, this is much more difficult to do.

In the cipher-text-only attack, the attacker tries a key on the cipher text until it produces recognizable clear text. Clear text may be recognized because it is not random. In the recent RSA DES Key Challenge, the correct clear-text message could be recognized because the message was known to begin with the words, "The correct message is...." However, even if this had not been the case, the message would have been recognizable because it was encoded in ASCII.

To resist cipher-text-only attacks, good practice requires that all such patterns as format, e.g., file or e-mail message, language (e.g., English), alphabet (e.g., Roman), and public code (e.g., ASCII or EBCDIC) in the clear text object must be disguised before the object is encrypted.

Note that neither of these attacks will work on a key-encrypting key if the principles of key management are adhered to. The first one cannot be made to work because the crypto engine cannot be duped into encrypting a known value under a key-encrypting key. The only thing that it will encrypt under a key-encrypting key is a random value which it produced inside itself. The cipher-text-only attack cannot be made to work because there is no information in the clear text key that will allow the attacker to recognize it. That is, the clear text key is, by definition, totally random, without recognizable pattern, information, or entropy.

Keys with a long life must be sparsely used. There are keys, such as the Visa master key mentioned earlier, whose application is such that a very long life is desirable. As we have already noted, the more a key is used, the more likely is a successful attack and the greater the consequences of its compromise. Therefore, we compensate by using this key very sparsely and only for a few other keys. There is so little data encrypted under this key and that data is so narrowly held that a successful attack is unlikely. Because only this limited number of keys is encrypted under this key, changing it is not prohibitively expensive.

Asymmetric Key Cryptography

In traditional and conventional cryptography, the key used for encrypting and the one used for decrypting have the same value; that is to say that the relationship between them is one of symmetry or equality. In 1976, Whitfield Diffie and Martin Hellman pointed out that although the relationship between these two numbers must be fixed, it need not be equality. Other relationships could serve. Thus was born the idea of asymmetric key cryptography.

In this kind of cryptography the key has two parts; the parts are mathematically related to each other in such a way that what is encrypted with one part can only be decrypted by the other. The value of one of the keys does not necessarily imply the other; one cannot easily calculate one from the other. However, one of the keys, plus a message encrypted under it, does imply the other key. From a message and one part of the key, it is mathematically possible to calculate the other but it is not computationally feasible to do so.

Only one part, called the *private key*, need be kept secret. The other part, the *public key*, is published to the world. Anyone can use the public key to encrypt a message that can only be decrypted and read by the owner of the private key. Conversely, anyone can read a message encrypted with the private key, but only the person with beneficial use of that key could have encrypted it.

Note that if A and B share a symmetric key, then either knows that a message encrypted under that key originated with the other. Because a change in as little as one bit of the message will cause it to decode to garbage, the receiver of a good message knows that the message has not been tampered with. However, because each party has beneficial use of the key and could have created the cryptogram, they cannot demonstrate that it originated with the other. In asymmetric key cryptography only the possessor of the private key can have created the cryptogram. Any message that will decrypt with the public key is therefore known to all to have originated with the person who published it. This mechanism provides us with a digital signature capability that is independent of medium and far more resistant to forgery than marks on paper.

Although key management can be accomplished using only symmetric key cryptography, it requires secret key exchange, a closed population, some prearrangement, and it benefits greatly from trusted hardware. Asymmetric key cryptography enables us to do key management without secret key exchange, in an open population, with a minimum of prearrangement. It reduces the need for trusted hardware for key distribution though it is still desirable for key storage and transcription.

However, when otherwise compared to symmetric key cryptography, asymmetric key cryptography comes up short. Exhibit 115.1 compares a symmetric key algorithm, DES, to an asymmetric key algorithm, RSA. Exhibit 115.1 shows that the asymmetric key algorithm requires much longer keys to achieve the same computational resistance to attack (i.e., to achieve the same security). It takes much longer to generate a key. It is much slower in operation, and its cost goes up faster than the size of the object to be encrypted.

However, for keys that are to be used for a long period of time, the time required to generate a key is not an issue. For short objects to be encrypted, performance is not an issue. Therefore, asymmetric key cryptography is well suited to key management applications, and in practice its use is limited to that role. Most products use symmetric key cryptography to encrypt files, messages, sessions, and other objects, but use asymmetric key cryptography to exchange and protect keys.

Hybrid Cryptography

If one reads the popular literature, he is likely to be gulled into believing that he has to make a choice between symmetric and asymmetric key cryptography. In fact and in practice, this is not the case. In practice we use a hybrid of the two that enables us to enjoy the benefits of each. In this style of use, a symmetric key algorithm is used to hide the object, while an asymmetric key mechanism is used to manage the keys of this symmetric algorithm.

The symmetric key algorithm is well suited for hiding the data object. It is fast and secure, even with a short key. Because keys are easily chosen, they can be changed for each object. The asymmetric key algorithm would not be suitable for this purpose because it is slow and requires a long key that is expensive to choose.

On the other hand, the asymmetric algorithm is well suited to managing keys. Because symmetric keys are short, one need not worry about the speed of encrypting them. Because key management keys are relatively stable, one need not worry about the cost of finding them.

Exhibit 115.2 illustrates a simple implementation of hybrid cryptography. A randomly selected 56-bit key is used to encrypt a message using the DES algorithm. This key is then encrypted using Jane's public key. The encrypted message along with its encrypted key are now broadcast. Everyone can see these; however, their meaning is hidden from all but Jane. Jane uses her private key to recover the message key and the message key to recover the message.

EXHIBIT 115.1 DES versus RSA

Characteristic	DES	RSA
Relative speed	Fast	Slow
Functions used	Transportation, Substitution	Multiplication
Key length	56 bits	400–800 bits
Least-cost attack	Exhaustion	Factoring
Cost of attack	Centuries	Centuries
Time to generate a key	Microseconds	Tens of seconds
Key type	Symmetric	Asymmetric

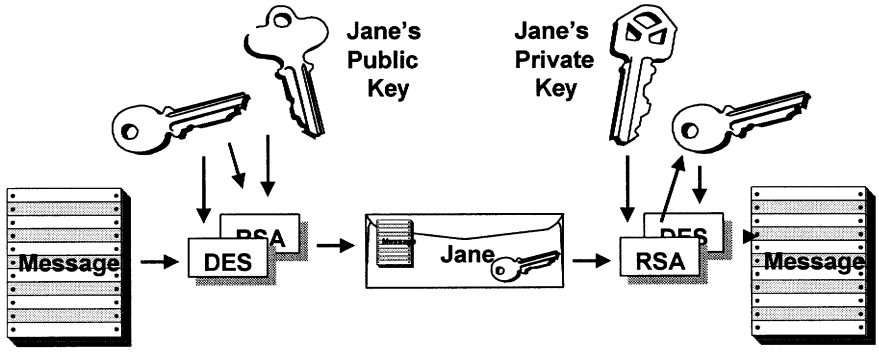

EXHIBIT 115.2 Hybrid cryptography.

Public Key Certificates

As we have noted, by definition, there is no need to keep public keys secret. However, it is necessary to ensure that one is using the correct public key. One must obtain the key in such a way as to preserve confidence that it is the right key. Also, as already noted, the best way to do that is to obtain the key directly from the party. However, in practice we will get public keys at the time of use and in the most expeditious manner.

As we do with traditional signatures, we may rely on a trusted third party to vouch for the association between a particular key and a particular person or institution. For example, the state issues credentials that vouch for the bind between a photo, name and address, and a signature. This may be a driver's license or a passport. Similar credentials, called *public key certificates*, will be issued for public keys by the same kinds of institutions that issue credentials today: employers, banks, credit card companies, telephone companies, state departments of motor vehicles, health insurers, and nation-states.

A public key certificate is a credential that vouches for the bind or join between a key pair and the identity of the owner of the key. Most certificates will vouch for the bind between the key pair and a legal person. It contains the identifiers of the key pair owner and the public half of the key pair. It is signed by the private key of the issuing authority and can be checked using the authority's public key. In addition to the identifiers of the owner and the key, it may also contain the start and end dates of its validity, and its intended purpose, use, and limitations. Like other credentials, it is revocable at the discretion of the issuer and used or not at the discretion of the key owner. Like other credentials, it is likely to be one of several and, for some purposes, may be used in combination with others.

Credential issuers or certification authorities (CAs) are legal persons trusted by others to vouch for the bind, join, or association between a public key and another person or entity. The CA may be a principal, such as the management of a company, a bank, or a credit card company. It may be the secretary of a "club" or other voluntary association, such as a bank clearing house association. It may be a government agency or designee, such as the post office or a notary public. It may be an independent third party operating as a fiduciary and for a profit.

The principal requirement for a certification authority is that it must be trusted by those who will use the certificate and for the purpose for which the certificate is intended. The necessary trust may come from its role, independence, affinity, reputation, contract, or other legal obligation.

Use of Certificates for Managing Keys

In one-to-one relationships, one knows that one is using the correct public key because one obtains it directly and personally from one's correspondent. However, for large populations and most applications, this is not feasible. In most such cases, it is desirable to obtain the key automatically and late, that is, at or near the time of use.

In a typical messaging application, one might look up one's correspondent in a public directory, using his name as a search argument. As a function, one would get an e-mail address, a public key, and a certificate that bound the key to the name and address.

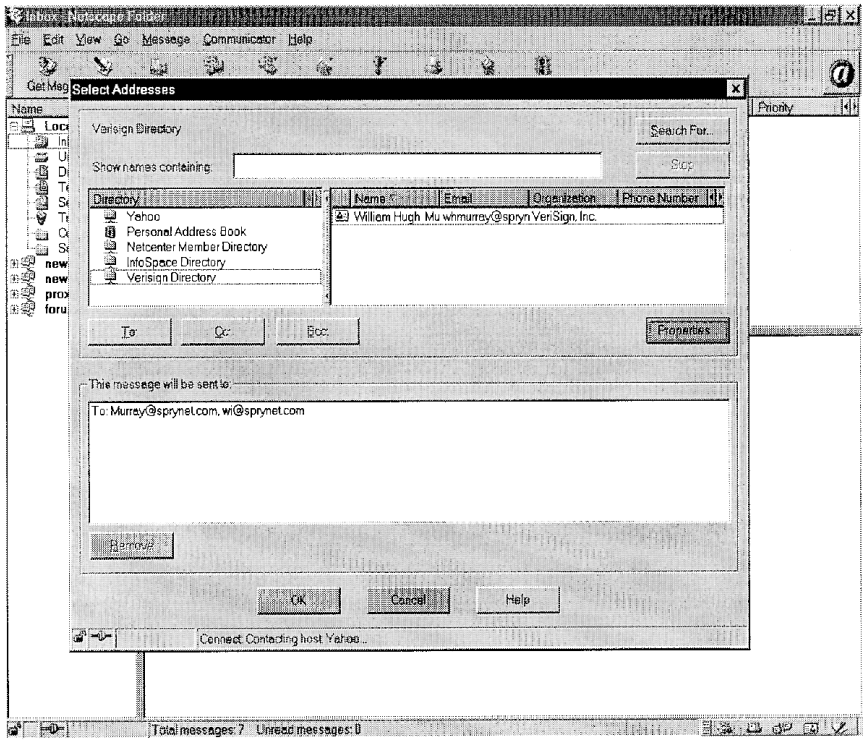

EXHIBIT 115.3

Exhibit 115.3 illustrates looking up the address whmurray@sprynet.com in the public directory operated by VeriSign, Inc. In addition to the address, the directory returns a public key that goes with that name and address. It also returns a certificate for that key. As a rule, the user will never see nor care about the key or the certificate. They will be handled automatically by the application. However, if one clicked on the <properties> button, one would see the certificate shown in Exhibit 115.4.

If one now clicks <Encrypt> on the message options, the message will now be encrypted using this key. If one signs a message using a private key, the corresponding public key and its certificate will automatically be attached to the message. Other applications work in a similar manner. Tool kits can be purchased to incorporate these functions into enterprise-developed applications.

Implementations

To illustrate the power, use, and limitations of modern key management, this section discusses a number of implementations or products. Because the purpose of this discussion is to make points about key management, it will not provide a complete discussion of any of the products. The products are used only for their value as examples of key management. The order of presentation is chosen for illustrative purposes rather than to imply importance.

Kerberos Key Distribution Center

The Kerberos key distribution center (KDC) is a trusted server to permit any two processes that it knows about to obtain trusted copies of a key-session key. Kerberos shares a secret with every process or principal in the population. When A wants to talk to B, it requests a key from the KDC. The KDC takes a random number and encrypts it under the secret it shares with B, appends a second copy of the key, and encrypts the result under the secret that it shares with A. It broadcasts the result into the network addressed to A.

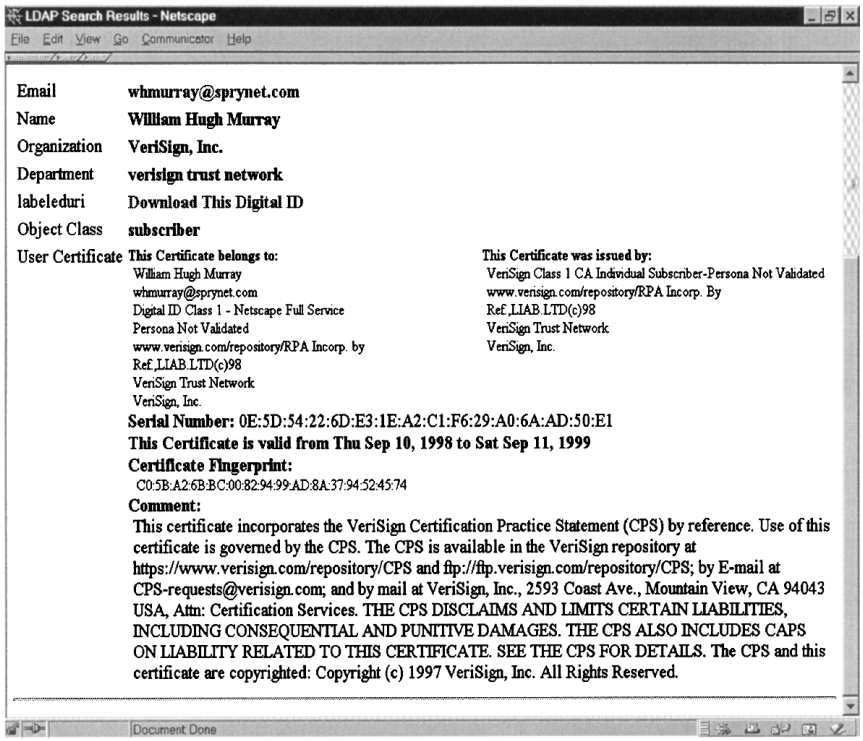

EXHIBIT 115.4

A uses the secret it shares with the KDC to recover its copy of the key and B's copy (encrypted under the secret that B shares with the KDC). It broadcasts B's copy into the network addressed to B. Although everyone in the network can see the messages, only A and B can use them. B uses its secret to recover its copy of the key. Now A and B share a key that they can use to talk securely to each other.

This process requires that the KDC be fully trusted to vouch for the identity of A and B, but not to divulge the secrets or the key to other processes or even to use it itself. If the KDC is compromised, all of the secrets will have to be changed, i.e., the principals must all be reenrolled. These limitations could be reduced if, instead of keeping a copy of the secret shared with the principals, the KDC kept only its public key. Then whatever other remedies might be necessary if the KDC were compromised, there would be no secrets to change.

PGP

PGP stands for Phil's "Pretty Good Privacy." Phil Zimmerman, its author, has received honors and awards for this product, not so much because of its elegant design and implementation, as for the fact that it brought the power of encryption to the masses. It is the encryption mechanism of choice for confidential communication among individuals.

PGP is implemented exclusively in software. It is available in source code, and implementations are available for all popular personal computers. It is available for download from servers all over the world and is free for private use. It is used to encrypt files for protection on the storage of the local system and to encrypt messages to be sent across a distance.

It uses a block cipher, IDEA, with a 128-bit key to encrypt files or messages. It automatically generates a new block-cipher key for each file or message to be encrypted. It uses an asymmetric key algorithm, Rivest–Shamir–Adelman (RSA), to safely exchange this key with the intended recipient by encrypting it using the recipient's public key. Only the intended recipient, by definition the person who has beneficial use of the mathematically corresponding private key, can recover the symmetric key and read the message.

Because the principles of key management require that this key not be stored in the clear, it is stored encrypted under the block cipher. The key for this step is not stored but is generated every time it is needed

by compressing to 128 bits an arbitrarily long passphrase chosen by the owner of the private key. Thus, beneficial use of the private key requires both a copy of the encrypted key and knowledge of the passphrase.

Of course, while PGP does not require secret exchange of a key in advance, it does require that the public key be securely acquired. That is, it must be obtained in a manner that preserves confidence that it is the key of the intended recipient. The easiest way to do this is to obtain it directly, hand-to-hand, from that recipient. However, PGP has features to preserve confidence while passing the public key via e-mail, public servers, or third parties.

Note that if the passphrase is forgotten, the legitimate owner will have lost beneficial use of the private key and all message or file keys that were hidden using the public key. For communication encryption the remedy is simply to generate a new key-pair, publish the new public key, and have the originator resend the message using the new key. However, for file encryption, access to the file is lost. As we will see, commercial products use key management to provide a remedy for this contingency.

PGP stores keys in files called *key rings*. These files associate user identifiers with their keys. It provides a number of mechanisms for ensuring that one is using the correct and intended public key for a correspondent. One of these is called the *key fingerprint*. This is a relatively short hash of the key that can be exchanged out of channel and used to check the identity of a key. Alice sends a key to Bob. On receiving the key, Bob computes the fingerprint and checks it with Alice. Note that although fingerprints are information about the public key, they contain even less information about the private key than does the public key itself. Therefore, the fingerprint need not be kept secret.

PGP also provides a record of the level of trust that was attributed to the source of the key when it was obtained. This information is available whenever the key is used. Of course, the existence of this mechanism suggests that all sources are not trusted equally nor equally trustworthy. In practice, entire key rings are often exchanged and then passed on to others. In the process, the provenance of and confidence in a key may be obscured; indeed, the confidence in a key is often no better than hearsay. The documentation of PGP suggests that the potential for duping someone into using the wrong key is one of the greatest limitations to the security of PGP.

ViaCrypt PGP, Business Edition

ViaCrypt PGP, Business Edition, is licensed for business or commercial use and includes emergency key recovery features to address some of the limitations of PGP noted above. Instead of encrypting the private key under a key generated on-the-fly from the passphrase, it introduces another level of key. This key will be used to encrypt the private key and will itself be hidden using the passphrases of the "owners" of the private key. This may be the sole user or it may be an employee and manager representing his employer. In the latter case, the employee is protected from management abuse of the private key by the fact that he has possession of it, and management only has possession of a copy of the key used to hide it. However, both the employee and management are protected from the consequences of loss of a single passphrase.

RSA SecurePC

RSA SecurePC is an add-in to the Windows file manager that is used for file encryption. It has features that extend the ideas in PGP BE and illustrate some other uses of key management. It encrypts specified files, directories, or folders, on command, that is, by marking and clicking; or by default, by marking a file or directory and indicating that everything in it is always to be encrypted. Marking the root of a drive would result in all files on the drive, except executables, always being stored in encrypted form.

The object of encryption is always the individual file rather than the drive or the directory. When a file is initially encrypted, the system generates a 64-bit block-cipher key to be used to encrypt the file. This file key is then encrypted using the public key of the system and is stored with the file.

The private key for the system is stored encrypted using a two-level key system and passphrase as in PGP BE. In order for a user to read an encrypted file, he must have the file key in the clear. To get that, he must have the private key in the clear. Therefore, when he opens a file, the system looks to see if the private key is in the clear in its memory. If not, then the user is prompted for his passphrase so that the private key can be recovered. At the time of this prompt, the user is asked to confirm or set the length of time that the private key is to be kept in the clear in system memory. The default is five minutes. Setting it to zero means that the user will be prompted for a second use. The maximum is 8 hours. The lower the user sets the time that the

key may remain in memory, the more secure it is; the higher he sets it, the less often he will be prompted for the passphrase.

RSA SecurePC also implements emergency key-recovery features. These features go beyond those described above in that management may specify that multiple parties must be involved in recovering the private key. These features not only permit management to specify the minimum number of parties that must be involved but also permits them to specify a larger set from which the minimum may be chosen. Multiparty emergency key recovery provides both the user and management with greater protection against abuse.

BBN SafeKeyper

BBN SafeKeyper is a book-size hardware box for generating and protecting private keys. It generates a private-key/public-key pair. The private key cannot be removed from the box. Beneficial use of the key requires possession of the box and its three physical keys. SafeKeyper is intended for the root key for institutions.

The box has a unique identity and a public key belonging to BBN. After it generates its key pair, it encrypts its public key and its identity under the public key of BBN and broadcasts it into the network addressed to BBN. When BBN recovers the key, it uses its own private key to create a "certificate" for the SafeKeyper that vouches for the bind between the public key and the identity of the person or institution to whom BBN sold the box.

Although the SafeKeyper box is very robust, it is still conceivable that it could be destroyed and its key lost. Therefore, it implements emergency key recovery. Although it is not possible to make an arbitrary copy of its key, it will publish information about its key sufficient to enable another SafeKeyper box to recreate it. For example, information about the Visa master key is held by five people. Any three of them acting in concert can reproduce this key.

Secure Sockets Layer (SSL)

SSL is both an API and a protocol intended for end-to-end encryption in client–server applications across an arbitrary network. The protocol was developed by Netscape, and the Navigator browser is its reference implementation. It uses public key certificates to authenticate the server to the client and, optionally, the client to the server.

When the browser connects to the secure server, the server sends its public key along with a certificate issued by a public certification authority. The browser automatically uses the issuer's public key to check the certificate, and manifests this by setting the URL to that of the server. It then uses the server's public key to negotiate a session key to be used for the session. It manifests this by setting a solid key icon in the lower left-hand corner of the screen.

Optionally, the client can send its public key and a certificate for that key issued by the management of the server or a certification authority trusted by the management of the server.

Recommendations for Key Management

To ensure rigor and discipline, automate all encryption, particularly including key management; hide all encryption from users.

To resist disclosure or arbitrary copies of a key, prefer trusted hardware for key storage. Prefer evaluated (FIPS-140)[4] hardware, dedicated single-application-only machines (such as those from Atalla, BBN, Cylink, and Zergo), smart cards, PCMCIA cards, laptops, diskettes, and trusted desktops, in that order. As a general rule, one should discourage the use of multi-user systems for key storage except for keys that are the property of the system owner or manager (e.g., payroll manager key).

Prefer one copy of a key; avoid strategies that require multiple copies of a key. Every copy of a key increases the potential for disclosure. For example, rather than replicating a single key across multiple servers, use different keys on each server with a certificate from a common source.

Change keys for each file, message, session, or other object.

Prefer one key per use or application rather than sharing a key across multiple uses. The more data that is encrypted under a single key, the greater the potential for successful cryptanalysis and the more damaging the consequences. With modern key management, keys are cheap.

To reduce the consequences of forgotten passphrases, use emergency key recovery for file encryption applications. Do not use emergency key recovery for communication encryption; change the key and resend the message.

Employ multiparty control for emergency key recovery; this reduces the potential for abuse, improves accountability, and increases trust all around. Consider requiring that the parties come from different levels of management and from different business or staff functions.

To ensure that keys are randomly selected from the entire keyspace, prefer closed and trusted processes for key generation. Avoid any manual operations in key selection.

Prefer encryption and key management that are integrated into the application. The easiest way to hide encryption from the user and to avoid errors is to integrate the encryption into the application.

Similarly, prefer applications with integrated encryption and key management. No serious business applications can be done in the modern network environment without encryption. Integrated encryption is a mark of good application design.

Finally, buy key management code from competent laboratories; do not attempt to write your own.

Notes:

1. Dr. Dorothy Denning has told me privately that she believes that automated key management was invented by the National Security Agency prior to IBM. Whether or not that is true is classified. In the absence of contemporaneous publication, it is unknowable. However, even if it is true, their invention did not ever make a difference; as far as we know, it never appeared in a system or an implementation. The IBM team actually implemented theirs, and it has made a huge difference. I remember being told by a member of the IBM team about the reaction of NSA to IBM's discussion of key management. He indicated that the reaction was as to a novel concept.

Getting Started with PKI

Harry DeMaio

In the recent history of information protection there has been an ongoing parade of technologies that loudly promises new and total solutions but frequently does not make it past the reviewing stand. In some cases, it breaks down completely at the start of the march. In others, it ends up turning down a side street. Is Public-Key Infrastructure (PKI) just another gaudy float behind more brass bands, or is there sufficient rationale to believe that this one might make it? There are some very good reasons for optimism in this case, but optimism has been high before.

To examine PKI, one needs to know more than just the design principles. Many a slick and sophisticated design has turned embarrassingly sour when implemented and put into application and operational contexts. There are also the questions of economics, market readiness, and operational/technological prerequisites, all of which can march a brilliant idea into a blind alley.

APPROACH AND PRELIMINARY DISCUSSION

We'll start with a short review of the changing requirements for security. Is there really a need, especially in networking, that didn't exist before for new security technologies and approaches?

- We'll (very) briefly describe encryption, public-key encryption and PKI.
- We'll see how well PKI satisfies today's needs from a design standpoint.
- We'll look at what's involved in actually making PKI a cost-effective reality.
- Finally, we'll ask whether PKI is an exceptional approach or just one of many alternatives worth looking at.

THE CHANGING WORLD OF NETWORKED SYSTEMS

First a few characteristics of yesterday's and today's network-based information processing need to be considered. If the differences can be summed up in a single phrase, it is "accelerated dynamics." The structure and components of most major networks are in a constant state of flux — as are the applications, transactions, and users that traverse its pathways. This has a profound influence on the nature, location, scope, and effectiveness of protective mechanisms.

Exhibit 22.1 illustrates some of the fundamental differences between traditional closed systems and open (often Internet-based) environments. These differences do much to explain the significant upsurge in interest in encryption technologies.

	LEGACY/CLOSED NETWORK	MODERN OPEN NETWORK
User Environments	Known and stable	Mobile/variable
End Points	Established	Dynamic/open
Network Structure	Established/known	Dynamic/open
Processing	Mainframe/internally distributed	Multisite/Multienterprise
Data Objects	Linked to defined process	Often independent

Exhibit 22.1. Open vs. Closed Networks

Clearly, each network is unique, and most display a mix of the above characteristics. But the trends toward openness and variability are clear. The implications for security can be profound. Security embedded in or "hard-wired" to the system and network infrastructure cannot carry the entire load in many of the more mobile and open environments, especially where dial-up is dominant. A more flexible mode that addresses the infrastructure, user, work station, environment, and data objects is required.

An example: Envision the following differences:

- A route salesperson who returns to the office work station in the evening to enter the day's orders (online batch)
- That same worker now entering on a laptop through a radio or dial-up phone link those same orders as they are being taken at the customer's premises (dial-up interactive)
- Third-party operators taking orders at an 800/888 call center
- Those same orders being entered by the customer on a Web site
- A combination of the above

The application is still the same: order entry. But the process is dramatically different, ranging from batch entry to Web-based electronic commerce.

In the first case, the infrastructure, environment, process, and user are known, stable, and can be well controlled. The classic access control facility or security server generally carries the load.

In the second (interactive dial-up) instance, the employee is still directly involved. However, now there is a portable device and its on-board functions and data, the dial-up connections, the network, the points of entry to the enterprise, and the enterprise processes to protect if the level of control that existed in the first instance is to be achieved.

The third instance involves a third party, and the network connection may be closed or open.

The fourth (Web-based) approach adds the unknowns created by the customer's direct involvement and linkage through the Internet to the company's system.

The fifth, hybrid scenario calls for significant compatibility adjustments on top of the other considerations. By the way, this scenario is not unlikely. A fallacious assumption in promoting Web-based services is that one can readily discontinue the other service modes. It seldom happens.

Consider the changes to identification, authentication, and authorization targets and processes in each instance. Consider monitoring and the audit trail. Then consider the integrity and availability issues. Finally, the potential for repudiation begins to rear its ugly head. The differences are real and significant.

THE EVOLVING BUSINESS NETWORK

Remember, too, that most network-based systems in operation today have evolved, or in many cases, accreted into their current state — adding infrastructures and applications on demand and using the technology available at the time. Darwin notwithstanding, some of the currently surviving networks are not necessarily the fittest. In most of the literature, networks are characterized as examples of a specific class — open–closed; intranet–extranet; LAN–WAN–Internet; protocol-X or protocol-Y. Although these necessary and valuable distinctions can be used to describe physical and logical infrastructures, remember that when viewed from the business processes they support supply chain, order entry, funds transfer, and patient record processing. Most "business process" networks are technological and structural hybrids.

The important point is that today security strategy and architecture decisions are being driven increasingly by specific business requirements, not just technology. This is especially true in the application of encryption-related techniques such as PKI. Looking again at the order entry example above, the application of consistent protective mechanisms for a hybrid order entry scenario will undoubtedly require compatibility and interoperability across platform and network types unless the entire system is rebuilt to one specification. This seldom happens unless the enterprise is embarking on a massive reengineering effort or deploying major application suites such as the SAP AG R/3 or PeopleSoft.

The Disintegration and Reintegration of Security Mechanisms

To be effective, a protective mechanism must appropriately bind with the object and the environment requiring protection. In open networks, the connection, structure, and relationship of the components are more loosely defined and variable. Therefore, the protective mechanisms must be more granular, focused, and more directly linked to the object or process to be protected than was the case with legacy systems. Formerly, protection processes operated primarily at a "subterranean plumbing" level, surfacing only in password and authorization administration and log-ons. Now the castle moat is being supplemented with "no-go" zones, personal bodyguards posted at strategic spots, food tasters, and trusted messengers.

Encryption mechanisms fit this direct, granular requirement often ideally, since they can protect individual files, data elements (including passwords), paths (tunneling and Virtual Private Networks) and manage access management requirements. (Identification and authentication through encryption is easier than authorization.) But saying that encryption is granular is not the same as saying that a PKI system is interoperable, portable, or scalable. In fact, it means that most encryption-related systems today are still piece parts, although some effective suites such as Entrust are in the market and several others, such as IBM SecureWay and RSA/SD Keon, are just entering.

This "disintegrated" and specialized approach to providing security function creates a frustrating problem for security professionals accustomed to integrated suites. Now the user becomes the integrator or must use a third-party integrator. The products may not integrate well or even be able to interface with one another. At the 1999 RSA Conference in San Jose, CA, the clarion call for security suites was loud and clear.

Encryption Defined

Encryption is a process for making intelligible information unintelligible through the application of sophisticated mathematical conversion

techniques. Obviously, to be useful the process must be reversible (decryption). The three major components of the encryption/decryption process are as follows:

1. *The information stream in clear or encrypted form.*
2. *The mathematical encryption process* — the algorithm. Interestingly, most commercial algorithms are publicly available and are not secret. What turns a public process into a uniquely secret one is the encryption key.
3. *The encryption key.* The encryption key is a data string that is mathematically combined with the information (clear or encrypted) by the algorithm to produce the opposite version of the data (encrypted or clear). Remember that all data on computers is represented in binary number coding. Binary numbers can be operated upon by the same arithmetic functions as those that apply to decimal numbers. So by combining complex arithmetic operations, the data and key are converted into an encrypted message form and decrypted using the same process and *same key — with one critical exception.*

Before explaining the exception, one more definition is required. The process that uses the *same key* to decrypt and encrypt is called *symmetric* cryptography. It has several advantages, including exceptional speed on computers. It has a serious drawback. In any population of communicating users (n), in order to have *individually unique* links between each pair of users, the total number of keys required is n (n + 1)/2. Try it with a small number and round up. If the population of users gets large enough, the number of individual keys required rapidly becomes unmanageable. This is one (but not the only) reason why symmetric cryptography has not had a great reception in the commercial marketplace in the last 20 years.

The salvation of cryptography for practical business use has been the application of a different class of cryptographic algorithms using *asymmetric* key pairs. The mathematics is complex and is not intuitively obvious, but the result is a *pair of linked keys* that must be used together. However, only one of the pair, the private key, must be kept secret by the key owner. The other half of the pair — the public key — can be openly distributed to anyone wishing to communicate with the key owner. A partial analogy is the cash depository in which all customers have the same key for depositing through a one-way door, but only the bank official has a key to open the door to extract the cash. This technique vastly reduces the number of keys required for the same population to communicate safely and uniquely.

ENTER PKI

If the public key is distributed openly, how do you know that it is valid and belongs with the appropriate secret key and the key owner? How do you manage the creation, use, and termination of these key pairs. That is the foundation of PKI. Several definitions follow:

> The comprehensive system required to provide public-key encryption and digital signature services is known as the *public-key infrastructure* (PKI). The purpose of a public-key infrastructure is to manage keys and certificates.
>
> *Entrust Inc.*

> A public-key infrastructure (PKI) consists of the programs, data formats, communications protocols, institutional policies, and procedures required for enterprise use of public-key cryptography.
>
> *Office of Information Technology, University of Minnesota*

> In its most simple form, a PKI is a system for publishing the public-key values used in public-key cryptography. There are two basic operations common to all PKIs:
>
> 1. Certification is the process of binding a public-key value to an individual organization or other entity, or even to some other piece of information such as a permission or credential.
> 2. Validation is the process of verifying that a certificate is still valid.
>
> How these two operations are implemented is the basic defining characteristic of all PKIs.
>
> *Marc Branchaud*

The Digital Certificate and Certificate Authorities

Obviously, from these definitions, a digital certificate is the focal point of the PKI process. What is it? In simplest terms, a digital certificate is a credential (in digital form) in which the public key of the individual is embedded along with other identifying data. That credential is encrypted (signed) by a trusted third party or certificate authority (CA) who has established the identity of the key owner (similar to but more rigorous than notarization). The "signing key" ties the certificate back to the CA and ultimately to the process that bound the certificate holder to his or her credentials and identity proof process.

By "signing" the certificate, the CA establishes and takes liability for the authenticity of the public key contained in the certificate and the fact that it is bound to the named user. Now total strangers who know or at least trust a common CA can use encryption not just to *conceal* the data but also to *authenticate* the other party. The *integrity* of the message is also ensured.

If you change it once encrypted, it will not decrypt. The message *cannot be repudiated* because it has been encrypted using the sender's certificate.

Who are CAs? Some large institutions are their own CAs, especially banks (private CAs). There are some independent services (public CAs) developing, and government, using the licensing model as a take off point, is moving into this environment. It may become a new security industry. In The Netherlands, KNB, the Dutch notary service, supplies digital certificates.

As you would expect, there has been a move by some security professionals to include more information in the certificate, making it a multipurpose "document." There is one major problem with this. Consider a driver's license, which is printed on special watermarked paper, includes the driver's picture and is encapsulated in plastic. If one wished to maintain more volatile information on it, such as current make of car(s), doctor's name and address, or next of kin, the person would have to get a new license for each change.

The same is true for a certificate. The user would have to go back to the CA for a new certificate each time he made a change. For a small and readily accessible population, this may be reasonable. However, PKI is usually justified based on large populations in open environments, often across multiple enterprises. The cost and administrative logjam can build up with the addition of authorization updates *embedded in the certificate*. This is why relatively changeable authorization data (permissions) are seldom embedded in the certificate but rather attached. There are several certificate structures that allow attachments or permissions that can be changed independently of the certificate itself.

To review, the certificate is the heart of the PKI system. A given population of users who wish to intercommunicate selects or is required to use a specific CA to obtain a certificate. That certificate contains the public-key half of an asymmetric key pair as well as other indicative information about the target individual. This individual is referred to as the "distinguished name" — implying that there can be no ambiguities in certificate-based identification — all Smiths must be separately distinguished by ancillary data.

Where are Certificates Used?

Certificates are used primarily in open environments in which closed network security techniques are inappropriate or insufficient for any or all of the following:

- Identification/authentication
- Confidentiality

- Message/transaction integrity
- Nonrepudiation

Not all PKI systems serve the same purposes or have the same protective priorities. This is important to understand when one is trying to justify a PKI system for a specific business environment.

How Does PKI Satisfy Those Business Environment Needs?

Market Expectation. As PKI becomes interoperable, scalable, and generally accepted, companies will begin to accept the wide use of encryption-related products. Large enterprises such as government, banks, and large commercial firms will develop trust models to easily incorporate PKI into everyday business use.

Current Reality. It is not that easy. Thus far, a significant number of PKI projects have been curtailed, revised, or temporarily shelved for reevaluation. The reasons most often given include the following:

- Immature technology
- Insufficient planning and preparation
- Underestimated scope
- Infrastructure and procedural costs
- Operational and technical incompatibilities
- Unclear cost-benefits

Apparent Conclusions about the Marketplace

PKI has compelling justifications for many enterprises, but there are usually more variables and pitfalls than anticipated. Broadside implementation, though sometimes necessary, has not been as cost-effective. Pilots and test beds are strongly recommended.

A properly designed CA/RA administrative function is always a critical success factor.

CERTIFICATES, CERTIFICATE AUTHORITIES (CA), AND REGISTRATION AUTHORITIES (RA)

How do they work and how are they related?

First look at the PKI certificate lifecycle. It is more involved than one may think. A digital certificate is a secure and trustworthy credential, and the process of its creation, use, and termination must be appropriately controlled.

Not all certificates are considered equally secure and trustworthy, and this is an active subject of standards and industry discussion. The strength

of the cryptography supporting the certificate is only one discriminating factor. The degree to which the certificate complies with a given standard, X.509, for example, is another criterion for trustworthiness. The standards cover a wide range of requirements, including content, configuration, and process. The following is hardly an exhaustive list, but it will provide some insight into some of the basic requirements of process.

- *Application* — How do the "certificate owners to be" apply for a certificate? To whom do they apply? What supporting materials are required? Must a face-to-face interview be conducted, or can a surrogate act for the subject? What sanctions are imposed for false, incomplete, or misleading statements? How is the application stored and protected, etc?
- *Validation* — How is the applicant's identity validated? By what instruments? By what agencies? For what period of time?
- *Issuance* — Assuming the application meets the criteria and the validation is successful, how is the certificate actually issued? Are third parties involved? Is the certificate sent to the individual or, in the case of an organization, some officer of that organization? How is issuance recorded? How are those records maintained and protected?
- *Acceptance* — How does the applicant indicate acceptance of the certificate? To whom? Is nonrepudiation of acceptance eliminated?
- *Use* — What are the conditions of use? Environments, systems, and applications?
- *Suspension or Revocation* — In the event of compromise or suspension, who must be notified? How? How soon after the event? How is the notice of revocation published?
- *Expiration and Renewal* — Terms, process, and authority?

Who and What Are the PKI Functional Entities That Must Be Considered?

Certification Authority (CAs)

- A person or institution who is trusted and can vouch for the authenticity of a public key
- May be a principal (e.g., management, bank, credit card issuer)
- May be a secretary of a "club" (e.g., bank clearing house)
- May be a government agency or designee (e.g., notary public, Department of Motor Vehicles, or post office)
- May be an independent third party operating for a profit (e.g., VeriSign)
- Makes a decision on evidence or knowledge after due diligence
- Records the decision by signing a certificate with its private key
- Authorizes issuance of certificate

Registration Authority (RA)

- Manages certificate life cycle, including Certificate Directory maintenance and Certificate Revocation List (s) maintenance and publication
- Thus can be a critical choke point in PKI process and a critical liability point, especially as it relates to CRLs
- An RA may or may not be CA

Other Entities

- *Other Trusted Third Parties* — These may be service organizations that manage the PKI process, brokers who procure certificates from certificate suppliers, or independent audit or consulting groups that evaluate the security of the PKI procedure
- *Individual Subscribers*
- *Business Subscribers* — In many large organizations, two additional constructs are used:
    1. *The Responsible Individual* (RI) — The enterprise certificate administrator
    2. *The Responsible Officer* (RO) — The enterprise officer who legally assures the company's commitment to the certificate. In many business instances, it is more important to know that this certificate is backed by a viable organization that will accept liability than to be able to fully identify the actual certificate holder. In a business transaction, the fact that a person can prove he or she is a partner in Deloitte & Touche LLP who is empowered to commit the firm usually means more than who that person is personally.

PKI policies and related statements include the following:

- Certificate policy
- Named set of rules governing certificate usage with common security requirements tailored to the operating environment within the enterprise
- Certificate practices statement (CPS)
- Detailed set of rules governing the Certificate Authority's operations
- Technical and administrative security controls
- Audit
- Key management
- Liability, financial stability, due diligence
- CA contractual requirements and documents
- Subscriber enrollment and termination processes

The Certificate Revocation List (CRL)

Of all the administrative and control mechanisms required by a PKI, the CRL function can be one of the more complex and subtle activities. The CRL is an important index of the overall trustworthiness of the specific PKI environment. Normally it is considered part of the RA's duties. Essentially the CRL is the instrument for checking the continued validity of the certificates for which the RA has responsibility. If a certificate is compromised, if the holder is no longer authorized to use the certificate or if there is a fault in the binding of the certificate to the holder, it must be revoked and taken out of circulation as rapidly as possible. All parties in the trust relationship must be informed. The CRL is usually a highly controlled online database (it may take any number of graphic forms) at which subscribers and administrators may determine the currency of a target partner's certificate. This process can vary dramatically by the following:

- *Timing/frequency of update*. Be careful of the language here. Many RAs claim a 24-hour update. That means the CRL is refreshed every 24 hours. It does not necessarily mean that the total cycle time for a particular revocation to be posted is 24 hours. It may be longer.
- *Push-pull*. This refers to the way in which subscribers can get updates from the CRL. Most CRLs require subscribers to pull the current update. A few private RAs (see below) employ a push methodology. There is a significant difference in cost and complexity and most important the line of demarcation between an RA's and subscriber's responsibility and liability. For lessened liability alone, most RAs prefer the pull mode.
- *Up link/down link*. There are two transmissions in the CRL process. The link from the revoking agent to the CRL and the distribution by the CRL to the subscribing universe. Much work has been exerted by RAs to increase the efficiency of the latter process, but because it depends on the revoking agency, the up link is often an Achilles' heel. Obviously, the overall time is a combination of both processes, plus file update time.
- *Cross domain*. The world of certificates may involve multiple domains and hierarchies. Each domain has a need to know the validity status of all certificates that are used within its bounds. In some large extranet environments, this may involve multiple and multilayer RA and CRL structures. Think this one through very carefully and be aware that the relationships may change each time the network encompasses a new environment.
- *Integrity*. One major way to undermine the trustworthiness of a PKI environment is to compromise the integrity of the CRL process. If the continued validity of the certificate population cannot be assured, the whole system is at risk.

- *Archiving*. How long should individual CRLs be kept and for what purposes?
- *Liabilities and commitments*. These should be clearly, unambiguously, and completely stated by all parties involved. In any case of message or transaction compromise traceable to faulty PKI process, the RA is invariably going to be involved. Make very sure you have a common understanding.

As you might expect, CAs and RAs come in a variety of types. Some of the more common include the following:

- *Full-service public CA* providing RA, certificate generation, issuance, and life-cycle management. Examples: VeriSign, U.S. Postal Service, TradeWave
- *Branded public CA* providing RA, certificate issuance and lifecycle management
- *Certificates generated by a trusted party*, e.g., VeriSign, GTE CyberTrust. Examples: IDMetrix/*GTE CyberTrust*, Sumitomo Bank/*VeriSign*
- *Private CAs* using CA turn-key system solutions internally. Examples: ScotiaBank (*Entrust*), Lexis–Nexis (*VeriSign On-Site*)
- *IBM Vault Registry*

There are also wide variations in trust structure models. This is driven by the business process and network architecture:

- Hierarchical trust (a classical hierarchy that may involve multiple levels and a large number of individual domains)
- VeriSign, Entrust
- X.509v3 certificates
- One-to-one binding of certificate and public key
- Web of Trust (a variation on peer relationships between domains)
- PGP
- Many-to-one binding of certificates and public key
- Constrained or Lattice of Trust structures
- Hybrid of hierarchical and Web models
- Xcert

There are several standards, guidelines, and practices that are applicable to PKI. This is both a blessing and a curse. The most common are listed below. Individual explanations can be found at several Web sites. Start at the following site, which has a very comprehensive set of PKI links — http://www.cert.dfn.de/eng/team/ske/pem-dok.html. This is one of the best PKI link sites available.

- X.500 Directory Services and X.509 Authentication
- Common Criteria (CC)
- ANSI X9 series

- Department of Defense Standards
- TCSEC, TSDM, SEI CMM
- IETF RFC — PKIX, PGP
- S/MIME, SSL, IPSEC
- SET
- ABA Guidelines
- Digital Signatures, Certification Practices
- FIPS Publications 46, 140-1, 180-1, 186

CA/RA Targets of Evaluation. To comprehensively assess the trustworthiness of the individual CA/RA and the associated processes, Deloitte & Touche has developed the following list of required evaluation targets:

- System level (in support of the CA/RA process and certificate usage if applicable)
- System components comprising an CA/RA environment
- Network devices
- Firewalls, routers, and switches
- Network servers
- IP addresses of all devices
- Client work stations

How Well Does PKI Satisfy Today's Open Systems Security Needs?

In a nutshell, PKI is an evolving process. It has the fundamental strength, granularity, and flexibility required to support the security requirements outlined. In that respect, it is the best available alternative. But wholesale adoption of PKI as the best, final, and global solution for security needs is naïve and dangerous. It should be examined selectively by business process or application to determine whether there is sufficient "value-added" to justify the direct and indirect cost associated with deployment. As suites such as Entrust become more adaptive and rich interfaces to ERP systems such as the SAP R/3 become more commonplace, PKI will be the security technology of choice for major, high-value processes. It will never be the only game in town. Uncomfortable or disillusioning as it may be, the security world will be a multisolution environment for quite a while.

What Is Involved in Making PKI a Cost-Effective Reality?

The most common approach to launching PKI is a pilot environment. Get your feet wet. Map the due diligence and procedural requirements against the culture of the organization. Look at the volatility of the certificates that will be issued. What is their life expectancy and need for modification? Check the interface issues. What is the prospective growth curve for certificate use? How many entities will be involved? Is cross-certification necessary? Above all else, examine the authorization process requirements that must co-exist with PKI. PKI is not a full-function access-control process. Look into the standards and regulations that affect your industry. Are there export control issues associated with the PKI solution being deployed? Is interoperability a major requirement? If so, how flexible is the design of the solutions being considered?

CA PILOT CONSIDERATIONS

Type of Pilot

- *Proof of concept* — May be a test bed or an actual production environment
- *Operational* — A total but carefully scoped environment. Be sure to have a clear statement of expectations against which to measure functional and business results.
- *Interenterprise* — Avoid this as a start-up if possible. But sometimes it is the real justification for adopting PKI. If so, spend considerable time and effort getting a set of procedures and objectives agreed upon by

all of the partners involved. An objective third-party evaluation can be very helpful.
- Examine standards alternatives and requirements carefully — especially in a regulated industry.
- Check product and package compatibility, interoperability, and scalability *very carefully.*
- Develop alternative compatible product scenarios. At this stage of market maturity, a Plan B is essential. Obviously not all products are universally interchangeable. Develop a backup suite and do some preliminary testing on it.
- Investigate outsourced support as an initial step into the environment. Although a company's philosophy may dictate an internally developed solution, the first round may be better deployed using outside resources.
- What are the service levels explicitly or implicitly required?
- Start internally with a friendly environment. You need all the support you can get, especially from business process owners.
- Provide sufficient time and resources for procedural infrastructure development, including CA policy, CPS, and training
- Do not promise more than you can deliver.

Is PKI an Exceptional Approach or Just One of Many Alternatives Worth Looking At?

The answer depends largely on the security objectives of the organization. PKI is ideal (but potentially expensive) for extranets and environments in which more traditional identification and authentication are insufficient. Tempting as it may be, resist the urge to find the *single solution.* Most networked-based environments and the associated enterprises are too complex for one global solution. Examine the potential for SSL, SMIME, Kerberos, single sign-on, and VPNs. If you can make the technical, operational and cost-justification case for a single, PKI-based security approach, do so. PKI is a powerful structure, but it is not a religious icon. Leave yourself room for tailored multi-solution environments.

Harry DeMaio is president of Deloitte & Touche Security Services LLC, (DTS) a wholly owned subsidiary of Deloitte & Touche LLP, Deerfield, IL. In addition to his current assignment, he is a director in Deloitte & Touche (D&T) Enterprise Risk Services, delivering the D&T family of information security and continuity planning services to major clients globally.

Mitigating E-business Security Risks: Public Key Infrastructures in the Real World

Douglas C. Merrill
Eran Feigenbaum

MANY ORGANIZATIONS WANT TO GET INVOLVED WITH ELECTRONIC COMMERCE — OR ARE BEING FORCED TO BECOME AN E-BUSINESS BY THEIR COMPETITORS. The goal of this business decision is to realize bottom-line benefits from their information technology investment, such as more efficient vendor interactions and improved asset management. Such benefits have indeed been realized by organizations, but so have the associated risks, especially those related to information security. Managed risk is a good thing, but risk for its own sake, without proper management, can drive a company out of existence. More and more corporate management teams — even up to the board of directors level — are requiring evidence that security risks are being managed. In fact, when asked about the major stumbling blocks to widespread adoption of electronic business, upper management pointed to a lack of security as a primary source of hesitation.

An enterprisewide security architecture, including technology, appropriate security policies, and audit trails, can provide reasonable measures of risk management to address senior management concerns about E-business opportunities. One technology involved in enterprisewide security architectures is public key cryptography, often implemented in the form of a public key infrastructure (PKI). This chapter describes several hands-on

examples of PKI, including business cases and implementation plans. The authors attempt to present detail from a very practical, hands-on approach, based on their experience implementing PKI and providing large-scale systems integration services. Several shortcuts are taken in the technical discussions to simplify or clarify points, while endeavoring to ensure that these did not detract from the overall message.

Although this chapter focuses on a technology — PKI — it is important to realize that large implementations involve organizational transformation. Many nontechnical aspects are integral to the success of a PKI implementation, including organizational governance, performance monitoring, stakeholder management, and process adjustment. Failing to consider these aspects greatly increases the risk of project failure, although many of these factors are outside the domain of information security. In the authors' experience, successful PKI implementations involve not only information security personnel, but also business unit leaders and senior executives to ensure that these nontechnical aspects are handled appropriately.

NETWORK SECURITY: THE PROBLEM

As more and more data is made network-accessible, security mechanisms must be put in place to ensure only authorized users access the data. An organization does not want its competitor to read, for example, its internal pricing and availability information. Security breaches often arise through failures in authentication. Authentication is the process of identifying an individual so that one can determine the individual's access privileges. To start my car, I must authenticate myself to my car. When I start my car, I have to "prove" that I have the required token — the car key — before my car will start. Without a key, it is difficult to start my car. However, a car key is a poor authentication mechanism — it is not that difficult to get my car keys, and hence be me, at least as far as my car is concerned. In the everyday world, there are several stronger authentication mechanisms, such as presenting one's driver's license with a picture. People are asked to present their driver's licenses at events ranging from getting on a plane to withdrawing large amounts of money from a bank. Each of these uses involves comparing the image on the license to one's appearance. This strengthens the authentication process by requiring two-factor authentication — an attacker must not only have my license, but he must also resemble me. In the electronic world, it is far more difficult to get strong authentication: a computer cannot, in general, check to be sure a person looks like the picture on their driver's license. Typically, a user is required to memorize a username and password. These username and password pairs must be stored in operating system-specific files, application tables, and the user's head (or desk). Any individual sitting at a keyboard that can produce a user's password is assumed to be that user.

Traditional implementations of this model, although useful, have several significant problems. When a new user is added, a new username must be generated and a new password stored on each of the relevant machines. This can be a significant effort. Additionally, when a user leaves the company, that user's access must be terminated. If there are several machines and databases, ensuring that users are completely removed is not easy. The authors' experience with PricewaterhouseCoopers LLP (PricewaterhouseCoopers) assessing security of large corporations suggests that users are often not removed when they leave, creating significant security vulnerabilities.

Additionally, many studies have shown that users pick amazingly poor passwords, especially when constrained to use a maximum of eight characters, as is often the case in operating system authentication. For example, a recent assessment of a FORTUNE 50 company found that almost 10 percent of users chose a variant of the company's logo as their password. Such practices often make it possible for an intruder to simply guess a valid password for a user and hence obtain access to all the data that user could (legitimately) view or alter.

Finally, even if a strong password is selected, the mechanics of network transmission make the password vulnerable. When the user enters a username and password, there must be some mechanism for getting the identification materials to the server itself. This can be done in a variety of ways. The most common method is to simply transmit the username and password across the network. However, this information can be intercepted during transmission using commonly available tools called "sniffers." A sniffer reads data as it passes across a network — data such as one's username and password. After reading the information, the culprit could use the stolen credentials to masquerade as the legitimate user, attaining access to any information that the legitimate user could access. To prevent sniffing of passwords, many systems use cryptography to hide the plaintext of the password before sending it across the network. In this event, an attacker can still sniff the password off the network, but cannot simply read its plaintext; rather, the attacker sees only the encrypted version. The attacker is not entirely blocked, however. There are publicly available tools to attack the encrypted passwords using dictionary words or brute-force guessing to get the plaintext password from the encrypted password. These attacks exploit the use of unchanging passwords and functions. Although this requires substantial effort, many demonstrated examples of accounts being compromised through this sort of attack are known.

These concerns — lack of updates after users leave, poor password selection, and the capability to sniff passwords off networks — make reliance on username and password pairs for remote identification to business-critical information unsatisfactory.

WHY CRYPTOGRAPHY IS USEFUL

Cryptography (from the Greek for "secret writing") provides techniques for ensuring data integrity and confidentiality during transport and for lessening the threat associated with traditional passwords. These techniques include codes, ciphers, and steganography. This chapter only considers ciphers; for information on other types of cryptography, one could read Bruce Schneier's *Applied Cryptography* or David Kahn's *The Codebreakers*. Ciphers use mathematics to transform plaintext into "ciphertext." It is very difficult to transform ciphertext back into plaintext without a special key. The key is distributed only to select individuals. Anyone who does not have the key cannot read or alter the data without significant effort. Hence, authentication becomes the question, "does this person have the expected key?" Additionally, the property that only a certain person (or set of people) has access to a key implies that only those individuals could have done anything to an object encrypted with that key. This so-called "nonrepudiation" provides assurance about an action that was performed, such as that the action was performed by John Doe, or at a certain time, etc.

There are two types of ciphers. The first method is called secret key cryptography. In secret key cryptography, a secret — a password — must be shared between sender and recipient in order for the recipient to decrypt the object. The best-known secret key cryptographic algorithm is the Data Encryption Standard (DES). Other methods include IDEA, RC4, Blowfish, and CAST. Secret key cryptography methods are, in general, very fast, because they use fairly simple mathematics, such as binary additions, bit shifts, and table lookups.

However, transporting the secret key from sender to recipient — or recipients — is very difficult. If four people must all have access to a particular encrypted object, the creator of the object must get the same key to each person in a safe manner. This is difficult enough. However, an even more difficult situation occurs when each of the four people must be able to communicate with each of the others without the remaining individuals being able to read the communication (see Exhibit 16-1). In this event, each pair of people must share a secret key known only to those two individuals. To accomplish this with four people requires that six keys be created and distributed. With ten people, the situation requires 45 key exchanges (see Exhibit 16-2). Also, if keys were compromised — such as would happen when a previously authorized person leaves the company — all the keys known to the departing employee must be changed. Again, in the four-person case, the departure requires three new key exchanges; nine are required in the ten-person case. Clearly, this will not work for large organizations with hundreds or thousands of employees.

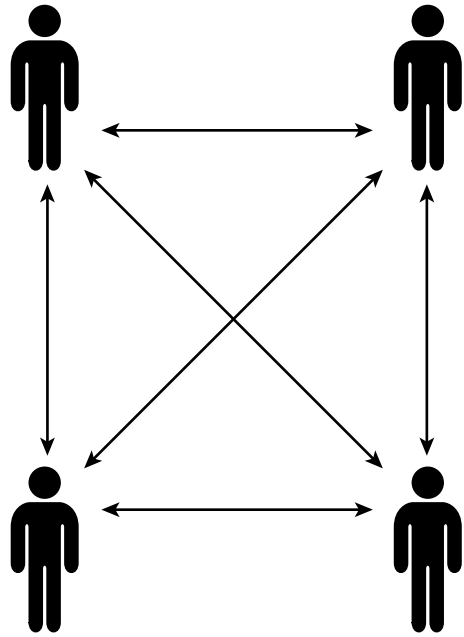

Exhibit 16-1. Four people require six keys.

In short, secret key cryptography has great power, employs fairly simple mathematics, and can quickly encrypt large volumes of data. However, its Achilles heel is the problem of key distribution and maintenance.

This Achilles heel led a group of mathematicians to develop a new paradigm for cryptography — asymmetric cryptography, also known as public key cryptography. Public key cryptography lessens the key distribution problem by splitting the encryption key into a public portion — which is given out to anyone — and a secret component that must be controlled by the user. The public and private keys, which jointly are called a key pair, are generated together and are related through complex mathematics. In the public key model, a sender looks up the recipient's public keys, typically stored in certificates, and encrypts the document using those public keys. No previous connection between sender and recipient is required, because only the recipient's public key is needed for secure transmission, and the certificates are stored in public databases. Only the private key that is associated with the public key can decrypt the document. The public and private keys can be stored as files, as entries in a database, or on a piece of hardware called a token. These tokens are often smart cards that look like credit cards but store user keys and are able to perform cryptographic computations far more quickly than general-purpose CPUs.

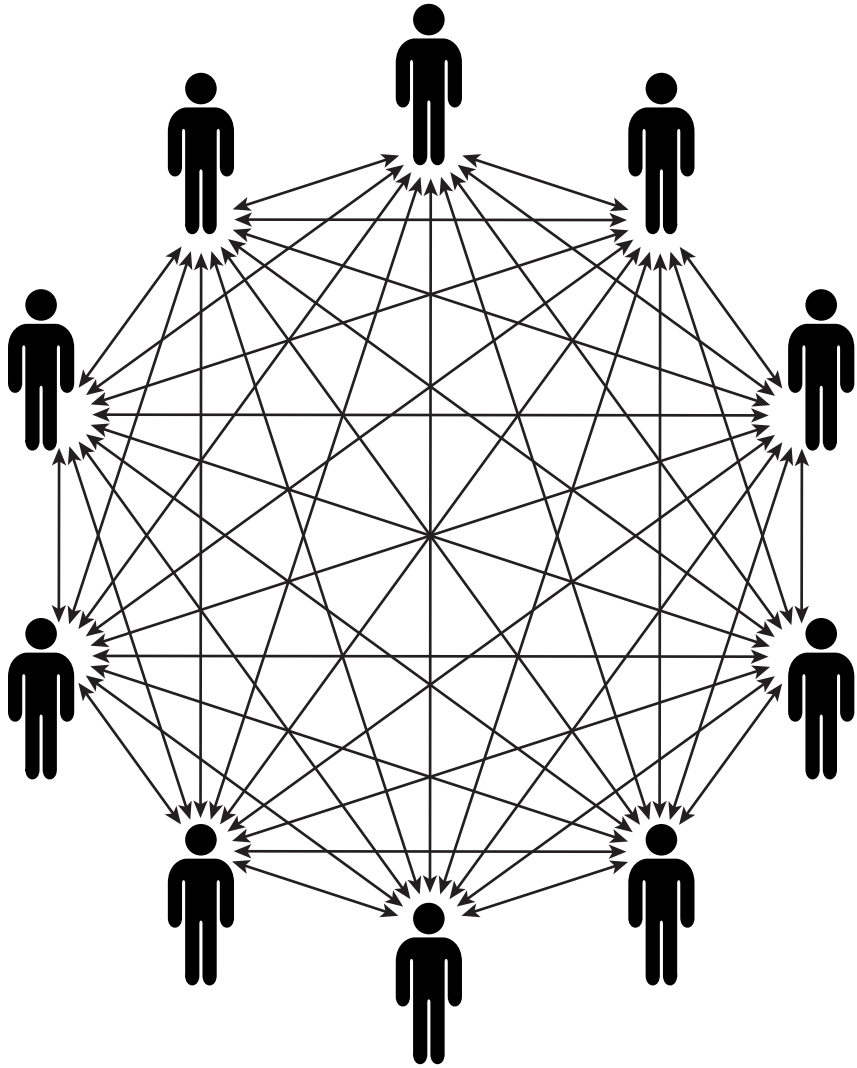

Exhibit 16-2. Ten people require 45 keys.

There are several public key cryptographic algorithms, including RSA, Diffie-Hellman, and Elliptic Curve cryptography. These algorithms relay on the assumption that there are mathematical problems that are easy to perform but difficult to do in reverse. To demonstrate this to yourself, calculate 11 squared (11^2). Now calculate the square root of 160. The square root is a bit more difficult, right? This is the extremely simplified idea behind public key cryptography. Encrypting a document to someone is akin to squaring a number, while decrypting it without the private key is somewhat

like taking the square root. Each of the public key algorithms uses a different type of problem, but all rely on the assumption that the particular problem chosen is difficult to perform in reverse without the key.

Most public key algorithms have associated "signature" algorithms that can be used to ensure that a piece of data was sent by the owner of a private key and was unchanged in transit. These digital signature algorithms are commonly employed to ensure data integrity, but do not, in and of themselves, keep data confidential.

Public key cryptography can be employed to protect data confidentiality and integrity while it is being transported across the network. In fact, Secure Sockets Layer (SSL) is just that: a server's public key is used to create an encrypted tunnel across which World Wide Web (WWW) data is sent. SSL is commonly used for WWW sites that accept credit card information; in fact, the major browsers support SSL natively, as do most Web servers. Unfortunately, SSL does not address all the issues facing an organization that wants to open up its data to network access. By default, SSL authenticates only the server, not the client. However, an organization would want to provide its data only to the correct person; in other words, the whole point of this exercise is to ensure that the client is authenticated.

The SSL standards provide methods to authenticate not only the server, but also the client. Doing this requires having the client side generate a key pair and having the server check the client keys. However, how can the server know that the supposed client is not an imposter even if the client has a key pair? Additionally, even if a key does belong to a valid user, what happens when that user leaves the company, or when the user's key is compromised? Dealing with these situations requires a process called key revocation. Finally, if a user generates a key pair, and then uses that key pair to, for example, encrypt attachments to business-related electronic mail, the user's employer may be required by law to provide access to user data when served with a warrant. For an organization to be able to answer such a warrant, it must have "escrowed" a copy of the users' private keys — but how could the organization get a copy of the private key, since the user generated the pair?

Public key cryptography has a major advantage over secret key cryptography. Recall that secret key cryptography required that the sender and recipient share a secret key in advance. Public key cryptography does not require the sharing of a secret between sender and recipients, but is far slower than secret key cryptography, because the mathematics involved are far more difficult.

Although this simplifies key distribution, it does not solve the problem. Public key cryptography requires a way to ensure that John Doe's public key in fact belongs to him, not to an imposter. In other words, anyone could

generate a key pair and assert that the public key belongs to the President of the United States. However, if one were to want to communicate with the President securely, one would need to ensure that the key was in fact his. This assurance requires that a trusted third party assert a particular public key does, in fact, belong to the supposed user. Providing this assurance requires additional elements, which, together make up a public key infrastructure (PKI).

The next section describes a complete solution that can provide data confidentiality and integrity protection for remote access to applications. Subsequent sections point out other advantages yielded by the development of a full-fledged infrastructure.

USING A PKI TO AUTHENTICATE TO AN APPLICATION

Let us first describe, at a high level, how a WWW-based application might employ a PKI to authenticate its users (see Exhibit 16-3). The user directs her WWW browser to the (secured) WWW server that connects to the application. The WWW page uses the form of SSL that requires both server and client authentication. The user must unlock her private key; this is done by entering a password that decrypts the private key. The server asks for the identity of the user, and looks up her public key in a database. After retrieving her public key, the server checks to be sure that the user is still authorized to access the application system, by checking to be sure that the user's key has not been revoked. Meanwhile, the client accesses the key database to get the public key for the server and checks to be sure it has not been revoked. Assuming that the keys are still valid, the server and client engage in mutual authentication.

There are several methods for mutual authentication. Regardless of approach, mutual authentication requires several steps; the major difference between methods is the order in which the steps occur. Exhibit 16-4 presents a simple method for clarity. First, the server generates a piece of random data, encrypts it with the client's public key, and signs it with its own private key. This encrypted and signed data is sent to the client, who checks the signature using the server's public key and decrypts the data. Only the client could have decrypted the data, because only the client has access to the user's private key; and only the server could have signed the data, because to sign the encrypted data, the server requires access to the server's private key. Hence, if the client can produce the decrypted data, the server can believe that the client has access to the user's private key. Similarly, if the client verifies the signature using the server's public key, the client is assured that the server signed the data. After decrypting the data, the client takes it, along with another piece of unique data, and encrypts both with the server's public key. The client then signs this piece of encrypted data and sends it off to the server. The server checks the

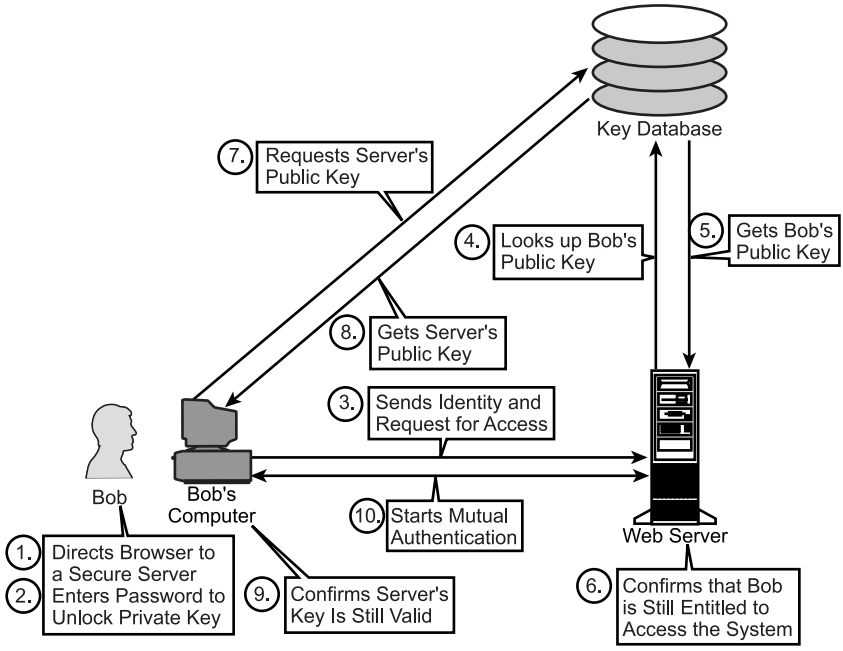

Exhibit 16-3. Using a PKI to authenticate users.

signature, decrypts the data, checks to be sure the first piece of data is the same as what the server sent off before, and gathers the new piece of data. The server generates another random number, takes this new number along with the decrypted data received from the client, and encrypts both together. After signing this new piece of data, the resulting data is sent off to the client. Only the client can decrypt this data, and only the server could have signed it. This series of steps guarantees the identity of each party. After mutual authentication, the server sends a notice to the log server, including information such as the identity of the user, client location, and time.

Recall that public key cryptography is relatively slow; the time required to encrypt and decrypt data could interfere with the user experience. However, if the application used a secret key algorithm to encrypt the data passing over the connection, after the initial public key authentication, the data would be kept confidential to the two participants, but with a lower overhead. This is the purpose of the additional piece of random data in the second message sent by the server. This additional piece of random data will be used as a session key — a secret shared by client and server. Both client and server will use the session key to encrypt all network transactions in the current network connection using a secret key algorithm such as DES, IDEA, or RC4. The secret key algorithm provides confidentiality and

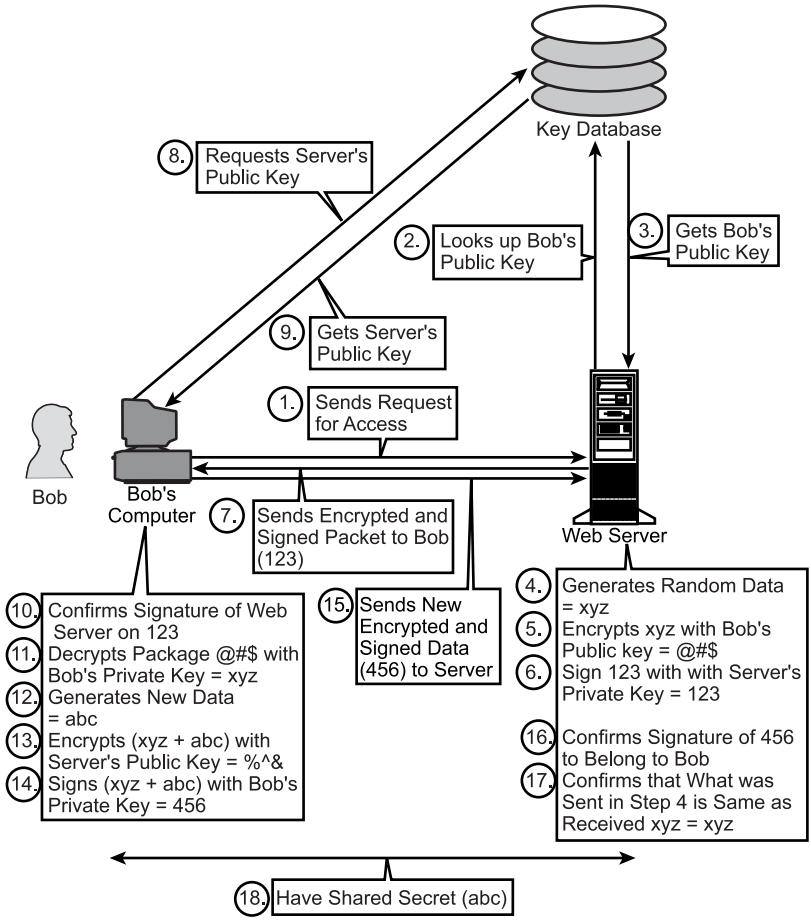

Exhibit 16-4. Mutual authentication.

integrity assurance for all data and queries as they traverse the network without the delay required by a public key algorithm. The public key algorithm handles key exchange and authentication. This combination of both a public key algorithm and a private key one offers the benefits of each.

How did these steps ensure that both client and server were authenticated? The client, after decrypting the data sent by the server, knows that the server was able to decrypt what the client sent, and hence knows that the server can access the server's private key. The server knows that the client has decrypted what it sent in the first step, and thus knows that the client has access to the user's private key. Both parties have authenticated the other, but no passwords have traversed the network, and no information that could be useful to an attacker has left the client or server machines.

Additionally, the server can pass the authentication through to the various application servers without resorting to insecure operating system-level trust relationships, as is often done in multi-system installations. In other words, a user might be able to leverage the public key authentication to not only the WWW-based application, but also other business applications. More details on this reduced sign-on functionality are provided in a later section.

COMPONENTS OF A PKI

The behavior described in the example above seemed very simple, but actually involved several different entities behind the scenes. As is so often the case, a lot of work must be done to make something seem simple. The entities involved here include a certificate authority, registration authorities, directory servers, various application programming interfaces and semi-custom development, third-party applications, and hardware. Some of these entities would be provided by a PKI vendor, such as the CA, RA, and a directory server, but other components would be acquired from other sources. Additionally, the policies that define the overall infrastructure and how the pieces interact with each other and the users are a central component. This section describes each component and tells why it is important to the overall desired behavior.

The basic element of a PKI is the certificate authority. One of the problems facing public key solutions is that anyone can generate a public key and claim to be anyone they like. For example, using publicly available tools, one can generate a public key belonging, supposedly, to the President of the United States. The public key will say that it belongs to the President, but it actually would belong to an imposter. It is important for a PKI to provide assurance that public keys actually belong to the person who is named in the public key. This is done via an external assurance link; to get a key pair, one demonstrates to a human that they are who they claim to be. For example, the user could, as part of the routine on the first day of employment, show his driver's license to the appropriate individual, known as a registration authority. The registration authority (RA) generates a key pair for the individual and tells the certificate authority (CA) to attest that the public key belongs to the individual. The CA does this attestation by signing the public key with the CA's private key. All users trust the CA. Because only the CA could access the CA's private key, and the private key is used to attest to the identity, all will believe that the user is in fact who the user claims to be. Thus, the CA (and associated RA) is required in order for the PKI to be useful, and any compromise of the CA's key is fatal for the entire PKI. CAs and RAs are usually part of the basic package bought from a PKI vendor. An abridged list of PKI vendors (in alphabetical order) includes Baltimore, Entrust Technologies, RSA Security, and Verisign.

When one user (or server) wants to send an encrypted object to another, the sender must get the recipient's public key. For large organizations, there can be thousands of public keys, stored as certificates signed by the CA. It does not make sense for every user to store all other certificates, due to storage constraints. Hence, a centralized storage site (or sites) must store the certificates. These sites are databases, usually accessed via the Lightweight Directory Access Protocol (LDAP), and normally called directory servers. A directory server will provide access throughout the enterprise to the certificates when an entity requires one. There are several vendors for LDAP directories, including Netscape, ICL, Novell, and Microsoft.

There are other roles for directory servers, including escrow of users' private keys. There are several reasons why an organization might need access to users' private keys. If an organization is served by a warrant, it may be required to provide access to encrypted objects. Achieving this usually involves having a separate copy of users' private keys; this copy is called an "escrowed" key. LDAP directories are usually used for escrow purposes. Obviously, these escrow databases must be extremely tightly secured, because access to a user's private key compromises all that user's correspondence and actions. Other reasons to store users' private keys include business continuity planning and compliance monitoring.

When a sender gets a recipient's public key, the sender cannot be sure that the recipient still works for the organization, and does not know if someone has somehow compromised that key pair. Human resources, however, will know that the recipient has left the organization and the user may know that the private key has been compromised. In either case, the certificate signed by the CA — and the associated private key — must be revoked. Key revocation is the process through which a key is declared invalid. Much as it makes little sense for clients to store all certificates, it is not sensible for clients to store all revoked certificates. Rather, a centralized database — called a certificate revocation list (CRL) — should be used to store revoked certificates. The CRL holds identifiers for all revoked certificates. Whenever an entity tries to use a certificate, it must check the CRL in order to ensure that the certificate is still valid; if an entity is presented a revoked certificate, it should log the event as a possible attack on the infrastructure. CRLs are often stored in LDAP databases, in data structures accessible through Online Certificate Status Processing (OCSP), or on centralized revocation servers, as in Valicert's Certificate Revocation Tree service. Some PKIs have ability to check CRLs, such as Entrust's Entelligence client, but most rely on custom software development to handle CRL checking. Additionally, even for PKIs supporting CRL checking, the capabilities do not provide access to other organization's CRLs — only a custom LDAP solution or a service such as, for example, Valicert's can provide this inter-organization (or inter-PKI) capability.

Off-the-shelf PKI tools are often insufficient to provide complete auditing, dual authentication, CRL checking, operating system integration, and application integration. To provide these services, custom development must be performed. Such development requires that the application and PKI both support application programming interfaces (APIs). The API is the language that the application talks and through which the application is extended. There are public APIs for directory servers, operating system authentication, CRL checking, and many more functions. It is very common for applications to support one or more APIs. Many PKI vendors have invested heavily in the creation of toolkits — notably, RSA Security, Entrust Technologies, and Baltimore.

For both performance and security reasons, hardware cryptographic support can be used as part of a PKI. The hardware support is used to generate and store keys and also to speed cryptographic operations. The CA and RAs will almost always require some sort of hardware support to generate and store keys. Potential devices include smart cards, PCMCIA cards, or external devices. An abridged list of manufactures includes Spyrus, BBN, Atalla, Schlumberger, and Rainbow. These devices can cost anywhere from a few dollars up to $5000, depending on model and functionality. They serve not only to increase the performance of CA encryption, but also to provide additional security for the CA private key, because it is difficult to extract the private key from a hardware device.

Normally, one would not employ a smart card on a CA but, if desired, user private keys can be stored on smart cards. Such smart cards may provide additional functionality, such as physical access to company premises. Employing a smart card provides higher security for the user's private key because there is (virtually) no way for the user's private key to be removed from the card, and all computations are performed on the card itself. The downside of smart cards is that each card user must be given both a card and a card reader. Note that additional readers are required anywhere a user wishes to employ the card. There are several card manufacturers, but only some cards work with some PKI selections. The card manufacturers include Spyrus, Litronic, Datakey, and GemPlus. In general, the cards cost approximately $100 per user, including both card and reader.

However, the most important element of a PKI is not a physical element at all, but rather the policies that guide design, implementation, and operation of the PKI. These policies are critical to the success of a PKI, yet are often given short shrift during implementation. The policies are called a "Certificate Practice Statement" (CPS). A CPS includes, among other things, direction about how users are to identify themselves to an RA in order to get their key pair; what the RA should do when a user loses his password (and hence cannot unlock his private key); and how keys should be escrowed, if at all. Additionally, the CPS covers areas such as backup

policies for the directory servers, CA, and RA machines. There are several good CPS examples that serve as the starting point for an implementation. A critical element of the security of the entire system is the sanctity of the CA itself — the root key material, the software that signs certificate requests, and the OS security itself. Extremely serious attention must be paid to the operational policies — how the system is administered, background checks on the administrators, multiple-person control, etc. — of the CA server.

The technology that underpins a PKI is little different from that of other enterprisewide systems. The same concerns that would apply to, for example, a mission-critical database system should be applied to the PKI components. These concerns include business continuity planning, stress and load modeling, service-level agreements with any outsourced providers or contract support, etc. The CA software often runs either on Windows NT or one of the UNIX variants, depending on the CA vendor. The RA software is often a Windows 9x client. There are different architectures for a PKI. These architectures vary on, among other things, the number and location of CA and RA servers, the location, hierarchy, and replication settings of directory servers, and the "chain of trust" that carries from sub-CA servers (if any) back to the root CA server. Latency, load requirements, and the overall security policy should dictate the particular architecture employed by the PKI.

OTHER PKI BENEFITS: REDUCED SIGN-ON

There are other benefits of a PKI implementation — especially the promise of reduced sign-on for users. Many applications require several authentication steps. For example, a user may employ one username and password pair to log on to his local desktop, others to log on to the servers, and yet more to access the application and data itself. This creates a user interaction nightmare; how many usernames and passwords can a user remember? A common solution to this problem is to employ "trust" relationships between the servers supporting an application. This reduces the number of logins a user must perform, because logging into one trusted host provides access to all others. However, it also creates a significant security vulnerability; if an attacker can access one trusted machine, the attacker has full access to all of them. This point has been exploited many times during PricewaterhouseCoopers attack and penetration exercises. The "attackers" find a development machine, because development machines typically are less secure than production machines, and attack it. After compromising the development machine, the trust relationships allow access to the production machines. Hence, the trust relationships mean that the security of the entire system is dependent not on the most secure systems — the production servers — but rather on the least secure ones.

Even using a trust relationship does not entirely solve the user interaction problem; the user still has at least one operating system username and password pair to remember and another application username and password. PKI systems offer a promising solution to this problem. The major PKI vendors have produced connecting software that replaces most operating system authentication processes with a process that is close to the PKI authentication system described above.

The operating system authentication uses access to the user's private key, which is unlocked with a password. After unlocking the private key, it can be used in the PKI authentication process described above. Once the private key is unlocked, it remains unlocked for a configurable period of time. The user would unlock the private key when first used, which would typically be when logging in to the user's desktop system. Hence, if the servers and applications use the PKI authentication mechanism, the users will not need to reenter a password — they need unlock the private key only once. Each system or application can, if it desires, engage in authentication with the user's machine, but the user need not interact, because the private key is already unlocked. From the user's perspective, this is single sign-on, but without the loss of security provided by other partial solutions (such as trust relationships).

There are other authentications involved in day-to-day business operations. For example, many of us deal with legacy systems. These legacy systems have their own, often proprietary, authentication mechanisms. Third-party products provide connections between a PKI and these legacy applications. A username and password pair is stored in a protected database. When the user attempts to access the legacy application, a "proxy" application requests PKI-based authentication. After successfully authenticating the user — which may not require reentry of the user's PKI password — the server passes the legacy application the appropriate username and password and connects the client to the legacy application. The users need not remember the username and password for the legacy application because they are stored in the database. Because the users need not remember the password, the password can be as complicated as the legacy application will accept, thus making security compromise of the legacy application more difficult while still minimizing user interaction headaches.

Finally, user keys, as mentioned above, can be stored as files or on tokens, often called smart cards. When using a smart card, the user inserts the card into a reader attached to the desktop and authenticates to the card, which unlocks the private key. From then on, the card will answer challenges sent to it and issue them in turn, taking the part of the client machine in the example above. Smart cards can contain more than simply the user keys, although this is their main function. For example, a person's picture can be printed onto the smart card, thus providing a corporate

identification badge. Magnetic stripes can be put on the back of the smart card and encoded with normal magnetic information. Additionally, smart card manufacturers can build proximity transmitters into their smart card. These techniques allow the same card that authenticates the user to the systems to allow the user access to the physical premises of the office. In this model, the PKI provides not only secure access to the entity's systems and applications with single sign-on, but also to physically secured areas of the entity. Such benefits are driving the increase in the use of smart cards for cryptographic security.

PKI IN OPERATION

With the background of how a PKI works and descriptions of its components, one can now walk through an end-to-end example of how a hypothetical organization might operate its PKI.

Imagine a company, DCMEF, Inc., which has a few thousand employees located primarily in southern California. DCMEF, Inc. makes widgets used in the manufacture of automobile air bags. DCMEF uses an ERP system for manufacturing planning and scheduling as well as for its general ledger and payables. It uses a shop-floor data management system to track the manufacturing process, and has a legacy system to maintain human resource-related information. Employees are required to wear badges at all times when in the facility, and these same picture badges unlock the various secured doors at the facility near the elevators and at the entrances to the shop floor via badge readers.

DCMEF implemented its PKI in 1999, using commercial products for CA and directory services. The CA is located in a separately secured data center, with a warm standby machine locked in a disaster recovery site in the Midwest. The warm standby machine does not have keying material. The emergency backup CA key is stored in a safety deposit box that requires the presence of two corporate officers or directors to access. The CA is administered by a specially cleared operations staff member who does not have access to the logging server, which ensures that that operations person cannot ask the CA to do anything (such as create certificates) without a third person seeing the event. The RA clients are scattered through human resources, but are activated with separate keys, not the HR representatives' normal day-to-day keys.

When new employees are hired, they are first put through a two-day orientation course. At this course, the employees fill out their benefits forms, tax information, and also sign the data security policy form. After signing the form, each employee is given individual access to a machine that uses cryptographic hardware support to generate a key pair for that user. The public half of the key pair is submitted to the organization's CA for certification by

the human resources representative, who is serving as the RA, along with the new employee's role in the organization.

The CA checks to be sure that the certificate request is correctly formed and originated with the RA. Then, the CA creates and signs a certificate for the new employee, and returns the signed certificate to the human resources representative. The resulting certificate is stored on a smart card at that time, along with the private key. The private key is locked on the smart card with a PIN selected by the user (and known only to that user). DCMEF's CPS specifies a four-digit PIN, and prohibits use of common patterns like "1234" or "1111." Hence, each user selects four digits; those who select inappropriate PIN values are prompted to select again until their selection meets DCMEF policies.

A few last steps are required before the user is ready to go. First, a copy of each user's private key is encrypted with the public key of DCMEF's escrow agent and stored in the escrow database. Then, the HR representative activates the WWW-based program that stores the new employee's certificate in the directory server, along with the employee's phone number and other information, and adds the employee to the appropriate role entry in the authentication database server. After this step, other employees will be able to look up the new employee in the company electronic phone book, be able to encrypt e-mail to the new employee, and applications will be able to determine the information to which the employee should have access. After these few steps, the user is done generating key material.

The key generating machine is rebooted before the next new employee uses it. During this time, the new employee who is finished generating a key pair is taken over to a digital camera for an identification photograph. This photograph is printed onto the smart card, and the employee's identification number is stored on the magnetic strip on the back of the card to enable physical access to the appropriate parts of the building.

At this point, the new employees return to the orientation course, armed with their smart cards for building access loaded with credentials for authentication to the PKI. This entire process took less than 15 minutes per employee, with most of that spent typing in information.

The next portion of the orientation course is hands-on instruction on using the ERP modules. In a normal ERP implementation, users have to log on to their client workstation, to an ERP presentation server and, finally, to the application itself. In DCMEF, Inc., the users need only insert their smart cards into the readers attached to their workstations (via either the serial port or a USB port, in this case), and they are logged in transparently to their local machine and to every PKI-aware application — including the ERP system. When the employees insert their smart cards, they are

prompted for the PIN to unlock their secret key. The remainder of the authentication to the client workstation is done automatically, in roughly the manner described above. When the user starts the ERP front-end application, it expects to be given a valid certificate for authentication purposes, and expects to be able to look that certificate up in an authorization database to select which ERP data this user's role can access. Hence, after the authentication process between ERP application server and user (with the smart card providing the user's credentials) completes, the user has full access to the appropriate ERP data. The major ERP packages are PKI-enabled using vendor toolkits and internal application-level controls. However, it is not always so easy to PKI-enable a legacy application, such as DCMEF's shop-floor data manager. In this case, DCMEF could have chosen to leave the legacy application entirely alone, but that would have meant users would need to remember a different username and password pair to gain access to the shop-floor information, and corporate security would need to manage a second set of user credentials. Instead, DCMEF decided to use a gateway approach to the legacy application. All network access to the shop-floor data manager system was removed, to be replaced by a single gateway in or out. This gateway ran customized proxy software that uses certificates to authenticate users. However, the proxy issues usernames and passwords that match the user's role to the shop-floor data manager. There are fewer roles than users, so it is easier to maintain a database of role-password pairs, and the shop-floor data manager itself does not know that anything has changed. The proxy application must be carefully designed and implemented, because it is now a single point of failure for the entire application, and the gateway machine should be hardened against attack.

The user credentials issued by HR expire in 24 months — this period was selected based on the average length of employment at DCMEF, Inc. Hence, every two years, users must renew their certificates. This is done via an automatic process; users visit an intranet WWW site and ask for renewal. This request is routed to human resources, which verifies that the person is still employed and is still in the same role. If appropriate, the HR representative approves the request, and the CA issues a new certificate — with the same public key — to the employee, and adds the old certificate to DCMEF's revocation list. If an employee leaves the company, HR revokes the user's certificate (and hence their access to applications) by asking the CA to add the certificate to the public revocation list. In DCMEF's architecture, a promoted user needs no new certificate, but HR must change the permissions associated with that certificate in the authorization database.

This example is not futuristic at all — everything mentioned here is easily achievable using commercial tools. The difficult portions of this example are related to DCMEF itself. HR, manufacturing, planning, and accounting

use the PKI on a day-to-day basis. Each of these departments has its own needs and concerns that need to be addressed up-front, before implementation, and then training, user acceptance, and updates must include each department going forward. A successful PKI implementation will involve far more than corporate information security — it will involve all the stakeholders in the resulting product.

IMPLEMENTING A PKI: GETTING THERE FROM HERE

The technical component of building a PKI requires five logical steps:

1. The policies that govern the PKI, known as a Certificate Practice Statement (CPS), must be created.
2. The PKI that embodies the CPS must be initialized.
3. Users and administration staff must be trained.
4. Connections to secured systems that could circumvent the PKI must be ended.
5. Any other system integration work — such as integrating legacy applications with the PKI, using the PKI for operating system authentication, or connecting back-office systems including electronic mail or human resource systems to the PKI — must be done.

The fourth and fifth steps may not be appropriate for all organizations.

The times included here are based on the authors' experience in designing and building PKI systems, but will vary for each situation. Some of the variability comes from the size of clients; it requires more time to build a PKI for more users. Other variability derives from a lack of other standards; it is difficult to build a PKI if the organization supports neither Windows NT nor UNIX, for example. In any case, the numbers provided here offer a glimpse into the effort involved in implementing a PKI as part of an ERP implementation.

The first step is to create a CPS. Creating a CPS involves taking a commonly accepted framework, such as the National Automated Clearing House Association guidelines, PKIX-4, or the framework promulgated by Entrust Technologies, and adapting it to the needs of the particular organization. The adaptations involve modification of roles to fit organizational structures and differences in state and federal regulation. This step involves interviews and extensive study of the structure and the environment within which the organization falls. Additionally, the CPS specifies the vendor for the PKI as well as for any supporting hardware or software, such as smart cards or directories. Hence, building a CPS includes the analysis stage of the PKI selection. Building a CPS normally requires approximately three person-months, assuming that the organization has in place certain components, such as an electronic mail policy and Internet use policy, and results in a document that needs high-level approval, often including legal review.

The CPS drives the creation of the PKI, as described above. Once the CPS is complete, the selected PKI vendor and products must be acquired. This involves hardware acquisition for the CA, any RA stations, the directories, and secure logging servers, as well as any smart cards, readers, and other hardware cryptographic modules. Operating system and supporting software must be installed on all servers, along with current security-related operating system patches. The servers must all be hardened, as the security of the entire system will rely to some extent on their security. Additional traditional information security work, such as the creation of intrusion detection systems, is normally required in this phase. Many of the servers — especially the logging server — will require hardware support for the cryptographic operations they must perform; these cryptographic support modules must be installed on each server. Finally, with the pieces complete, the PKI can be installed.

Installing the PKI requires, first, generating a "root" key and using that root key to generate a CA key. This generation normally requires hardware support. The CA key is used to generate the RA keys that in turn generate all user public keys and associated private keys. The CA private key signs users' public keys, creating the certificates that are stored on the directory server. Additionally, the RA must generate certificates for each server that requires authentication. Each user and server certificate and the associated role — the user's job — must be entered into a directory server to support use of the PKI by, for example, secure electronic mail. The server keys must be installed in the hardware cryptographic support modules, where appropriate. Client-side software must be installed on each client to support use of the client-side certificates. Additionally, each client browser must be configured to accept the organization's CA key and to use the client's certificate. These steps, taken together, constitute the initialization of the PKI. The time required to initialize a PKI is largely driven by the number of certificates required. In a recent project involving 1000 certificates, ten applications, and widespread use of smart cards, the PKI initialization phase required approximately twelve person-months. Approximately two person-months of that time were spent solely on the installation of the smart cards and readers.

Training cannot be overlooked when installing large-scale systems such as a PKI. With the correct architecture, much of the PKI details are below users' awareness, which minimizes training requirements. However, the users have to be shown how to unlock their certificates, a process that replaces their login, and how to use any ancillary PKI services, such as secure e-mail and the directory. This training is usually done in groups of 15 to 30 and lasts approximately one to two hours, including hands-on time for the trainees.

After training is completed, users and system administration staff are ready to use the PKI. At this point, one can begin to employ the PKI itself.

This involves ensuring that any applications or servers that should employ the PKI cannot be reached without using the PKI. Achieving this goal often requires employing third-party network programs that interrupt normal network processing to require the PKI. Additionally, it may require making configuration changes to routers and operating systems to block back door entry into the applications and servers. Blocking these back-doors requires finding all connections to servers and applications; this is a non-trivial analysis effort that must be included in the project planning.

Finally, an organization may want to use the PKI to secure applications and other business processes. For example, organizations, as described above, may want to employ the PKI to provide single sign-on or legacy system authentication. This involves employing traditional systems integration methodologies — and leveraged software methodologies — to mate the PKI to these other applications using various application programming interfaces. Estimating this effort requires analysis and requirements assessment.

As outlined here, a work plan for creating a PKI would include five steps. The first step is to create a CPS. Then, the PKI is initialized. Third, user and administrator training must be performed. After training, the PKI connections must be enforced by cutting off extraneous connections. Finally, other system integration work, including custom development, is performed.

CONCLUSION

Security is an enabler for electronic business; without adequate security, senior management may not feel confident moving away from more expensive and slower traditional processes to more computer-intensive ones. Security designers must find usable solutions to organizational requirements for authentication, authorization, confidentiality, and integrity. Public key infrastructures offer a promising technology to serve as the foundation for E-business security designs. The technology itself has many components — certificate authorities, registration authorities, directory servers — but, even more importantly, requires careful policy and procedure implementation.

This chapter has described some of the basics of cryptography, both secret and public key cryptography, and has highlighted the technical and procedural requirements for a PKI. The authors have presented the five high-level steps that are required to implement a PKI, and have mentioned some vendors in each of the component areas. Obviously, in a chapter this brief, it is not possible to present an entire workplan for implementing a PKI — especially since the plans vary significantly from situation to situation. However, the authors have tried to give the reader a start toward such a plan by describing the critical factors that must be addressed, and showing how they all work together to provide an adequate return on investment.

116

Preserving Public Key Hierarchy

Geoffrey C. Grabow, CISSP

Public key infrastructures (PKIs) have always been designed with a top-level key called a root key. This single key is responsible for providing the starting point of trust for all entities below it in the hierarchy. If this root key is ever compromised, the entire trust hierarchy is immediately questionable.

The root key is primarily responsible for digitally signing subordinate Certificate Authorities (CAs). A compromise of the root means that an unauthorized CA will appear perfectly valid to users. Users will then engage in a transaction completely unaware that the security upon which they are relying is worse than worthless.

This single root key introduces a single point of failure.

It is a standard practice in security to design and build systems with a series of checks and balances to prevent any one part of the system from causing a catastrophic failure. However, this practice, for all practical purposes, has been ignored when it comes to a hierarchical PKI.

It is the intention of this chapter to propose a system in which this single point of failure is removed.

Cryptographically secure digital timestamps (CSDTs) have been used for a wide variety of purposes, including document archiving, digital notary services, etc. By adding a CSDT to every digital certificate issued within a PKI, one now has a method for ensuring not only that the certificate is valid, but also at what point in time that validity was declared.

When properly configured, certificates within a PKI, which are protected using CSDTs, can survive the compromise of the root key. If the root key is exposed, certificates still have their original value, and all that is lost is the ability to create new certificates. This allows transactions to continue, and the recovery process only requires the replacement of the root key.

A significant advantage of the system proposed herein is that it works within the parameters set forth in existing PKI standards.

Public Key Infrastructure (PKI)

Public key (or asymmetric) cryptography uses two different keys, usually referred to as a public key and a private key. Any information encrypted by K_{PUB}(Recipient) can only be decrypted by K_{PRI}(Recipient), and vice versa. The two keys are mathematically linked and it is computationally infeasible[1] to determine the private key from the public key. This allows the recipient to create a key pair and to publish K_{PUB}(Recipient) in a location that anyone can find it. Once the sender has a copy of K_{PUB}(Recipient), encrypted information can be sent to the recipient without the problem of transporting a secret key.

Sender:

$$\text{DATA} + K_{PUB}(\text{Recipient}) + \text{Encryption algorithm} = EK_{PUB}(\text{Recipient})[\text{Data}]$$

Recipient:

$$EK_{PUB}(Recipient)[DATA] + K_{PRI}(Recipient) + Decryption\ algorithm = Data$$

The reverse of this process is also true. If the recipient encrypts data with K_{PRI}(Recipient), it can be decrypted with K_{PUB}(Recipient). This means that anyone can decrypt the information and confidentiality has not been achieved; but if it can be decrypted using K_{PUB}(Recipient), then only K_{PRI}(Recipient) could have encrypted it, thereby identifying the individual[2] who sent the data. This is the principle behind a digital signature. However, in a true digital signature scheme, only a hash of the data is encrypted/decrypted to save processing time.

Standard PKI Hierarchical Construction

While asymmetric key systems have solved the key management problem in traditional symmetric key systems, they have introduced a new problem called "trust management." This problem raises the question of "How can I be sure the public key I am using really belongs to the intended recipient?" This problem, typically referred to as a man-in-the-middle attack, happens when a third party (attacker) introduces its public key to the sender, who is fooled into believing that it is the public key of recipient, and vice versa. Obviously, this would allow the attacker to read and potentially modify all communication between the sender and the recipient without either of them being aware of the attacker whatsoever.

This problem is solved through the use of a Certificate Authority. The CA digitally signs a certificate that belongs to the sender and another certificate that belongs to the recipient. The certificate includes the name and public key of its owners, the integrity of which can be checked through the use of the CA's public key. Unfortunately, that means that the sender and the recipient must belong to the same CA. If they are not members of the same CA, a hierarchy of CAs must be established (see Exhibit 116.1).

Each entity in Exhibit 116.1 has its own certificate that is signed by an entity higher up in the hierarchy. This is the method used to transfer trust from a known entity to one that is unknown. The exception to this is the Root, which creates a self-signed certificate. The Root must establish trust through direct contact and business relationships with the CAs.

In this environment, Alice can digitally sign a document and send it to Bob, along with a copy of her certificate as well as the certificate of CA#1. Because Bob already has a trust relationship with CA#2, and CA#2 has a trust relationship with the Root, Bob can validate the certificate of CA#2 and then validate Alice's certificate. Once Bob trusts Alice's certificate, he believes that anything that he can verify with Alice's public key must have been signed by Alice's private key, and therefore must have come from Alice.

The Impact of a Root Key Compromise

The problem with this hierarchical construction is the total reliance on the security of the Root private key. If the K_{PRI}(Root) is compromised by an attacker, that attacker can create a fraudulent CA#3, and then fraudulent

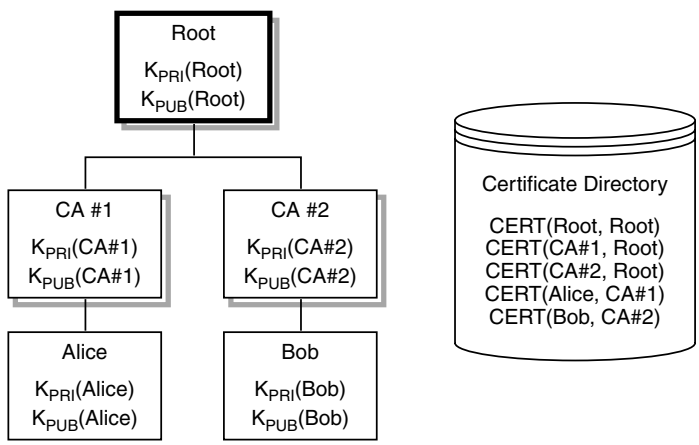

EXHIBIT 116.1 Basic PKI hierarchy

users under that CA. Because CA#3 can be positively validated using the public key of the Root, Alice, Bob, and everyone who trusts the Root will accept any users under CA#3. This puts Alice, Bob, and everyone else in this hierarchy in a situation in which they are trusting fraudulent users and are unaware that there is a problem.

If this occurs, the entire system falls apart. No transactions can take place because there is no basis for trust. An even more significant impact of this situation is that as soon as Alice and Bob are informed about the problem, they will not only stop trusting users under CA#3, but also not be able to trust anyone in the entire hierarchy. Because a CA#3 was created fraudulently, any number of fraudulent CAs can be created and there is no way to determine the CAs not to be trusted from those that should be.

If one cannot determine which CAs are to be trusted, then there is no way to determine which users' certificates are to be trusted. This causes the complete collapse of the entire hierarchy, from the top down.

Constructing Cryptographically Secure Digital Timestamps

Cryptographically secure digital timestamps (CSDTs) are nothing new. A wide variety of applications have been making use of secure timestamps for many years. It is not the intention of this chapter to delve into the details of the actual creation of a CSDT, but rather to indicate the minimum required data for inclusion within digital certificates.

Timestamp

Of course, because one of the primary components of a CSDT is the timestamp itself, a "trusted" time source is required. This can be achieved in several accepted methods and, for the purposes of this construct, it will be assumed that the actual timestamp within the CSDT is the correct one.

To allow for high-volume transaction environments, a 16-bit sequence number is appended to the timestamp to ensure that there can be no two CSDTs with the identical time. This tie-breaker value should be reset with each new timestamp. Therefore, if the time resolution is 0.0001 seconds, it is possible to issue 65,536 CSDTs that all happen within that same 0.0001 second, but the exact sequence of CSDT creation can be determined at any future time.

Hash of the Certificate

For a CSDT to be bound to a particular certificate, some data must be included to tie it to the certificate in question. A hash generated by a known and trusted algorithm, such as SHA-1 or MD5, is used to provide this connection. This is the same hash that is calculated and encrypted during the Certificate Authority signing process.

More importantly, it is critical to know that the time in the CSDT is the time when the CA signs the certificate. Therefore, not just the hash of the certificate should be included, but rather the entire digital signature added to the certificate by the CA. Using the CA's signature will also provide for future changes in CA signing standards.

However, because one of the goals of this chapter is to provide a new feature to existing certificate standards without changing the standards, one cannot append information to the certificate after the signature. Rather, the CSDT must be added to the certificate prior to it being signed by the CA and inserted into an x.509v3 extension field.

Certificate Authority Certificate Hash

As an additional measure, the hash of the CA's certificate is embedded in the CSDT to provide a record of which CA made the request to the Time Authority (TA).

Digital Signature of the Time Authority

To prevent tampering, the CSDT must be cryptographically sealed using a standard digital signature. Because the total amount of data in a CSDT is small, this can be accomplished by simply encrypting the data fields

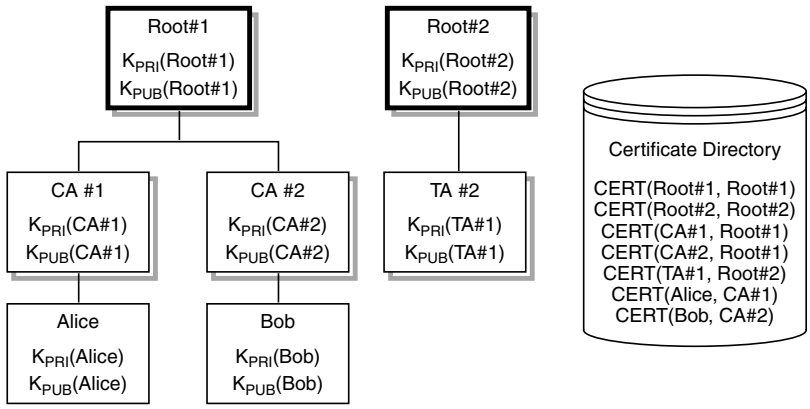

EXHIBIT 116.2 PKI with time authority

with the private key of the TA. However, to allow for growth and additional fields to be added in the future, it is better to encrypt a hash of all of the data to be secured.

Separation of Hierarchies

Of course, the x.509 standard already includes a timestamp so it can be determined at what date and time a certificate was signed by its CA. However, if the root private key was compromised and a fraudulent CA is created, that CA could simply set the time to any value desired prior to signing the certificate.

What is proposed is the inclusion of a timestamp signed by an authority that exists outside the hierarchy of which the CA is part (see Exhibit 116.2).

When a CA creates a certificate, it would follow its normal process for acquiring the public key and other data to be included in the certificate. However, prior to signing the certificate, it would request a CSDT from the Time Authority (TA). This CSDT would then be generated by the TA and returned to the CA. The CA would add the CSDT to the certificate, then sign it in the usual manner.

Should Root#1 be compromised at some point thereafter, all of the CAs created prior to the compromise can still be trusted because access to Root#1 does not give the ability to create the CSDTs. Users can then be informed that anything signed by the Root after a specific date is not to be trusted, but anything signed before that date is still trustworthy.

Walk-Through of Issuance of a Certificate Containing a CSDT

The sequence of events to add a CSDT to a public key certificate is as follows:

1. User generates the public/private key pair.
2. User sends public key and user-specific information to the Registration Authority (RA).
3. RA validates user's request and forwards the certificate request to the CA.
4. CA forms the certificate and calculates the User Certificate Hash (UCH).
5. CA sends a digitally signed request to the Time Authority (TA) containing the UCH.
6. TA receives the request and validates the CA's signature on the request using the CA's public key certificate.
7. TA gets the current time from its secure time source.
8. TA calculates the sequential tie-breaker counter value.
9. TA forms the contents of the CSDT:
   a. UCH (Step 4)
   b. Timestamp (Step 7)
   c. Tie-breaker counter (Step 8)
   d. Hash of CA's certificate (same value used in Step 6)
10. TA calculates the hash of the contents of the CSDT.

11. TA encrypts hash with its private key.
12. TA returns CSDT to the CA.
13. CA validates the TA's signature on the CSDT using the TA's public key certificate.
14. CA verifies UCH in the CSDT against the UCH sent to the TA.
15. CA adds CSDT to the user certificate.
16. CA performs a standard signing process on the completed certificate.
17. CA sends digital certificate to the user.

Recovery Walk-Through

With any system providing assurance, it is necessary to have a plan of action in the event of some problem. The following outlines the minimum necessary steps if a CA is compromised.

Given:

- A CA signed by a CA Root
- A TA signed by a TA Root
- 10,000 users, each of which has generated a public/private key pair
- Each user has gone through the process of getting a public key certificate
- The CA root key is compromised by some form of attack

In infrastructures where CSDTs are not used, all 10,000 user certificates are immediately questionable and cannot be trusted for further transactions. A typical scenario requires the CA to have already created a second replacement root, and to have distributed the second root's self-signed public key certificate when the first was distributed. Users then are told to stop trusting the first root or to delete it from their applications. All users must then generate new key pairs and go through the enrollment process under the new root before business can return to normal.

This is obviously a scenario that requires considerable time and effort, and causes considerable inconvenience for users attempting to execute E-business transactions. Additionally, as the number of users increases, the recovery time increases linearly.

When CSDTs are employed and CSDT-aware applications are used, much of that effort is not required. Immediately upon determining that a compromise has occurred, the CA must:

- Inform the TA not to accept any further requests under the compromised key
- Inform its users
- Generate a new set of keys
- Issue no further certificates under the compromised key

Users need take no action other than to inform their applications of the date/time of the compromise of the CA. All future certificate validation is tested with the CA's certificate as well as the CSDT. If the CA's signature on a certificate is valid, but the CSDT is not present or indicates a date after the compromise, the certificate is rejected and the users are informed that they were presented with an invalid certificate.

Known Issues

Because events such as generating a hash, encryption, and decryption are processes of nonzero duration, it must be acknowledged that the actual time of certificate issuance is not the time within the CSDT. This is not a problem because the time within the CSDT, and within the certificate itself, are not to be used as an absolute time, but rather as a starting point from which the certificate is to be considered valid.

As with any cryptographic system, timely knowledge of any compromise of the system is a critical factor in limiting any "window of opportunity" for an attacker. In this case, it is up to the CA to inform its users that it has had a compromise. Information regarding a compromise of the TA must also be disseminated to users, but users need not take any direct action as a result.

One of the primary responsibilities of a CA is to ensure that everyone who wished to rely on its signature has access to its public key certificate. This is also true for the TA, which must use similar methods to establish trust in its public keys. This may cause some extra effort on the part the CA and its users.

Summary

What has been proposed and discussed in this chapter is a method of providing redundancy in a PKI where none has previously existed. Previous methods of breaking the Root private key into multiple parts created dual control over a single point of failure, but did nothing to provide any systemic redundancy.

It is worthwhile noting that this system is being prototyped by beTRUSTed, the trusted third-party service established by PricewaterhouseCoopers. Their testing, in cooperation with several PKI software vendors, may prove the usefulness and security of this system in a real-world environment.

As with any cryptographic system or protocol, the system of using CSDTs described herein must be analyzed and checked by numerous third parties for possible weaknesses or areas where an attacker may compromise the system.

Notes

1. "Computationally infeasible" indicates that the time or resources required to determine the private key, given only the public key, are well beyond what is available.
2. This assumes that the private keys are generated, used, stored, and destroyed in a secure and proper manner.

PKI Registration

Alex Golod, CISSP

PKI is comprised of many components: technical infrastructure, policies, procedures, and people. Initial registration of subscribers (users, organizations, hardware, or software) for a PKI service has many facets, pertaining to almost every one of the PKI components. There are many steps between the moment when subscribers apply for PKI certificates and the final state, when keys have been generated and certificates have been signed and placed in the appropriate locations in the system. These steps are described either explicitly or implicitly in the PKI Certificate Practices Statement (CPS).

Some of the companies in the PKI business provide all services: hosting Certificate and Registration Authorities (CAs and RAs); registering subscribers; issuing, publishing, and maintaining the current status of all types of certificates; and supporting a network of trust. Other companies sell their extraordinarily powerful software, which includes CAs, RAs, gateways, connectors, toolkits, etc. These components allow buyers (clients) to build their own PKIs to meet their business needs. In all the scenarios, the processes for registration of PKI subscribers may be very different.

This chapter does not claim to be a comprehensive survey of PKI registration. We will simply follow a logical flow. For example, when issuing a new document, we first define the type of document, the purpose it will serve, and by which policy the document will abide. Second, we define policies by which all participants will abide in the process of issuing that document. Third, we define procedures that the parties will follow and which standards, practices, and technologies will be employed. Having this plan in mind, we will try to cover most of the aspects and phases of PKI registration.

CP, CPS, and the Registration Process

The process of the registration of subjects, as well as a majority of the aspects of PKI, are regulated by its Certificate Policies (CP) and Certification Practices Statement (CPS). The definition of CP and CPS is given in RFC 2527, which provides a conduit for implementation of PKIs:

Certificate Policy: A named set of rules indicating the applicability of a certificate to a particular community or class of application with common security requirements. For example, a particular certificate policy might indicate applicability of a type of certificate to the authentication of electronic data interchange transactions for the trading of goods within a given price range.

Certification Practice Statement (CPS): A statement of the practices that a certification authority employs in issuing certificates.

In other words, CP says where and how a relying party will be able to use the certificates. CPS says which practice the PKI (and in many cases its supporting services) will follow to guarantee to all the parties, primarily relying parties and subscribers, that the issued certificates may be used as is declared in CP. The relying parties and subscribers are guided by the paradigm that a certificate "… binds a public key value to a set of information that identifies the entity (such as person, organization, account, or site) associated with use of the corresponding private key (this entity is known as the "subject" of the certificate)."[1] The entity or subject in this quote is also called an *end entity* (EE) or *subscriber.*

A CPS is expressed in a set of provisions. In this chapter we focus only on those provisions that pertain to the process of registration, which generally include:

- Identification and authentication
- Certificate issuance
- Procedural controls
- Key-pairs generation and installation
- Private key protection
- Network security in the process of registration
- Publishing

Reference to CP and CPS associated with a certificate may be presented in the X509.V3 certificates extension called "Certificate Policies." This extension may give to a relying party a great deal of information, identified by attributes *Policy Identifier* in the form of Abstract Syntax Notation One Object IDs (ASN.1 OID) and *Policy Qualifier*. One type of Policy Qualifier is a reference to CPS, which describes the practice employed by the issuer to register the subscriber (the subject of the certificate; see Exhibit 117.1).

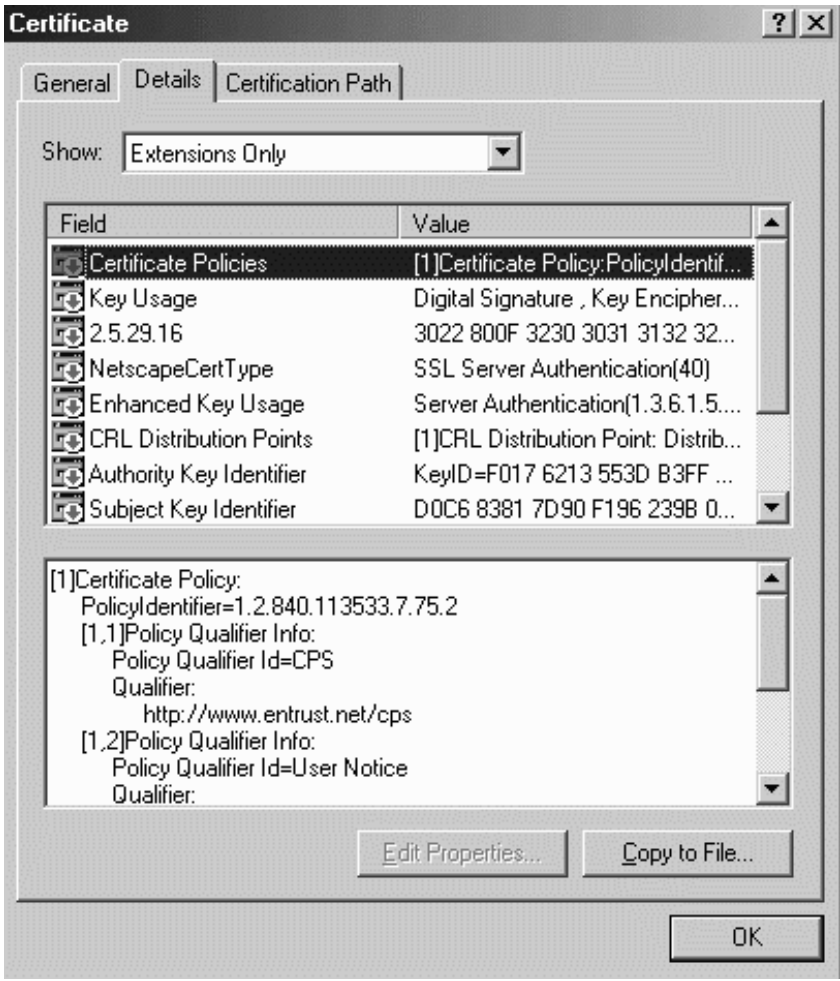

EXHIBIT 117.1 Certificate policies.

Registration, Identification, and Authentication

For initial registration with PKI, a subscriber usually has to go through the processes of identification and authentication. Among the rules and elements that may comprise these processes in a CPS are:

1. Types of names assigned to the subject
2. Whether names have to be meaningful
3. Rules for interpreting various name forms
4. Whether names have to be unique
5. How name claim disputes are resolved
6. Recognition, authentication, and role of trademarks
7. If and how the subject must prove possession of the companion private key for the public key being registered
8. Authentication requirements for organizational identity of subject (CA, RA, or EE)
9. Authentication requirements for a person acting on behalf of a subject (CA, RA, or EE), including:
   - Number of pieces of identification required
   - How a CA or RA validates the pieces of identification provided
   - If the individual must present personally to the authenticating CA or RA
   - How an individual as an organizational person is authenticated

The first six items of the list are more a concern of the legal and naming conventions. They are beyond the scope of this chapter.

Other items basically focus on three issues:

1. How the subject proves its organizational entity (above)
2. How the person, acting on behalf of the subject, authenticates himself in the process of requesting a certificate (above)
3. How the certificate issuer can be sure that the subject, whose name is in the certificate request, is really in the possession of the private key, and which public key is presented in the certificate request along with the subject name (above)

Another important component is the integrity of the process. Infrastructure components and subscribers should be able to authenticate themselves and support data integrity in all the transactions during the process of registration.

How the Subject Proves Its Organizational Entity

Authentication requirements in the process of registration with PKI depend on the nature of applying EE and CP, stating the purpose of the certificate. Among end entities, there can be individuals, organizations, applications, elements of infrastructure, etc.

Organizational certificates are usually issued to the subscribing organization's devices, services, or individuals representing the organization. These certificates support authentication, encryption, data integrity, and other PKI-enabled functionality when relying parties communicate to the organization. Among organizational devices and services may be:

- Web servers with enabled SSL, which support server authentication and encryption
- WAP gateways with WTLS enabled, which support gateway authentication
- Services and devices, signing a content (software codes, documents etc.) on behalf of the organization
- VPN gateways
- Devices, services, applications, supporting authentication, integrity, and encryption of electronic data interchange (EDI), B2B, or B2C transactions

Among procedures enforced within applying organizations (before a certificate request is issued) are:

- An authority inside the organization should approve the certificate request.
- After that, an authorized person within the organization will submit a certificate application on behalf of the organization.

- The organizational certificate application will be submitted for authentication of the organizational identity.

Depending on the purpose of the certificate, a certificate issuer will try to authenticate the applying organization, which may include some but not all of the following steps, as in the example below:[2]

- Verify that the organization exists.
- Verify that the certificate applicant is the owner of the domain name that is the subject of the certificate.
- Verify employment of the certificate applicant and if the organization authorized the applicant to represent the organization.

There is always a correlation between the level of assurance provided by the certificate and the strength of the process of validation and authentication of the EE registering with PKI and obtaining that certificate.

How the Person, Acting on Behalf of the Subject, Authenticates Himself in the Process of Requesting Certificate (Case Study)

Individual certificates may serve different purposes, for example, for e-mail signing and encryption, for user authentication when they are connecting to servers (Web, directory, etc.), to obtain information, or for establishing a VPN encryption channel. These kinds of certificates, according to their policy, may be issued to anybody who is listed as a member of a group (for example, an employee of an organization) in the group's directory and who can authenticate himself. An additional authorization for an organizational person may or may not be required for PKI registration.

An individual who does not belong to any organization can register with some commercial certificate authorities with or without direct authentication and with or without presenting personal information. As a result, an individual receives his general use certificate.

Different cases are briefly described below.

Online Certificate Request without Explicit Authentication

As in the example with VeriSign certificate of Class 1, a CA can issue an individual certificate (a.k.a. digital ID) to any EE with an unambiguous name and e-mail address. In the process of submitting the certificate request to the CA, the keys are generated on the user's computer; and initial data for certificate request, entered by the user (user name and e-mail address) is encrypted with a newly generated private key. It is sent to the CA. Soon the user receives by e-mail his PIN and the URL of a secure Web page to enter that PIN to complete the process of issuing the user's certificate. As a consequence, the person's e-mail address and ability to log into this e-mail account may serve as indirect minimal proof of authenticity. However, nothing prevents person A from registering in the public Internet e-mail as person B and requesting, receiving, and using person B's certificate (see Exhibit 117.2).

Authentication of an Organizational Person

The ability of the EE to authenticate in the organization's network, (e.g., e-mail, domain) or with the organization's authentication database may provide an acceptable level of authentication for PKI registration. Even the person's organizational e-mail authentication is much stronger from a PKI registration perspective than authentication with public e-mail. In this case, a user authentication for PKI registration is basically delegated to e-mail or domain user authentication. In addition to corporate e-mail and domain controllers, an organization's HR database, directory servers, or databases can be used for the user's authentication and authorization for PKI registration. In each case an integration of the PKI registration process and the process of user authentication with corporate resources needs to be done (see Exhibit 117.3).

A simplified case occurs when a certificate request is initiated by a Registration Authority upon management authorization. In this case, no initial user authentication is involved.

Individual Authentication

In the broader case, a PKI registration will require a person to authenticate potentially with any authentication bases defined in accordance with CPS. For example, to obtain a purchasing certificate from the CA, which is integrated into a B2C system, a person will have to authenticate with financial institutions — which will secure the person's Internet purchasing transactions. In many cases, an authentication gateway or server will do it, using a user's credentials (see Exhibit 117.4).

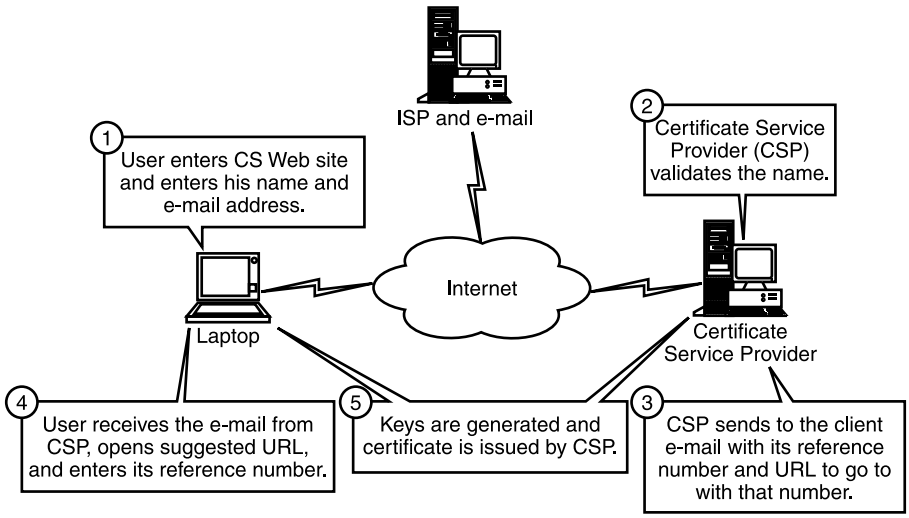

EXHIBIT 117.2 Certificate request via e-mail or Web with no authentication.

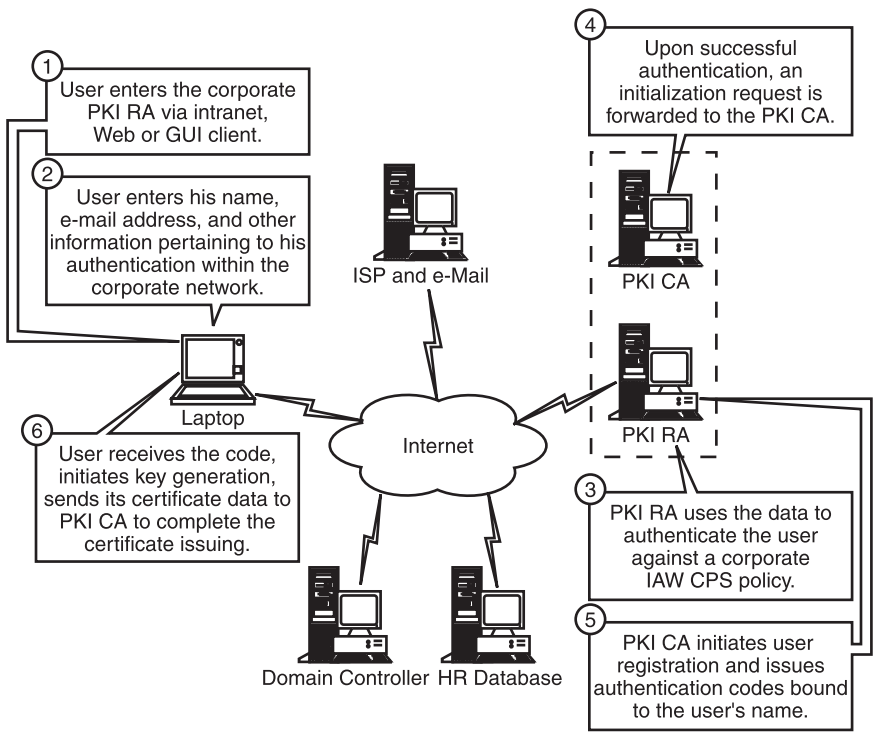

EXHIBIT 117.3 Certificate request via corporate e-mail or Web or GUI interface.

Dedicated Authentication Bases

In rare cases, when a PKI CPS requires a user authentication that cannot be satisfied by the existing authentication bases, a dedicated authentication base may be created to meet all CPS requirements. For example, for this purpose, a prepopulated PKI directory may be created, where each person eligible for PKI registration will be presented with a password and personal data attributes (favorite drink and color, car, etc.). Among

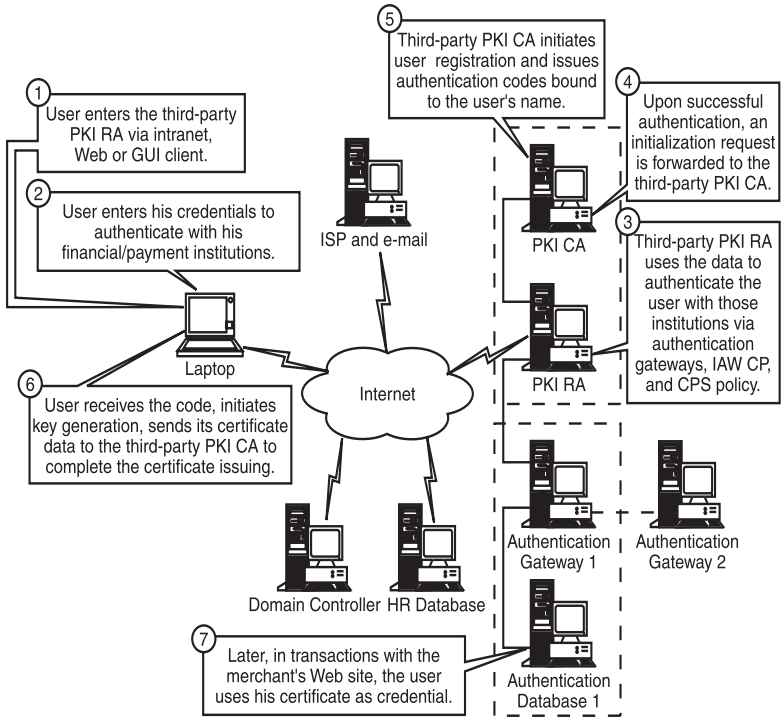

EXHIBIT 117.4 Certificate request via gateway interfaces.

possible authentication schemes with dedicated or existing authentication bases may be personal entropy, biometrics, and others.

Face-to-Face

The most reliable but most expensive method to authenticate an EE for PKI registration is face-to-face authentication. It is applied when the issued certificate will secure either high-risk and responsibility transactions (certificates for VPN gateways, CA and RA administrators) or transactions of high value, especially when the subscriber will authenticate and sign transactions on behalf of an organization. To obtain this type of certificate, the individual must be personally present and show a badge and other valid identification to the dedicated corporate registration security office and sign a document obliging use of the certificate only for assigned purposes. Another example is a healthcare application (e.g., Baltimore-based Healthcare eSignature Authority). All the procedures and sets of ID and documents that must be presented before an authentication authority are described in CPS.

Certificate Request Processing

So far we have looked at the process of EE authentication that may be required by CPS; but from the perspective of the PKI transactions, this process includes out-of-bound transactions. Whether the RA is contacting an authentication database online, or the EE is going through face-to-face authentication, there are still no PKI-specific messages. The RA only carries out the function of personal authentication of an EE before the true PKI registration of the EE can be initialized. This step can also be considered as the first part of the process of initial registration with PKI. Another part of initial registration includes the step of EE initialization, when the EE is requesting information about the PKI-supported functions and acquiring CA public key. The EE is also making itself known to the CA, generating the EE key-pairs and creating a personal secure environment (PSE).

The initial PKI registration process, among other functions, should provide an assurance that the certificate request is really coming from the subject whose name is in the request, and that the subject holds private keys that are the counterparts to the public keys in the certificate request.

These and other PKI functions in many cases rely on PKI Certificate Management Protocols[3] and Certificate Request Management Format.[4]

PKIX-CMP establishes a framework for most of the aspects of PKI management. It is implemented as a message-handling system with a general message format as presented below:[3]

```
PKIMessage :: = SEQUENCE {
header PKIHeader,
body PKIBody,
protection [0] PKIProtection OPTIONAL,
extraCerts [1] SEQUENCE SIZE (1..MAX) OF Certificate
OPTIONAL
}
```

The various messages used in implementing PKI management functions are presented in the PKI message body[3] (see Exhibit 117.5).

Initial Registration

In the PKIX-CMP framework, the first PKI message, related to the EE, may be considered as the start of the initial registration, provided that out-of-bound required EE authentication and CA public key installation have been successfully completed by this time. All the messages that are sent from PKI to the EE must be authenticated. The messages from the EE to PKI may or may not require authentication, depending on the implemented scheme, which includes the location of key generation and the requirements for confirmation messages.

- In the centralized scheme, initialization starts at the CA, and key-pair generation also occurs on the CA. Neither EE message authentication nor confirmation messages are required. Basically, the entire initial registration job is done on the CA, which may send to the EE a message containing the EE's PSE.
- In the basic scheme, initiation and key-pair generation start on the EE's site. As a consequence, its messages to RA and CA must be authenticated. This scheme also requires a confirmation message from the EE to RA/CA when the registration cycle is complete.

Issuing to the EE an authentication key or reference value facilitates authentication of any message from the EE to RA/CA. The EE will use the authentication key to encrypt its certificate request before sending it to the CA/RA.

Proof of Possession

A group of the key PKIX-CMP messages, sent by the EE in the process of initial registration, includes "ir," "cr," and "p10cr" messages (see the PKI message body above). The full structure of these messages is described in RFC 2511 and RSA Laboratories' Public-Key Cryptography Standards (PKCS). Certificate request messages, among other information, include "publicKey" and "subject" name attributes.

The EE has authenticated itself out-of-bound with RA on the initialization phase of initial registration (see above section on registration, identification, and authentication). Now an additional proof is required — that the EE, or the subject, is in possession of a private key, which is a counterpart of the public Key in the certificate request message. It is a proof of binding, or so-called proof of possession, or POP, which the EE submits to the RA.

Depending on the types of requested certificates and public/private key-pairs, different POP mechanisms may be implemented:

- For encryption certificates, the EE can simply provide a private key to the RA/CA, or the EE can be required to decrypt with its private key a value of the following data, which is sent back by RA/CA:
  - In the direct method it will be a challenge value, generated and encrypted and sent to the EE by the RA. The EE is expected to decrypt and send the value back.

EXHIBIT 117.5 Messages Used in Implementing PKI Management Functions

```
PKIBody :: = CHOICE {— message-specific body elements
      ir    [0] CertReqMessages,— Initialization Request
      ip    [1] CertRepMessage,— Initialization Response
      cr    [2] CertReqMessages,— Certification Request

}
```

* RSA Laboratories, Public-Key Cryptography Standards (PKCS), RSA Data Security Inc., Redwood City, CA, November 1993 release.

Source: RFC 2510.

- In the indirect method, the CA will issue the certificate, encrypt it with the given public encryption key, and send it to the EE. The subsequent use of the certificate by the EE will demonstrate its ability to decrypt it, hence the possession of a private key.
- For signing certificates, the EE merely signs a value with its private key and sends it to the RA/CA.

Depending on implementation and policy, PKI parties may employ different schemes of PKIX-CMP message exchange in the process of initial registration (see Exhibit 117.6).

An initialization request ("ir") contains, as the PKIBody, a CertReqMessages data structure that specifies the requested certificate. This structure is represented in RFC 2511 (see Exhibit 117.7).

A registration/certification request ("cr") may also use as PKIBody a CertReqMessages data structure, or alternatively ("p10cr"), a CertificationRequest.[5]

Administrative and Auto-Registration

As we saw above, the rich PKIX-CMP messaging framework supports the inbound initial certificate request and reply, message authentication, and POP. However, it does not support some important out-of-bound steps of PKI initial registration, such as:

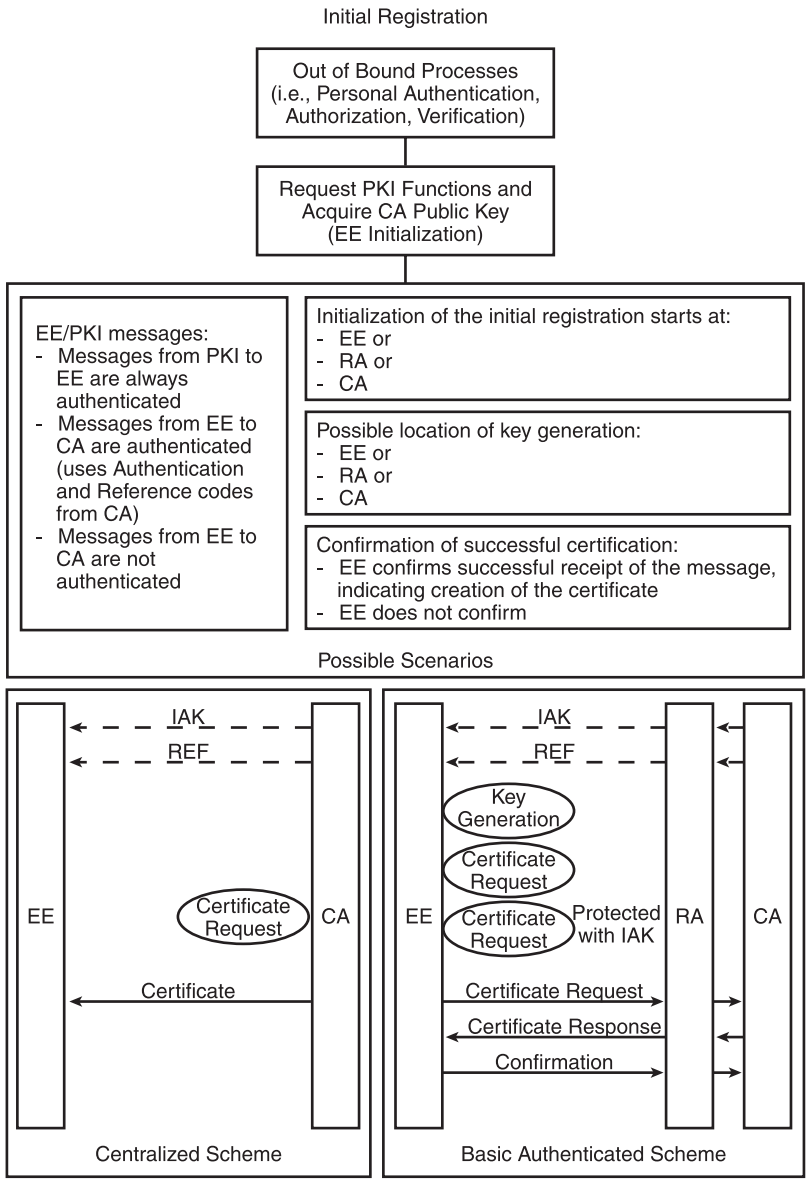

EXHIBIT 117.6 Different schemes of PKIX-CMP message exchange.

- Authentication of an EE and binding its personal identification attributes with the name, which is a part of the registration request
- Administrative processes, such as managers' approval for PKI registration

To keep the PKIX-CMP framework functioning, the EE can generally communicate either directly with the CA or via the RA, depending on specific implementation. However, the CA cannot support the out-of-bound steps of initial registration. That is where the role of the RA is important. In addition to the two functions above, the RA also assumes some CA or EE functionality, such as initializing the whole process of initial registration and completing it by publishing a new certificate in the directory.

In the previous section on "Certificate Request Processing," we briefly mentioned several scenarios of user authentication. In the following analysis we will not consider the first scenario (online certificate request without explicit authentication) because certificates issued in this way have a very limited value.

```
CertReqMessages :: = SEQUENCE SIZE (1..MAX) OF CertReqMsg
CertReqMsg :: = SEQUENCE {
      certReqCertRequest,
      pop   ProofOfPossession OPTIONAL,
 —    content depends upon key type
      regInfoSEQUENCE SIZE(1..MAX) OF AttributeTypeAndValue
                  OPTIONAL}
CertRequest :: = SEQUENCE {
      certReqIdINTEGER,— ID for matching request and reply
      certTemplateCertTemplate,— Selected fields of cert to be issued
      controlsControls OPTIONAL}— Attributes affecting issuance
CertTemplate :: = SEQUENCE {
      version[0] VersionOPTIONAL,
      serialNumber[1] INTEGEROPTIONAL,
      signingAlg[2] AlgorithmIdentifierOPTIONAL,
      issuer[3] NameOPTIONAL,
      validity[4] OptionalValidityOPTIONAL,
      subject[5] NameOPTIONAL,
      publicKey[6] SubjectPublicKeyInfoOPTIONAL,
      issuerUID[7] UniqueIdentifierOPTIONAL,
      subjectUID[8] UniqueIdentifierOPTIONAL,
      extensions[9] ExtensionsOPTIONAL}
OptionalValidity :: = SEQUENCE {
      notBefore[0] Time OPTIONAL,
      notAfter[1] Time OPTIONAL} — at least one must be present
Time :: = CHOICE {
      utcTimeUTCTime,
      generalTimeGeneralizedTime}
```

EXHIBIT 117.7 Data structure specifying the requested certificate.

Case Study

The following are examples of the initial registration, which requires explicit EE authentication.

Administrative Registration

1. An EE issues an out-of-bound request to become a PKI subscriber (either organizational or commercial third party).
2. An authorized administrator or commercial PKI clerk will authenticate EE and verify its request. Upon successful authentication and verification, an authorized administrator submits the request to the RA administrator.
3. The RA administrator enters the EE subject name and, optionally, additional attributes into the RA to pass it to the CA. The CA will verify if the subject name is not ambiguous and will issue a reference number (RN) to associate the forthcoming certificate request with the subject and an authentication code (AC) to encrypt forthcoming communications with EE.
4. The RA administrator sends the AC and RN in a secure out-of-bound way to the EE.
5. The EE generates a signing key-pair, and using AC and RN, establishes inbound "ir" PKIX-CMP exchange.
6. As a result, the EE's verification and encryption certificates, along with signing and decryption keys, are placed in the EE PSE. The EE's encryption certificate is also placed in the public directory.
7. If the keys are compromised or destroyed, the PKI administrator should start a recovery process, which quite closely repeats the steps of initial registration described here.

As we see, most of the out-of-bound steps in each individual case of administrative PKI registration are handled by administrators and clerks. Moreover, the out-of-bound distribution of AC/RN requires high confidentiality.

Auto-Registration

1. Optionally (depending on the policy), an EE may have to issue an out-of-bound application to become a PKI subscriber (either organizational or commercial third party). An authorized administrator or commercial PKI clerk will evaluate the request. Upon evaluation, the EE will be defined in the organizational or commercial database as a user, authorized to become a PKI subscriber.
2. The EE enters his authentication attributes online in the predefined GUI form.
3. The form processor (background process of the GUI form) checks if the EE is authorized to become a PKI subscriber and then tries to authenticate the EE based on the entered credentials.
4. Upon successful authentication of the EE, the subsequent registration steps are performed automatically, as well as the previous step.
5. As a result, the EE's verification and encryption certificates, along with signing and decryption keys, are placed in the EE PSE. The EE's encryption certificate is also placed in the public directory.
6. If the keys are compromised or destroyed, the EE can invoke via a GUI form a recovery process without any administrator's participation.

Comparing the two scenarios, we can see an obvious advantage to auto-registration. It is substantially a self-registration process. From an administration perspective, it requires simply to authorize the EE to become a PKI subscriber. After that, only exceptional situations may require a PKI administrator's intervention.

Authentication Is a Key Factor

We may assume that in both scenarios described above, all the inbound communications follow the same steps of the same protocol (PKIX-CMP). The difference is in the out-of-bound steps, and more specifically, in the user (EE) authentication. Generally, possible authentication scenarios are described in the section on "Registration, Identification, and Authentication." Most of those scenarios (except face-to-face scenarios) may be implemented either in the administrative or auto-registration stage. The form, sources, and quality of authentication data should be described in the CPS. The stronger the authentication criteria for PKI registration, the more trust the relying parties or applications can use. There may be explicit and implicit authentication factors.

In the administrative registration case above, authentication of the organizational user may be totally implicit, because his PKI subscription may have been authorized by his manager, and AC/RN data may have been delivered via organizational channels with good authentication mechanisms and access control. On the other hand, registration with a commercial PKI may require an EE to supply personal information (SSN, DOB, address, bank account, etc.), which may be verified by a clerk or administrator.

Auto-registration generally accommodates verification of all the pieces of the personal information. If it is implemented correctly, it may help to protect subscribers' privacy, because no personal information will be passed via clerks and administrators. In both the organizational and commercial PKI registration cases, it may even add additional authentication factors — the ability of the EE/user to authenticate himself online with his existing accounts using one or many authentication bases within one or many organizations.

Conclusion

For most common-use certificates, which do not assume a top fiscal or a highest legal responsibility, an automated process of PKI registration may be the best option, especially for large-scale PKI applications and for the geographically dispersed subscribers' base. Improvement of this technology in mitigating possible security risk, enlarging online authentication bases, methods of online authentication, and making the entire automated process more reliable, will allow the organization to rely on it when registering subscribers for more expensive certificates, which assume more responsibility.

For user registration for certificates carrying a very high responsibility and liability, the process will probably remain manual, with face-to face appearance of the applicant in front of the RA, with more than one proof of his identity. It will be complemented by application forms (from the applicant and his superior) and

verification (both online and offline) with appropriate authorities. The number of certificates of this type is not high, and thus does not create a burden for the RA or another agency performing its role.

Implementing Kerberos in Distributed Systems

Joe Kovara, CTP and Ray Kaplan, CISSP, CISA, CISM

Kerberos is a distributed security system that provides a wide range of security services for distributed environments. Those services include authentication and message protection, as well as providing the ability to securely carry authorization information needed by applications, operating systems, and networks. Kerberos also provides the facilities necessary for delegation, where limited-trust intermediaries perform operations on behalf of a client. Entering its second decade of use, Kerberos is arguably the best tested and most scrutinized distributed security system in widespread use today.

Kerberos differs from many other distributed security systems in its ability to incorporate a very wide range of security technologies and mechanisms. That flexibility allows a mixture of security technologies and mechanisms to be used, as narrowly or broadly as required, while still providing the economies of scale that come from a common, reusable, and technology-neutral Kerberos security infrastructure. Technologies and mechanisms that have been incorporated into Kerberos and that are in use today include certificate-based public key systems, smart cards, token cards, asymmetric-key cryptography, as well as the venerable user ID and password.

Kerberos' longevity and acceptance in the commercial market are testaments to its reliability, efficiency, cost of ownership, and its adaptability to security technologies past, present, and — we believe — future. Those factors have made Kerberos the *de facto* standard for distributed security in large, heterogeneous network environments. Kerberos has been in production on a large scale for years at a variety of commercial, government, and educational organizations, and for over a decade in one of the world's most challenging open systems environments: Project Athena[1] at MIT, where it protects campus users and services from what is possibly the security practitioner's worst nightmare.

History of Development

Many of the ideas for Kerberos originated in a discussion of how to use encryption for authentication in large networks that was published in 1978 by Roger Needham and Michael Schroeder.[2] Other early ideas can be attributed to continuing work by the security community, such as Dorothy Denning's and Giovanni Sacco's work on the use of time stamps in key distribution protocols.[3] Kerberos was designed and implemented in the mid-1980s as part of MIT's Project Athena. The original design and implementation of the first four versions of Kerberos were done by MIT Project Athena members Steve Miller (Digital Equipment Corp.) and Clifford Neuman, along with Jerome Salzer (Project Athena technical director) and Jeff Schiller (MIT campus network manager).

Kerberos versions 1 through 3 were internal development versions and, since its public release in 1989, version 4 of Kerberos has seen wide use in the Internet community. In 1990, John Kohl (Digital Equipment Corp.) and Clifford Neuman (University of Washington at that time and now with the Information Sciences Institute at the University of Southern California) presented a design for version 5 of the protocol based on input from many of those familiar with the limitations of version 4. Currently, Kerberos versions 4 and 5 are

available from several sources, including freely distributed versions (subject to export restrictions) and fully supported commercial versions. Kerberos 4 is in rapid decline, and support for it is very limited. This discussion is limited to Kerberos 5.

Current Development

Although there have been no fundamental changes to the Kerberos 5 protocol in recent years,[4] development and enhancement of Kerberos 5 continues today.[5] That development continues a history of incremental improvements to the protocol and implementations. Implementation improvements tend to be driven by commercial demands, lessons learned from large deployments, and the normal improvements in supporting technology and methodologies.

Standards efforts within the Internet Engineering Task Force (IETF) continue to play a predominant role in the Kerberos 5 protocol development, reflecting both the maturity of the protocol as well as the volatility of security technology. Protocol development is primarily driven by the emergence of new technologies, and standards efforts continue to provide an assurance of compatibility and interoperability between implementations as new capabilities and technologies are incorporated. Those efforts also ensure that new developments are vetted by the Internet community. Many additions to Kerberos take the form of separate standards, or IETF Request for Comments (RFCs).[6] Those standards make use of elements in the Kerberos protocol specifically intended to allow for extension and the addition and integration of new technologies. Some of those technologies and their integration into Kerberos are discussed in subsequent sections.

As of this writing, both Microsoft[7] and Sun[8] have committed to delivery of Kerberos 5 as a standard feature of their operating systems. Kerberos 5 has also been at the core of security for the Open Software Foundation's Distributed Computing Environment (OSF DCE) for many years.[9] Many application vendors have also implemented the ability to utilize Kerberos 5 in their products, either directly, or through the Generic Security Service Applications Programming Interface (GSS-API).

Standards and Implementations

When discussing any standard, care must be exercised in delineating the difference between what the standard defines, what is required for a solution, and what different vendors provide. As does any good protocol standard, the Kerberos 5 standard leaves as much freedom as possible to each implementation, and as little freedom as necessary to ensure interoperability. The basic Kerberos 5 protocol defines the syntax and semantics for authentication, secure messaging, limited syntax and semantics for authorization, and the application of various cryptographic algorithms within those elements.

The Kerberos 5 protocol implies, but does not define, the supporting infrastructure needed to build a solution that incorporates and makes useful all of the standard's elements. For example, the services that make up the logical grouping of the Kerberos security server are defined by the Kerberos 5 standard. The manifestation of those services — the underlying database that those services require, the supporting management tools, and the efficiency of the implementation — are not defined by the standard. Those elements make the difference between what is theoretically possible and what is real. That difference is a reflection of the state of technology, market demands, and vendor implementation abilities and priorities. In this discussion we have attempted to distinguish between the elements that make up the Kerberos 5 protocol, the elements that are needed to build and deploy a solution, and the variations that can be expected in different implementations.

Perceptions and Technology

A review of perceptions about Kerberos will find many anecdotal and casual assertions about its poor usability, inferior performance, or lack of scalability. This appears to be inconsistent with the acceptance of Kerberos by major vendors and can be confusing to those tasked with evaluating security technologies. Much of that confusion is the result of the unqualified use of the term "Kerberos." Kerberos 4 and Kerberos 5 are very different, and any historical references must be qualified as to which version of Kerberos is the subject. As an early effort in distributed security, considerable study was devoted to the weaknesses, vulnerabilities, and limitations of Kerberos 4 and early drafts of the Kerberos 5 standard.[10] Modern implementations of Kerberos 5 address most, if not all, of those issues.

As a pioneering effort in distributed security, Kerberos exposed many new, and sometimes surprising, security issues. Many of those issues are endemic to distributed environments and are a reflection of organization and culture, and the changing face of security as organizations moved from a centralized to a distributed model. As a product of organization and culture, there is little if anything that technology alone can do to address most of those issues. Many of the resulting problems have been attributed to Kerberos, the vast majority of which are common to all distributed security systems, regardless of the technology used.

Various implementations of Kerberos have dealt with the broader organizational security issues in different ways, and with different degrees of success. The variability in the success of those implementations has also been a source of confusion. Enterprises that have a business need for distributed security and that understand the organizational, cultural, and security implications of distributed environments — or more accurately distributed business — tend to be most successful in deploying and applying Kerberos. Until very recently, organizations that fit that description have been in a small minority. Successes have also been achieved at other organizations, but those implementations tend to be narrowly focused on an application or a group within the organization. It should be no surprise that organizations that are in need of what Kerberos has to offer have been in the minority. Kerberos is a distributed security system. Distributed computing is still relatively young, and the technology and business paradigms are still far from convergence.

Outside of the minority of organizations with a business need for distributed security, attempts to implement broad-based distributed security systems such as Kerberos have generally failed. Horror stories of failed implementations tend to receive the most emphasis and are typically what an observer first encounters. Stories of successful implementations are more difficult to uncover. Those stories are rarely discussed outside of a small community of security practitioners or those directly involved, as there is generally little of interest to the broader community; "we're more secure than we were before" does not make for good press.

Whether drivers or indicators of change, the advent of the Internet and intranets bespeak a shift, as a greater number of enterprises move to more distributed organizational structures and business processes and discover a business need for solutions to distributed security problems. Those enterprises typically look first to the major vendors for solutions. Driven by customer business needs, those vendors have turned to Kerberos 5 as a key element in their security solutions.

Trust, Identity, and Cost

The vast majority of identity information used in organizations by computer systems and applications today is based on IDs and passwords, identity information that is bound to individuals. That is the result of years of evolution of our computer systems and applications. Any security based on that existing identity information is fundamentally limited by the trust placed in that information. In other words, security is limited by the level of trust we place in our current IDs and passwords as a means of identifying individuals.

Fundamentally increasing the level of trust placed in our identity information and the security of any system that uses those identities requires rebinding, or reverifying, individual identities. That is a very, very expensive proposition for all but the smallest organizations. In simple and extreme terms: any authentication technology purporting to improve the authenticity of individuals that is based on existing identity information is a waste of money; any authentication technology that is not based on existing identity information is too expensive to deploy on any but a small scale. This very simple but very fundamental equation limits all security technologies and the level of security that is practical and achievable.

We must use most of our existing identity information; the alternatives are not affordable. Although the situation appears bleak, it is far from hopeless; we must simply be realistic about what can be achieved, and at what cost. There is no "silver bullet." The best that any cost-effective solution can hope to do is establish the current level of trust in individual identities as a baseline and not allow further erosion of that trust. Once that baseline is established, measures can be taken to incrementally improve the situation as needed and as budgets allow. The cheaper those goals can be accomplished, the sooner we will start solving the problem and improving the level of trust we can place in our systems.

Kerberos provides the ability to stop further erosion of our trust in existing identities. Kerberos also allows that level of trust to be improved incrementally, by using technologies that are more secure than IDs and passwords. Kerberos allows both of those to be achieved at the lowest possible cost. The ability for Kerberos to effectively utilize what we have today, stop the erosion, and allow incremental improvement is one of the key factors in the success of Kerberos in real-world environments.

Technology Influences

Although technology continues to advance and provide us with the raw materials for improving Kerberos, many of the assumptions and influences that originally shaped Kerberos are still valid today. Although new security technologies may captivate audiences, the fundamentals have not changed. One fundamental of security that should never be forgotten is that a security system must be affordable and reliable if it is to achieve the goal of improving an organization's security.

An affordable and reliable security system makes the most of what exists, and does not require the use of new, expensive or unproven technologies as a prerequisite to improving security. A good security system such as Kerberos allows those newer technologies to be used but does not mandate them. With rapid advances in technology, single-technology solutions are also doomed to rapid obsolescence. Solutions that are predicated on new technologies will, by definition, see limited deployment until the cost and reliability of those solutions are acceptable to a broad range of organizations. The longer that evolution takes, the higher the probability that even newer technologies will render them, and any investment made in them, obsolete.

Moreover, history teaches us that time provides the only real validation of security. That is a difficult proposition for security practitioners when the norm in the information industry is a constant race of the latest and greatest. However, the historical landscape is littered with security technologies, most created by very smart people, that could not stand the test of time and the scrutiny of the security community. The technology influences that have shaped Kerberos have been based on simple and proven fundamentals that provide both a high degree of assurance and a continuing return on investment.

Protocol Placement

Kerberos is often described as an "application-layer protocol." Although that description is nominally correct, and most descriptions of Kerberos are from the perspective of the application, the unfortunate result is a perception that Kerberos requires modification of applications to be useful. Kerberos is not limited to use at the application layer, nor does Kerberos require modification of applications. Kerberos can be, and is, used very effectively at all layers of the network, as well as in middleware. Placing Kerberos authentication, integrity, confidentiality, and access control services below the application layer can provide significant improvements in security without the need to modify applications. The most obvious example of security "behind the scenes" is the use of Kerberos for authentication and key management in a virtual private network (VPN).

However, there are limits to what can be achieved without the cooperation and knowledge of an application. Those limits are a function of the application and apply to all security systems. Providing an authenticated and encrypted channel (e.g., using a VPN) may improve the security of access to the application and the security of information flowing between a client and the application. However, that alone does nothing to improve the usability of the application and does not take advantage of Kerberos' ability to provide secure single sign-on. For example, an application that insists on a local user ID for the users of that application will require mapping between the Kerberos identity and the application-specific user ID. An application that insists on a password will typically require some form of "password stuffing" to placate the application — even if the password is null. Some applications make life easier by providing hooks, call-outs, or exits that allow augmenting the application with alternative security mechanisms. Other applications that do not provide this flexibility require additional and complex infrastructure in order to provide the appearance of seamless operation. Note that these issues are a function of the applications, and not the security system. All security systems must deal with identical issues, and they will generally be forced to deal with those issues in similar ways.

Although we can formulate solutions to authentication, confidentiality, integrity, and access control that are useful and that are independent of a broad range of applications, the same cannot be said of delegation and authorization. In this context, the assertion that Kerberos requires modification of the application is correct. However, that requirement has little if any affect on the practical employment of Kerberos, because very few applications in use today need, or could make use of, those capabilities. Applications that can understand and make use of those capabilities are just starting to appear.

Passwords

One of the primary objectives of Kerberos has always been to provide security end-to-end. That is, all the way from an individual to a service, without the requirement to trust intermediaries. Kerberos can be, and is, also used to provide security for intermediate components such as computer systems, routers, and virtual private

networks. However, humans present the most significant challenge for any security system, and Kerberos does an exemplary job of meeting that challenge.

The simple user ID and password are far and away the most common basis for identification and authentication used by humans and applications today. Whatever their faults, simple IDs and passwords predominate the security landscape and will likely do so for the foreseeable future. They are cheap, portable, and provide adequate security for many applications — virtually all applications in use today. Kerberos is exceptional in its ability to provide a high level of security with nothing more than those IDs and passwords. Kerberos allows more sophisticated identification and authentication mechanisms to be used, but does not mandate their use.

Kerberos is specifically designed to eliminate the transmission of passwords over the network. Passwords are not transmitted in any form as a part of the Kerberos authentication process. The only case in which a password or a derivation of the password (i.e., a key derived from the password) is transmitted is during a password-change operation — assuming, of course, that passwords are being used for authentication, and not an alternative technology such as smart cards. During a password-change operation, the password or its derivation is always protected using Kerberos confidentiality services.

Cryptography

The need to provide effective security using nothing more than very low-cost methods such as an ID and password has had a significant influence on the Kerberos protocol and its use of cryptography. In particular, using a password as the sole means for identification and authentication requires that the password is the basis of a shared secret between the user and the Kerberos security server. That also requires the use of symmetric-key cryptography. Although shared secrets and symmetric-key cryptography have been derided as "legacy" authentication technology, there are few if any alternatives to passwords if we want to provide an affordable and deployable solution sooner rather than later.

The efficiency of cryptographic methods has also had a significant influence on the protocol and its use of cryptography. Although Kerberos can incorporate asymmetric-key cryptography, such as elliptic curve cryptography (ECC) and RSA, Kerberos can provide all of the basic security services using shared secrets and symmetric-key cryptography. Because of the CPU-intensive nature of asymmetric-key cryptography, the ability to use symmetric-key cryptography is extremely important for environments or applications that are performance-sensitive, such as high-volume transaction-processing systems, where each transaction is individually authenticated.

Online Operation

In a distributed environment, individuals and services are scattered across many computer systems and are geographically dispersed. Whatever their physical distribution, those individuals and services operate within a collective enterprise. Typically, the association between an individual and his access to enterprise services is reestablished at the beginning of each workday, such as through a log-in. Day-to-day work in the distributed enterprise requires an individual to make use of many different services, and an individual typically establishes an association with a service, performs work, and then terminates the association. All of these functions occur online.

The association between individual and service may be very short-lived, such as for the duration of a single transaction. In other cases that association is long-lived and spans the workday. Whatever the duration of the association, the vast majority of work is performed online. That is, the individual and the service interact in real-time. Offline operation, which is sometimes necessary, is fast becoming a rarity. Notable exceptions are "road warriors," who must be capable of operating offline. However, that is a function of the limitations of connectivity, not of any desire to operate offline — as any road warrior will tell you.

The combined ability to provide both efficient and secure access to services, and the ability to serve as the basis for a collective security mechanism is one of Kerberos's major strengths. To deliver those capabilities, and deliver them efficiently, the Kerberos security server operates online. Extending that concept to an aggregate "enterprise security service" that incorporates Kerberos allows economies and efficiencies to be achieved across multiple security functions, including authentication, authorization, access control, and key management — all of which can be provided by, or built from, Kerberos. Although the concept of an aggregate enterprise security service is not native to Kerberos, the union of the two is very natural. Moreover, given the direction of technology and the composition and conduct of modern distributed enterprises, online security services

are both required and desirable. These attributes have much to do with the adoption of Kerberos as the basis for providing enterprise security, as opposed to Internet security.

Organizational Model

There are many different approaches to distributed security, and each involves tradeoffs between scalability and resources. The only objective measure of a distributed security system is cost, as measured by the resources required to achieve a given level of security over a given scale. Resources include computational overhead, network bandwidth, and people. The resulting cost bounds the achievable security and the scalability of the system. The tradeoffs that must be made involve both the technology and the security model appropriate to an organization. The extremes of those organizational models are autocracy and anarchy.

Autocracy

All control flows from a central authority. That authority defines the association between itself and the individual and the level of trust it places in an individual. This model requires a level of control that is cost-prohibitive in today's distributed environments. The classic military or business models tend toward this end of the spectrum.

Anarchy

All authority flows from individuals. Each individual defines the association between himself and an enterprise and the level of trust they place in an enterprise. This model achieves no economies of scale or commonality. The Internet tends toward this end of the spectrum.

Where in that spectrum an enterprise lives depends on business practices and culture, and every enterprise is different. Within a single enterprise it is not unusual to find organizational units that span the entire spectrum. That variability places significant demands on a distributed security system, and in some cases those demands may conflict. Conflicting demands occur when multiple enterprises — or even different business units within the same enterprise — with very different business practices or cultures engage in a common activity, such as is typical in supplier and partner relationships. The extreme case of conflicting demands is most often seen when the enterprise meets the Internet. As enterprise boundaries continue to dissolve, the probability of conflicting demands increases, as does the need for security systems to cope with those conflicting demands.

Kerberos most naturally falls in the middle of the spectrum between the extremes of autocracy and anarchy. Depending on implementation and the technology that is incorporated, Kerberos can be applied to many points along that spectrum and can be used to bridge points along the spectrum. Kerberos' effectiveness drops as you approach the extreme ends of the spectrum. As a security system, Kerberos provides a means to express and enforce a common set of rules across a collective; by definition, that collective is not anarchy. As a distributed security system, Kerberos is designed to solve problems that result from autonomous (and hence untrusted) elements within the environment; by definition, that cannot be an autocracy. Note that "distributed" does not necessarily imply physically distributed. For example, if the LAN to which your computer is connected cannot ensure the confidentiality and integrity of data you send across it, then you are in a distributed security environment.

Trust Models

The level of trust that is required between entities in a distributed system is a distinguishing characteristic of all distributed security systems, and affects all other services that are built on the system, as well as the scalability of the system. A prerequisite to trust is authentication: knowing the identity of the person (or machine) you are dealing with. In Kerberos, the entities that authenticate with one another are referred to as "principals," as in "principals to a transaction."

Direct Trust

Historically, users and applications have established direct trust relationships with one another. For example, each user of each application requires a user ID and password to access that application; the user ID and password represents a direct trust relationship between the user and the application. As the number of users

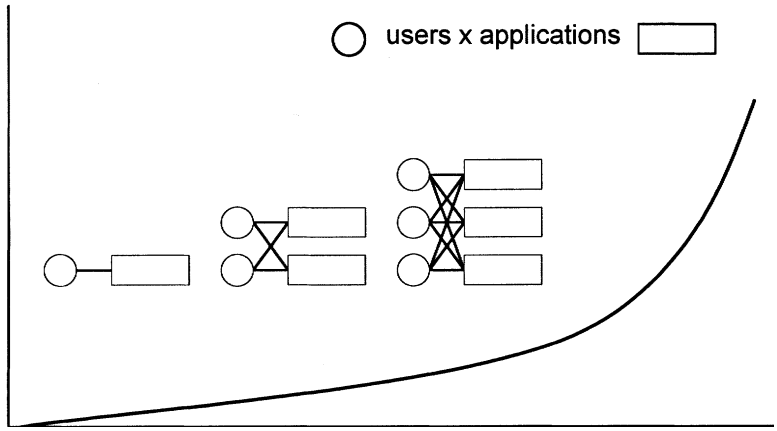

EXHIBIT 118.1 Direct trust relationships.

and applications grows, the number of direct relationships, and the cost of establishing and managing those relationships, increases geometrically (Exhibit 118.1). A geometric increase in complexity and cost is obviously not sustainable and limits the scalability of such solutions to a small number of applications or users.

A secure authentication system does not, in and of itself, reduce the complexity of this problem. The increase in complexity is a function of the number of direct trust relationships and has nothing to do with the security of the user-to-application authentication mechanism. An example of this is seen in Web-based applications that use IDs and passwords for authentication through the SSL (Secure Sockets Layer) protocol. The SSL protocol can provide secure transmission of the ID and password from the client to the server. However, that alone does not reduce the number of IDs and passwords that users and servers must manage.

Mitigating the increasing cost and complexity of direct trust relationships in the form of many IDs and passwords is the same problem that single sign-on systems attempt to solve. One solution is to use the same user ID and password for all applications. However, this assumes that all applications a user has access to are secured to the level of the most demanding application or user. That is required because an application has the information required to assume the identity of any of its users, and a compromise of any application compromises all users of that application. In a distributed environment, ensuring that all applications, their host computer systems, and network connections are secured to the required level is cost-prohibitive. The extreme case occurs with applications that are outside the enterprise boundaries. This is a nonscalable trust model.

Indirect Trust

Achieving scalable and cost-effective trust requires an indirect trust model. Indirect trust uses a third party, or parties, to assist in the authentication process. In this model, users and applications have a very strong trust relationship with a common third party, either directly or indirectly. The users and applications, or principals, trust that third party for verification of another principal's identity. The introduction of a third party reduces the geometric increase in complexity (shown in the previous section) to a linear increase in complexity (Exhibit 118.2).

All scalable distributed security systems use a trusted third party. In the Kerberos system, the trusted third party is known as the Key Distribution Center (KDC). In public key systems, the trusted third party is referred to as a Certificate Authority (CA). In token card systems, the token card vendor's server acts as a trusted third party. Many other applications of third-party trust exist in the world, one of the most obvious being credit cards, where the bank acts as the trusted third party between consumer and merchant. Neither consumer nor merchant shares a high degree of trust with each other, but both trust the credit card issuer. Note that without a credit card, each consumer would have to establish a direct trust relationship with each merchant (i.e., to obtain credit). Credit cards have made it much easier for consumers and merchants to do business, especially over long distances.

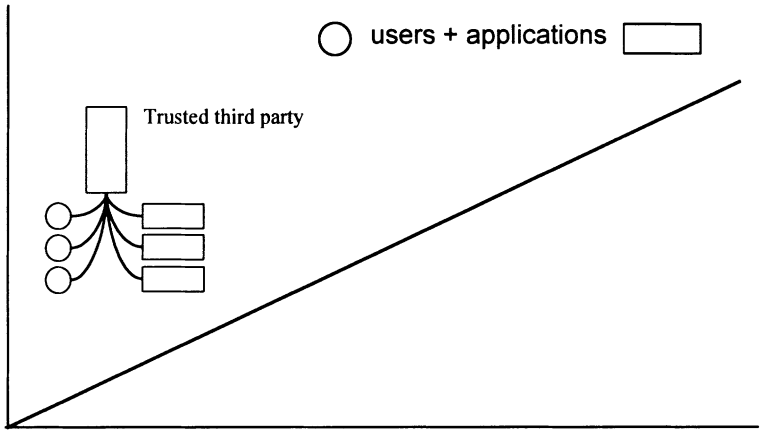

EXHIBIT 118.2 Indirect trust relationships.

Much like credit cards, a trusted third-party authentication system makes it easier for principals to do business — the first step of which is to verify each other's identity. In practical terms, that makes applications, information, and services more accessible in a secure manner. That benefits both consumers and providers of applications, information, and services, and reduces the cost to the enterprise.

Security Model

The manner in which a trusted third party provides proof of a principal's identity is a distinguishing characteristic of trusted third party security systems. This has a significant effect on all other services provided by the security system, as well as the scalability of the system. Kerberos uses a credential-based mechanism as the basis for identification and authentication. Those same credentials may also be used to carry authorization information. Kerberos credentials are referred to as "tickets."

Credentials

Requiring interaction with the trusted third party every time verification of identity needs to be done would put an onerous burden on users, applications, the trusted third party, and network resources. In order to minimize that interaction, principals must carry proof of their identity. That proof takes the form of a credential that is issued by the trusted third party to a principal. The principal presents that credential as proof of identity when requested.

All scalable distributed security systems use credentials. The Kerberos credential, or ticket, is analogous to an X.509 certificate in a public key system. These electronic credentials are little different conceptually than physical credentials, such as a passport or driver's license, except that cryptography is used to make the electronic credentials resistant to forgery and tampering. As with physical credentials, an electronic credential is something you can "carry around with you," without the need for you to constantly go back to an authority to reassert and verify your identity, and without the need for services to go back to that authority to verify your identity or the authenticity of the credential. Note that the use of a trusted third party for authentication does not imply the use of credentials. Token card systems are an example of trusted third-party authentication without credentials. The result of the authentication using such a card is a simple yes–no answer, not a reusable credential, and every demand for authentication results in an interaction with both the user and the token card server.

The stronger a credential, the stronger the assurance that the principal's claimed identity is genuine. The strength of a credential is dependent on both technology and environmental factors. Because a credential is carried by each principal, the credential must be tamper-proof and not forgeable. A credential's resistance to tampering and forgery is contingent on the strength of the cryptography used. Assurance of identity is contingent on the diligence of the trusted third party in verifying the identity of the principal's identity prior to issuing the credential. Assurance of identity is also contingent on the secure management of the credential

by the principal. As with physical credentials, electronic Kerberos credentials, and the information used to derive them must be protected, just as an individual's private key in a public key system must be protected.

As in the real world, all electronic credentials are not created equal. Simply possessing a credential does not imply universal acceptance or trust. As in the real world, the use and acceptance of a credential depends on the trust placed in the issuing authority, the integrity of the credential (resistance to forgery or tampering), and the purpose for which it is intended. For verification of identity, both passports and driver's licenses are widely accepted. A passport is typically trusted more than a driver's license, because the criteria for obtaining a passport are more stringent and a passport is more difficult to forge or alter. However, a passport says nothing about the holder's authorization or ability to operate a motor vehicle. A credential may also be single-purpose, such as a credit card. The issuing bank, as the trusted third party, provides protection to both the consumer and the merchant for a limited purpose: purchasing goods and services.

Credential Lifetime

As with physical credentials, the application and integrity of electronic credentials should limit the lifetime for which those credentials may be used. That lifetime may be measured in seconds or years, depending on the use of the credential. The strength of the cryptography that protects the integrity of the credential also effectively limits the lifetime of a credential. Credentials with longer lifetimes require stronger cryptography, because the credential is potentially exposed to attack for a longer period of time. However, cryptography is rarely the limiting factor in credential lifetime. Other issues, such as issuing cost and revocation cost, tend to be the determining factors for credential lifetime.

The distinguishing characteristic of credential-based systems is the lifetime of the credentials that they can feasibly accommodate. The longer the lifetime of a credential, the less often a new credential must be issued. However, the longer the life of a credential, the higher the probability that information embedded in the credential will change, or that the credential will be lost or stolen. The old "telephone book" revocation lists published by credit card companies is an example of the cost and complexity of revocation on a very large scale. Credit card companies have since moved to online authorization in order to lower costs and respond more rapidly.

Long-lived credentials reduce the credential-issuing cost but increase the credential-revocation cost. The shorter the lifetime of a credential, the more often a new credential must be issued. That increases the cost of the issuing process but reduces the cost of the revocation process. Credentials that are used only for authentication can have a relatively long lifetime. An individual's identity is not likely to change, and revocation would be necessary only if the credential was lost or stolen, or if the association between the individual and the issuing authority has been severed (e.g., such as when an employee leaves a company). Credentials that explicitly or implicitly carry authorization information generally require a shorter lifetime, because that information is more likely to change than identity information.

Different systems accommodate different lifetimes depending on the cost of issuing and revoking a credential and the intended use of the credential. While Kerberos credentials can have lifetimes of minutes or decades, they typically have lifetimes of hours or days. The process of constructing and issuing credentials is extremely efficient in Kerberos. That efficiency is key to Kerberos's ability to support authorization, capabilities, and delegation where new credentials may need to be issued frequently.

Capabilities

Credentials that carry authorization information are referred to as "capabilities," as they imply certain capabilities, or rights, upon the carrier of the credential. Kerberos supports capabilities by allowing authorization information to be carried within a Kerberos credential. As with other credentials, it is imperative that capabilities be resistant to tampering and forgery. We most often think of authorization information as coming from a central authorization service that provides commonly used information to various services (e.g., group membership information) where that information defines the limit of an individual's authorization. Kerberos supports this model by allowing authorization information from an authorization service to be embedded in a Kerberos credential when it is issued by the KDC; that authorization information is then available to services as a normal part of the Kerberos authentication process. Kerberos also supports a capability model based on "restricted proxies," in which the authorization granted to intermediate services may be restricted by the client.[11]

Delegation

There are also situations in which an individual authorizes another person to act on his behalf, thereby delegating some authority to that person. This is analogous to a power of attorney. Consider the simple example of a client who wants to print a file on a file server using a print server. The client wants to ensure that the print server can *print* (read) only the requested file, and not *write* on the file, or read any other files. The file server wants to ensure that the client really requested that the file be printed (and thus that the print server needs read-access to the file) and that the print server did not forge the request. The client should also limit the time for which the print server has access to the file, otherwise the print server would have access to the file for an indefinite period of time.

The extreme case is when an individual delegates unrestricted use of his identity to another person. As with an unrestricted power of attorney, allowing unrestricted use of another's identity can be extremely dangerous. (Obviously the authority that one individual can delegate to another must be limited by the authority of the delegating individual — we cannot allow an individual to grant authority they do not have, or the security of the entire system would crumble.) Unrestricted use of another's identity can also make end-to-end auditing much more difficult in many applications. Kerberos allows delegation of a subset of an individual's authority by allowing them to place authorization restrictions in a capability. The restricted proxy in Kerberos serves this function and is analogous to a restricted power of attorney. In the example above, the client would typically restrict the print server's right to read only the file that is to be printed using a restricted proxy. When the print server presents the resulting capability to the file server, the file server has all the information needed to ensure that neither the print server nor the client can exceed its authority, either individually or in combination.

In modern networks and business processes, it is common to find situations such as the above. Three-tier applications are another example. Here, the middle tier acts on the client's behalf for accessing back-end services. Delegation ensures the integrity and validity of the exchange and minimizes the amount of trust that must be placed in any intermediary. The need for delegation grows in significance as applications and services become more interconnected and as those connections become more dynamic. Without delegation, the identity and the rights of the originator, and the validity of a request, become difficult or impossible to determine with any degree of assurance. The alternative is to secure all intermediaries to the level required by the most sensitive application or user that makes use of the intermediary. This is cost-prohibitive on any but a very small scale.

Security Services

Many component security services are required to provide a complete distributed security service. The effectiveness of a distributed security system can be gauged by the component services it provides,[12] the degree to which those components operate together to provide a complete distributed security service, and the efficiency with which it provides those services.

Authentication

An authentication service permits one principal to determine the identity of another principal. The strength of an authentication service is the level of assurance that a principal's claimed identity is genuine. Put another way, the strength depends on the ease with which an attacker may assume the identity of another principal. For example, sending a person's ID and password across a network in the clear provides a very weak authentication, because the information needed to assume the identity of that person is readily available to any eavesdropper. Kerberos provides strong authentication by providing a high level of assurance that a principal's claimed identity is genuine. Kerberos also provides mutual authentication so that the identity of both client and service can be assured.

The reason for authentication is to ensure the identity of each principal prior to their conversing. However, without continuing assurance that their conversation has not been subverted, the utility of authentication alone is questionable. The Kerberos authentication protocol implicitly provides the cryptographic material, or "session keys," needed for establishing a secure channel that continues to protect the principal's conversation after authentication has occurred.

Secure Channels

A secure channel provides integrity and confidentiality services to communicating principals. Kerberos provides these services either directly through the use of Kerberos protocol messages, or indirectly by providing the cryptographic material needed by other protocols or applications to implement their own form of a secure channel.

Integrity

An integrity service protects information against unauthorized modification and provides assurance to the receiver that the information was sent by the proper party. Kerberos provides message integrity through the use of signed message checksums or one-way hashes using a choice of algorithms. Each principal in a Kerberos message exchange separately derives a checksum or hash for the message. That checksum or hash is then protected using a choice of cryptographic algorithms. The session keys needed for integrity protection are a product of the Kerberos authentication process.

Integrity applies not only to a single message, but to a stream of messages. As applied to a stream of messages, integrity also requires the ability to detect replays of messages. Simple confidentiality protection does not necessarily accomplish this. For example, recording and then replaying an encrypted message such as "Credit $100 to account X" several hundred times may achieve an attacker's goal without the need to decrypt or tamper with the message contents. The Kerberos protocol provides the mechanisms necessary to thwart replay attacks for both authentication and data.

Confidentiality

A confidentiality service protects information against unauthorized disclosure. Kerberos provides message confidentiality by encrypting messages using a choice of encryption algorithms. The session keys needed for confidentiality protection are a product of the Kerberos authentication process. Analysis based on message network addresses and traffic volume may also be used to infer information. An increase in the traffic between two business partners may predict a merger. Kerberos does not provide a defense against traffic analysis. Indeed, most don't since it is a very difficult problem.

Access Control

An access control service protects information from disclosure or modification in an unauthorized manner. Note that access control requires integrity and confidentiality services. Kerberos does not directly provide access control for persistent data, such as disk files. However, the Kerberos protocol provides for the inclusion and protection of authorization information needed by applications and operating systems in making access control decisions.

Authorization

An authorization service provides information that is used to make access control decisions. The secure transport of that authorization information is required in order to ensure that access control decisions are not subverted. Common mechanisms used to represent authorization information include access control lists (ACLs) and capabilities.

An ACL-based system uses access control lists to make access control decisions. An ACL-based system is built on top of other security services, including authentication, and integrity and confidentiality for distribution and management of ACLs. Kerberos does not provide an ACL-based authorization system but does provide all of the underlying services an ACL-based system requires.

Capability-based systems require the encapsulation of authorization information in a tamper-proof package that is bound to an identity. Capability-based authorization is a prerequisite to delegation in a distributed environment. Kerberos provides the facilities necessary for both capability-based authorization and delegation.

Non-Repudiation

Non-repudiation services provide assurance to senders and receivers that an exchange between the two cannot subsequently be repudiated by either. That assurance requires an arbitration authority that both parties agree to; presentation of sufficient and credible proof by the parties to the arbitrator; and evaluation of that proof by the arbitrator in order to settle the dispute. For example, in the case of an electronic funds transfer between two business entities, a court of law would be the arbitrator that adjudicates repudiation-based disputes that arise between the two businesses.

The technological strength of a non-repudiation service depends on the resistance to tampering or falsification of the information offered as proof and the arbitrator's ability to verify the validity of that information. Resistance to tampering or falsification must be sufficient to prevent modification of the proof for as long as a dispute might arise. Although Kerberos offers the basic authentication and integrity services from which a non-repudiation service could be built, the effectiveness of that service will depend on the required strength of the service, and it is dependent on what technologies are incorporated into a Kerberos implementation and the management of the implementation.

The symmetric-key cryptography as used by basic Kerberos implementations is generally not sufficient for non-repudiation, because two parties share a key. Since that key is the basis of any technical proof, either party in possession of that key can forge or alter the proof. If augmented with strict process controls and protection for the KDC, symmetric-key cryptography may be acceptable. However, that process control and protection can be quite expensive. (Note that banks face this issue with the use of PINs, which use symmetric-key cryptography; and the fact that two parties share that key — the consumer and the bank — is rarely an issue, because the bank provides sufficient process controls and protection for management of the PIN.) Kerberos does not offer the arbitration services that are required for the complete implementation of such a service.

Availability

Availability services provide an expected level of performance and availability such as error-free bandwidth. Perhaps the best example of an availability problem is a denial-of-service attack. Consider someone simply disconnecting the cable that connects a network segment to its router. Kerberos does not offer any services to deal with this set of problems. Distributed security systems generally do not offer availability services.

Functional Overview

The ultimate objective of any Kerberos user is to gain access to application services. The process by which that occurs involves several steps, the last step being the actual authentication between the user and the application service. A key part of that process involves the trusted third party in the Kerberos system, the Kerberos security server (KDC). Although descriptions of that process correctly focus on the interaction between users and the KDC, one of the key design elements of Kerberos is the ability for clients and services to securely interact, with little or no involvement of the KDC.

Kerberos is a trusted third-party, credentials-based authentication system. The KDC acts as the trusted third party for humans and services, or principals that operate on client or server computer systems. Kerberos principals authenticate with one another using Kerberos credentials, or tickets. These tickets are issued to principals by the KDC. A client principal authenticates to a service principal using a ticket. The Kerberos security server is not directly involved in that client–service authentication exchange. The result of an authentication exchange between a client and service is a shared session key that can be used to protect subsequent messages between the client and the service.

Components

The primary components of a Kerberos system are the client and server computer systems on which applications operate, and the Kerberos security server (KDC.) In addition to those physical components, there are a number of additional logical components and services that make up the Kerberos system, such as the authentication service and the principals that make use of Kerberos services.

KDC

The keystone of the Kerberos system is the Kerberos security server, generally referred to as the "KDC," or Key Distribution Center. Although the term KDC is not an accurate description of all the services provided, it has stuck. The KDC is the trusted third party in the Kerberos distributed security system. The KDC provides authentication services, as well as key distribution and management functions. There may be multiple KDCs, depending on the level of service and performance that is required. The KDC consists of a set of services and a database that contains information about principals.

Principal

The entities to which the KDC provides services are referred to as "principals." Principals share a very high degree of trust with the KDC. They may be human or may represent a service or a machine. Every principal has an identifier that is used by the KDC to uniquely identify a human or service and allow one principal to determine the identity of another during the Kerberos authentication process. Depending on the cryptographic mechanisms used, a principal may also share a secret key with the KDC, thus the high level of trust required between principals and the KDC.

The primary difference between human and service principals results from the available means for storing the password, or key, and the persistence of that key. A person can securely carry a password in his head, whereas services cannot. Services that use shared secrets for authentication require access to a key. Unlike keys that are used by humans — which are typically derived from a password — service keys are typically random bit strings. If unattended operation for services is required, that key must be kept in persistent storage that is accessible to the service. That key storage is referred to as a "key table" and is generally kept in a file on the host computer system on which the service operates. Key tables may contain keys for multiple services, or may be unique to a service. The security of key tables is dependent on the host computer system's security. This is identical to the problem of protecting private keys in public-key or asymmetric-key systems. More secure solutions for protection of key tables require tamper-proof hardware such as a smart card.

The most significant functional difference between a client and a service results from the difference in key persistence. Kerberos clients do not maintain the user's key in any form beyond a very short period of time during the initial authentication process. However, services always have ready access to their key in the key table. The result is that clients generally can only initiate communications, whereas services may either initiate or accept communications (i.e., a service may also act as a client).

Ticket

A ticket is part of a cryptographically sealed credential issued by the KDC to a client. A ticket, along with other confidential information, allows a client to prove their identity to a service, without the client and service having any preestablished relationship. A ticket is specific to a client–service pair. That is, a ticket specifies both a client principal and the service principal: the client principal to whom the ticket was issued, and the service principal for which it is intended. A client may reuse tickets. Once a client obtains a ticket for a service, subsequent authentication of the client to the service does not require involvement of the KDC.

Realm

The KDC logically consists of a set of services and a database that contains information about principals. In Kerberos that collective is referred to as a "realm," and the authentication service within the KDC is the trusted third party for all principals in the realm. Realms may be defined based on either security requirements in order to separate domains of trust, or as an administrative convenience for grouping principals. Some implementations allow a single KDC to serve multiple realms to reduce the number of physical systems needed. Principals in different realms can interact using "cross-realm" (sometimes referred to as "inter-realm") authentication. Cross-realm authentication generally requires prior agreement between the administrators of the different realms.

Principal Identifier

Kerberos defines several principal identifier forms, including a native Kerberos form, as well as an X.500 distinguished-name form. We describe only the native Kerberos name form here. Simple principal identifiers take the form name@REALM. Principal identifiers are case sensitive. By convention, the realm name is the DNS domain name in upper case. For example, hanley@Z.COM refers to the principal named hanley in domain

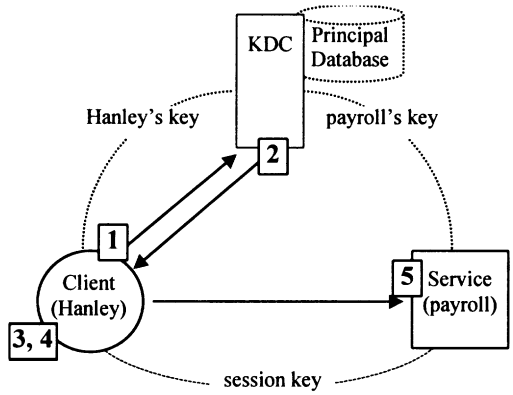

EXHIBIT 118.3 Basic Kerberos authentication.

z.com. Principal identifiers may also contain an instance. Instances are typically used only for service principals (discussed later in this chapter).

Authentication

The simplest and most basic form of the Kerberos protocol performs authentication using a shared secret and symmetric-key cryptography: the user and KDC share a secret key, and the service and KDC share a secret key. However, the user and service do not share a secret key. Providing the ability for a user and service to authenticate, and establish a shared secret, where none previously existed, is the fundamental purpose of the Kerberos protocol.

For this basic form of Kerberos authentication to work, users and services must first share a secret key with the KDC. Methods for first establishing that shared secret vary. The steps of the basic authentication process are discussed below and shown in Exhibit 118.3.

1. A user, or more precisely, Kerberos client software on the user's work station acting on behalf of the user, prompts the user for his ID. The client then sends that ID to the KDC as an assertion of the user's identity, along with the name of a service that the client wishes to access (for example, "I'm Hanley and I want access to the payroll service").
2. The authentication service (AS) of the KDC receives that request, constructs a reply, and sends that reply to the client.
   2.1. The AS checks to ensure that the requesting client (Hanley) and service (payroll) principals exist in the principal database maintained by the KDC. Assuming they exist, the AS constructs a "service ticket" for the requested service (payroll) and places the user's principal name (Hanley) into that service ticket.
   2.2. The AS then generates a random key, referred to as the "session key."
   2.3. The AS then places the session key into the service ticket. The service ticket is then encrypted, or "sealed," using the service's key, obtained from the principal database. That service key is a secret key the (payroll) service shares with the KDC. That key is held in the principal database, as well as by the service.
   2.4. The AS constructs the client part of the reply and places the same session key (from step 2.2) into the client part of the reply. The client part of the reply is then encrypted using the user's key, obtained from the principal database. That is, the secret key (i.e., password) the user (Hanley) shares with the KDC. That key is held in the principal database, as well as by the user.
3. The client receives the reply from the AS, and prompts the user for his password. That password is then converted to a key, and that key is then used to decrypt, or "unseal," the client part of the reply from the AS (from step 2.4).

   If that decryption succeeds, then the password/key entered by the user is the same as the user's key held by the KDC (i.e., the key used to encrypt the client part of the reply). The decryption process also exposes the session key placed into the reply by the AS (from step 2.4). Note that the client cannot

tamper with the service ticket in the reply, because it is encrypted, or "sealed," using the service's key, not the client's key.

If the decryption does not succeed, then the password the user entered is incorrect, or the real AS did not issue the reply, or the user is not who he claims to be. In any case, the information in the AS' reply is useless because it cannot be decrypted without the proper password/key, and the process ends.

The following steps assume that the decryption process succeeded. Note that the AS has no knowledge of whether or not the decryption process on the client succeeded.

4. When the client (Hanley) wishes to authenticate to the service (payroll), the client constructs a request to the service. That request contains the service ticket for the payroll service issued by the AS (from step 2.3).
5. The service receives the request from the client, and uses its service key to decrypt the ticket in the request, i.e., the key that is the shared secret between the (payroll) service and the KDC, and that was used to encrypt the service ticket by the AS (from step 2.3).

   If the decryption succeeds, the service's key and the key that the ticket is encrypted in are the same. Because the KDC is the only other entity that knows the service's key, the service knows that the ticket was issued by the KDC, and the information in the ticket can be trusted. Specifically, the client principal name placed into the ticket by the AS (from step 2.1) allows the service to authenticate the client's identity. The decryption process also exposes the session key placed into the service ticket by the AS (from step 2.3).

   If the decryption fails, then the ticket is not valid. It was either not issued by the real AS, or the user has tampered with the ticket. In any case, the ticket is useless because it cannot be decrypted, and the process ends.

At this point, the service (payroll) has proof of the client's identity (Hanley), and both the client and the service share a common key: the session key generated by the AS (from step 2.2), and successfully decrypted by the client (from step 3) and by the service (from step 5). That common session key can then be used for protecting subsequent messages between the client and the service. Note that once the ticket is issued to the client, there is no KDC involvement in the authentication exchange between the client and the service. Also note that the user's password/key is held on the work station, and thus exposed on the work station, only for the period of time required to decrypt the reply from the KDC.

A thief could eavesdrop on the transmission of the reply from the KDC to the client. However, without the user's key, that reply cannot be decrypted. A thief could also eavesdrop on the transmission of the service's ticket. However, without the service's key, that ticket cannot be decrypted. Without knowledge of the user's or service's keys, the attacker is left with encrypted blobs that are of no use. There are other more sophisticated attacks that can be mounted, such as a replay attack, and there are other countermeasures in Kerberos to help thwart those attacks; those attacks and countermeasures are discussed in subsequent sections.

Credentials Caching

The authentication exchange described above allows a client and service to securely authenticate and securely establish a shared secret — the session key — without requiring a preestablished secret between the client and service. While those are useful and necessary functions of any distributed authentication service, it requires that the user obtain a service ticket each time access is required to a service. It also requires that the user enter a password each time a service ticket is obtained in order to decrypt the ticket. This behavior would obviously not be a very efficient use of people's time or network bandwidth.

A simple additional step to cache credentials — that is, the service ticket and session key — would allow the reuse of credentials without having to constantly go back to the AS or requiring user involvement. A "credentials cache" on the client serves this purpose, and all Kerberos implementations provide a credentials cache. Thus, as the user collects service tickets during the day, they can be placed into the credentials cache and reused. This eliminates involvement between the user and the AS when the same service is accessed multiple times. Note that a client requires both a ticket and the ticket's associated session key (a credential) to make use of a ticket. Thus the term "credentials cache," and not "ticket cache."

Kerberos can also limit the usable life of credentials by placing an expiration time into the ticket when the AS constructs the ticket. The ticket expires after that time, and the user must go back to the AS to obtain another ticket. While Kerberos tickets can have virtually any lifetime, the typical lifetime of a Kerberos ticket is the average workday.

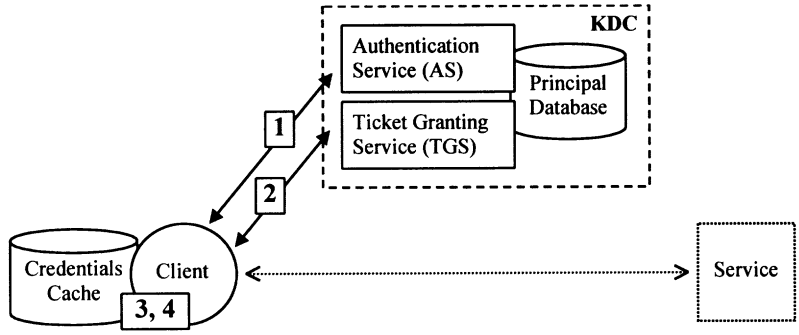

EXHIBIT 118.4 Authentication and ticket-granting services.

Ticket-Granting

Even with credentials caching, interaction between the user and the authentication service (AS) would still be required every time the user wants another ticket. For environments in which a user may access dozens of services during the day, this is unacceptable. One possible solution would be to cache the user's password in order to obtain service tickets without user interaction. However, that exposes the user's password to theft by rogue client software. Note that rogue software could also steal credentials from the credentials cache. However, those credentials will typically expire after a day or less. So, while a thief may have a day's fun with stolen credentials, at least the thief does not get indefinite use of the user's identity. Thus, we can limit the duration of such a compromise to the lifetime of the credentials. The ability to limit a compromise in both space and time is an extremely important attribute of a distributed security system. However, if the user's password is stolen, it is much more difficult to limit such a compromise.

The solution to this problem builds on the three parts that we already have: the authentication service (AS), which can issue tickets for services to clients; the credentials cache on the client that allows reuse of a ticket; and the ability to authenticate a user to a service using an existing credential. Using those components, we can then build a service that issues tickets for other services, much like the AS. However, our new service accepts a ticket issued by the AS, instead of requiring interaction with the user.

Our new service is known as the "ticket-granting service," or TGS. The TGS operates as part of the KDC along with the authentication service (AS) and has access to the same principal database as the AS. We have not dispensed with the AS, but the primary purpose of the AS is now to issue tickets for the TGS. A ticket issued by the AS for the TGS is known as a "ticket-granting ticket," or TGT. Using that ticket-granting ticket (TGT), a client can use the ticket-granting service (TGS) to obtain tickets for other services, or "service tickets." Thus, for example, instead of asking the authentication service (AS) for a ticket for the payroll service, the client first asks the AS for a ticket-granting ticket (TGT) for the ticket-granting service (TGS); then, using that TGT, asks the TGS for a service ticket for the payroll service. Although that introduces an additional exchange between the client and the KDC, it typically need be done only once at the beginning of the workday (see Exhibit 118.4).

By using the AS only once at the beginning of the day to obtain a TGT, and then using that TGT to obtain other service tickets from the TGS, we can make the entire operation invisible to the user and significantly improve the efficiency and security of the process. Thus, the behavior becomes:

1. The first action of the day is to obtain a TGT from the AS as previously described (e.g., providing an ID and password). Only, instead of the user specifying the name of a service, the client automatically requests a ticket for the TGS on behalf of the user.
2. The TGT and session key returned by the AS from the prior step is placed into the credentials cache, along with the TGT's session key.
3. When a service ticket is needed, the client sends a request to the TGS (instead of to the AS). That request includes the TGT and the name of the service for which a ticket is needed. The TGS authenticates the client using the TGT just like any other service and, just like the AS, constructs a service ticket for the requested service and returns that ticket and session key to the client.

4. The service ticket and session key returned from the TGS is placed into the credentials cache for reuse. The client may then contact the service and authenticate to the service using that service ticket.

A TGT is identical to any other service ticket and is simply shorthand for "a ticket for the TGS." The AS and TGS are virtually identical, and both can issue tickets for any other service. The primary difference between the AS and TGS is that the TGS uses a TGT as proof of identity, whereas the AS can be used to issue the first, or "initial" ticket. The proof the AS requires before that initial ticket is issued to a user can involves forms that are not a Kerberos ticket, such as a token card, smart card, public key X.509 certificate, etc. Those various forms of proof are referred to as "preauthentication." Subsequent sections describe the AS and TGS exchanges, the client–service exchanges, and preauthentication in greater detail.

Functional Description

This section builds on the previous discussions and provides a description of both the Kerberos protocol and the interaction of various components in a Kerberos system. Application of the protocol to solve various distributed security problems is also used to illustrate concepts and applications of the protocol. This description is not definitive or complete, and there are many details that have been omitted for clarity and brevity. For a complete description of the protocol, the official standard, Internet RFC 1510, should be consulted.

Initial Authentication

The Kerberos initial authentication process is the point in time when an individual proves his identity to Kerberos and obtains a ticket-granting ticket (TGT). Typical implementations integrate the initial authentication process with the host OS log-in, providing a single point of authentication for the user each morning. A variety of technologies can be brought to bear at this point, depending on the level of assurance that is needed for an individual's identity. Once initial authentication is completed, the TGT obtained as a result of that initial authentication can be used to obtain service tickets from the ticket-granting service (TGS) for other services. Those service tickets are the basis for client–service authentication, as well as the establishment of the keys needed to subsequently protect client–service interactions.

The simplest form of initial authentication uses an ID and password, as previously described:

1. The client asserts its identity by sending a Kerberos principal name to the KDC. The client sends no proof of its identity at this time. To put it another way, the proof offered by the client at this time is null.
2. The KDC then constructs a TGT and a reply that is encrypted in the user's key. That key is derived from the user's password and is a shared secret between the user and the KDC.
3. The KDC then sends the (encrypted) reply with the TGT back to the client.
4. The client receives the reply from the KDC, then prompts the user for his password and converts the password to a key. That key is then used to decrypt the reply from the KDC.
5. If the reply from the KDC decrypts properly, the user has authenticated. If the reply does not decrypt properly, the password provided by the user is incorrect.

Note that authentication actually occurs on the client, and the KDC has no knowledge of whether or not the authentication was successful. The KDC can infer that the authentication was successful only if the client subsequently uses the TGT that is part of the reply to obtain a service ticket. The drawback of this approach is that anyone can make a request to the KDC asserting any identity, which allows an attacker to collect replies from the KDC, and subsequently mount an offline attack on those replies. The Kerberos preauthentication facility can be used to help thwart those attacks.

Preauthentication

The term "preauthentication" is used to describe an exchange in which the user sends some proof of his identity to the KDC as part of the initial authentication process. If that proof is unacceptable to the KDC, the KDC may demand more, or alternate, preauthentication information from the client, or may summarily reject or ignore the client. In essence, the client must authenticate prior to the KDC issuing a credential to the client; thus the term "preauthentication." The proof of identity used in preauthentication can take many forms and

is how most technologies such as smart cards and tokens are integrated into the Kerberos initial authentication process.

What technologies are used depends on the level of assurance required for a user's identity and is typically associated with a user (or a role performed by a user). For example, Kerberos administrators might be required to use two-factor authentication, whereas a simple ID and password would suffice for other users. Implementations vary in the types of preauthentication they support. Preauthentication data may include a digital signature and an X.509 public key certificate; token card data; challenge–response; biometrics information; location information; or a combination of different types of those preauthentication data.

Preauthentication may require several messages between the client and KDC to complete the initial authentication process. For example, the challenge–response exchange used for some token cards may require additional messages for the challenge from the KDC and the response from the client. Only the simplest form of preauthentication is described here. The simplest form of preauthentication uses an ID and password, and an encrypted timestamp:

1. The client prompts the user for his principal ID and password, and converts the password to a key.
2. The client then obtains the current time and encrypts that (along with a random confounder), attaches its principal ID, and sends the request to the KDC.
3. If the KDC can decrypt the timestamp in the request from the client, it has some proof that the user is who he says he is. The KDC may also require that the timestamp be within certain limits.

After this point the process is the same as the simple (nonpreauthentication) exchange. Note that this approach affords greater protection by making it more difficult for an attacker to obtain a TGT for other users or otherwise attack a captured TGT.[13] However, an offline attack may still be mounted against replies sent from the KDC to other users that are sniffed off of the network. Thus, good passwords are still as important as ever, and most Kerberos implementations provide facilities for password policy enforcement to minimize the risk of weak passwords.

KDC–Client Exchanges

The exchanges used for initial authentication with the AS and the subsequent exchanges used to obtain service tickets with the TGS, are both built from the same basic mechanism. In this section we also identify the message names that Kerberos uses for the various requests and replies.

1. The client sends an authentication request (AS-REQ) message to the authentication service. In that request, the client specifies that it wants a ticket for the TGS.
2. The AS sends a ticket-granting ticket (TGT) back to the client in an AS reply (AS-REP) message. That TGT is simply a service ticket for the TGS. The AS-REP contains both the TGT and the session key required in order for the client to use that TGT.
3. When the client wants a service ticket for another service, it requests a ticket from the TGS by placing the TGT into a TGS request (TGS-REQ) message. The TGS sends a service ticket for the requested service back to the client in a TGS reply (TGS-REP) message. The TGS-REP contains both the service ticket and the session key required for the client to use that service ticket.

Again, a TGT is functionally no different than any other ticket. Nor is the TGS conceptually any different than any other service. The only reason for using a special TGS-REQ message to talk to the TGS is to codify the conventions used by the ticket-granting service and optimize the protocol. However, if you look closely at the AS-REQ and TGS-REQ messages, they are very similar and are sometimes referred to collectively as a KDC request (KDC-REQ) message. The same is true of the AS-REP and TGS-REP messages, which are collectively referred to as a KDC reply (KDC-REP) message.

Initial Tickets

Although the primary purpose of the AS is to issue TGTs, the AS may issue tickets for any service, not just TGTs for the TGS. The only real difference between tickets issued by the AS and tickets issued by the TGS are that tickets obtained from the AS are marked as "initial" tickets; tickets obtained from the TGS (using a TGT) are not marked "initial." Initial tickets can be useful if an application wants to ensure that the user obtained the ticket from the AS (i.e., the client went through initial authentication to obtain the service ticket) and did not obtain the service ticket using a TGT. For example, the change-password service requires that the user

obtain an initial ticket for the change-password service. This requires that the user enter his password to obtain a ticket that is marked initial (i.e., a ticket that the change-password service will accept). A ticket for the change-password service obtained from the TGS using a TGT will not be marked initial and will be rejected by the change-password service. This precludes the use of a stolen TGT to change a user's password, or someone using an unlocked work station to change the work station user's password using a cached TGT.

Ticket Construction

Every ticket adheres to the same basic format and contains the same basic information. That information includes the name of the client principal, the name of the service principal, the ticket expiration time, and a variety of other attributes and fields. When a client requests a ticket for a service, the reply from the KDC contains the service ticket, encrypted in the key of that service. Most of the information in the service ticket is also exposed to the client as part of the reply. That information is provided to the client so that the client can ensure that what it received is what the client requested.

The KDC may also provide defaults for various fields in the ticket, which the client did not specify, but which the client may need to know. For example, each ticket has a lifetime; the client may or may not specify the ticket lifetime in a request. If the client does not specify a lifetime, the KDC will provide a default value. The KDC may also enforce maximum values for various fields. For example, if the sitewide maximum ticket lifetime is eight hours, the KDC will not issue a ticket with a lifetime longer than eight hours, regardless of what the client requests. Knowing the lifetime of a ticket is important for a client so that if the ticket is expired, a new ticket can be requested automatically from the TGS without user involvement. For instance, long-running batch jobs.

Most implementations also allow each service to specify a maximum ticket lifetime, and the KDC will limit the lifetime of a ticket issued for a service to the service-defined maximum. Some services, such as the change-password service, typically have maximum ticket lifetimes that are very short (e.g., ten minutes), with the objective being to make those tickets "single use." Most password-change clients also do not cache such tickets, because holding on to them would be of no value.

Client–Service Exchanges

The authentication exchange that occurs between a client and a service is conceptually similar to the client–KDC exchanges. However, the messages used are different to accommodate specific needs of client–service authentication and to eliminate information that is required only for client–KDC exchanges. The messages used for client–service application authentication are collectively referred to as the application (AP) or client–server (CS), messages.

In the following example, we assume that the client already has a service ticket in its credentials cache and, if not, the client will obtain the required service ticket prior to beginning this exchange.

1. The client constructs an application request (AP-REQ) message and sends it to the service. The AP-REQ contains the service ticket as (previously issued by the KDC and stored in the credentials cache as part of a client-TGS exchange). The AP-REQ also contains an authenticator. The authenticator contains various information, including a time-stamp, and may be used by the service to ensure that the AP-REQ is not a replay. The client encrypts the authenticator, and some other information in the AP-REQ, with the session key that is associated with the service ticket (obtained originally from the KDC as part of the TGS-REP).
2. The service receives the AP-REQ and decrypts the ticket in the AP-REQ using its own service key. This exposes the information in the service ticket, including the client's identity, various flags, and the random session key generated by the KDC when the KDC issued the service ticket to the client. After this decryption process is completed, both the client and service are in possession of a common key: the random session key generated by the KDC when the service ticket was originally constructed and issued to the client by the KDC.
3. The session key obtained in the previous step is used to decrypt the authenticator. The authenticator contains information that allows the service to ensure that the AP-REQ message is not a replay. The authenticator may also contain a "subsession" key (see below).

4. If the client requests mutual authentication, the service is obliged to reply to the client with an application reply (AP-REP) message that is encrypted in either the session key from the ticket or a subsession key. The AP-REP allows the client to validate the identity of the service.

Other provisions of the AP-REQ and the AP-REP allow for the establishment of initial sequence numbers for data message sequencing, and the establishment of a new subsession key that is independent of the session key in the service ticket (which was generated by the KDC). Either the client or the service can generate a new subsession key. This allows a fresh session key, unknown to the KDC, to be used for every session between the client and the service.

Confidentiality and Integrity

Once the appropriate session keys are established, the Kerberos "safe" (SAFE) messages can be used for integrity protection, and "private" (PRIV) messages can be used for confidentiality protection. Those messages also provide for additional protection using sequence numbers, timestamps, and address restrictions (discussed later in this chapter). Alternatively, the application may choose to use its own form of integrity and confidentiality protection for data. For example, an IPSec (Internet Protocol Security) implementation could use the basic AP-REQ and AP-REP exchange to establish the keys for two end points, where the end points are network stacks or systems, instead of a human and a service.

TGS AP-REQ

Examination of the protocol will show that an AP-REQ is also used in the TGS request (TGS-REQ). The AP-REQ is the client's way of authenticating and securely communicating with a service, and the TGS is simply another service, albeit with special capabilities. The AP-REQ used to authenticate to the TGS contains the TGT (the service ticket for the TGS), just as any AP-REQ for any service. Because the TGS-REQ requires more than just an AP-REQ, the AP-REQ in the TGS-REQ is carried in a preauthentication element of the TGS-REQ.

Replay Protection

Replay protection ensures that an attacker cannot subvert the system by recording and replaying a previous message. As mentioned previously, confidentiality and integrity protection alone do not protect against replay attacks. Kerberos can use timestamps or a form of challenge response, to protect against replay attacks. The type of replay detection that is appropriate depends on whether a datagram-oriented protocol, such as UDP/IP, or a session-oriented protocol, such as TCP/IP, is used. Note that all protocols that provide replay protection will have mechanisms and requirements similar to those described here, regardless of the type of cryptography that is used.

Timestamps

Replay protection using timestamps is most suited to datagram- or transaction-oriented protocols and requires loosely synchronized clocks based on a secure time service and the use of a "replay cache" by the receiver. A replay cache is simply a cache of messages previously seen by the receiver, or more likely, a hash of each of those messages. The receiver must check each received message against the replay cache to determine if the message is a replay. Note that the replay cache must be maintained in persistent storage if replay detection is to survive a restart of the service.

Obviously, the replay cache could grow forever unless it is bounded in some manner. Timestamps help to limit the size of the replay cache. By defining a bounded window of time for the acceptance of messages, the replay cache can be limited to messages that are received within that window. A service will summarily reject any message with a timestamp outside of that window, and messages outside that window can be discarded from the cache. Thus, the replay cache must be checked only for messages that fall within that window, and the size of the replay cache can be limited to messages received within that window.

That window of time over which the replay cache must operate is referred to as the acceptable "clock skew." Clock skew represents the maximum difference that is allowable between the clocks of two different systems. If the systems' clocks differ by more than the clock skew, all messages will be rejected. A typical value for clock skew is five minutes. Smaller clock skew values require closer synchronization of system clocks but reduce the overhead of maintaining and checking the replay cache. Larger clock skew values allow looser synchronization of system clocks, but increase the overhead of maintaining and checking the replay cache.

Datagram- or transaction-based applications must deal with duplicate, dropped, and out-of-sequence messages as a normal network occurrence. Thus, well-behaved datagram- or transaction-based applications should already have mechanisms for replay detection within the application, regardless of security considerations. If those applications protect their messages using Kerberos confidentiality or integrity services, there is usually no need to use Kerberos replay protection for the application data. Although Kerberos can provide the necessary replay protection "out of the box" for those applications, the applications should be examined to ensure that the protection provided by Kerberos is not redundant and does not add unnecessary overhead.

Challenge–Response

Replay protection using a challenge–response exchange is most suited to session-oriented protocols, such as TCP/IP. The subsession key facility within the Kerberos AP-REQ and AP-REP messages provides a means to effect the challenge–response exchange. Challenge–response eliminates the requirement for clock synchronization between the client and the service, and the need for the service to maintain and check a replay cache. However, challenge–response adds an additional message from the service back to the client. Thus, challenge–response is typically suitable only for session-oriented communications where the cost of the messages can be amortized over an entire session, or where those messages can be piggybacked on the application's normal session-initiation messages. Individual messages within the session must then be protected using sequencing and confidentiality or integrity to ensure that the messages within the session are not subject to replay attacks. Mechanisms similar to what are described here can also be used to minimize the need for clock synchronization between clients and the KDC.

Making use of the subsession key facility within the AP-REQ and AP-REP messages requires mutual authentication. Challenge–response also requires that the service respond with a new random subsession key in the AP-REP for each AP-REQ. In effect, the new random subsession key in the AP-REP generated by the service is the challenge. The client's ability to subsequently decrypt the AP-REP, extract the new subsession key, and protect subsequent messages to the service using that subsession key provide proof that the AP-REQ was not a replay and serves as the client's response to the service's challenge.

Note that the service cannot verify that the client has passed the challenge until the service receives the first data message from the client to the service protected by the subsession key. Thus, the client is technically not authenticated to the service until the first data message from the client is successfully received and decrypted by the service. By the same token, the service is technically not authenticated to the client until the first data message from the service in reply to the client is received and decrypted by the client (the AP-REP from the service could be a replay to the client). Whether that technical issue is a security issue depends on the behavior of the client and server. If the client or service engage in a significant and irreversible act prior to the completion of authentication on both sides, damage could result. Generally however, the worst that can happen is a denial-of-service attack that is difficult to diagnose.

Session Keys

Tickets may be sniffed off the network by an attacker during client–KDC or client–service exchanges. Thus, a ticket alone is insufficient to prove the identity of the client principal name embedded in a ticket or the right of the holder to use that ticket. The session key associated with a ticket provides the additional information necessary for that proof. Every ticket issued by the KDC has a unique session key (unless a client specifically requests otherwise). A Kerberos credential is a ticket and the associated session key. The following sections review the role session keys play in the various exchanges.

Authentication Service

During the initial authentication exchange, the client uses the key derived from the user's password to decrypt the reply (the AS-REP message issued by the AS). That reply, as do all KDC replies, contains a ticket (in this case, the TGT returned by the AS). When the client decrypts that reply, the decryption exposes a session key. All requests and replies between the client and the TGS from that point onward are protected using that session key from the AS-REP. Using the session key that results from the initial AS exchange eliminates the need to store the user's key in any form on the work station. That is, once the initial authentication exchange between the client and the AS is completed, subsequent exchanges use the session key returned by that exchange and not the key derived from the user's password. The TGT, as with any ticket, is sealed with the service key of the service for which the ticket is intended, which in this case is the TGS. The client typically places the TGT and the TGT's session key into a credentials cache for future use.

Ticket-Granting Service

When the KDC builds a TGS reply (TGS-REP), it first constructs a ticket for the requested service. As part of that construction process, the KDC generates a random session key that is placed into the ticket. The KDC then encrypts that ticket in the service's key (the key it shares with the service.) That ticket is then placed into the reply (TGS-REP) to the client, with the ticket ultimately destined for the service. That same random session key is also placed into the reply destined for the client. The reply is then encrypted with the session key associated with the TGT in the client's request to the TGS (TGS-REQ). When the construction of the reply (TGS-REP) is completed by the KDC, we have: (1) a service ticket containing the session key; (2) that service ticket encrypted in the service's key; (3) a reply containing the same session key; and (4) that reply encrypted in the session key associated with the TGT.

When the reply is received and decrypted by the client — using the TGT's session key — one copy of the ticket's session key, along with other relevant information about the ticket, is exposed to the client. The other copy of the session key, along with most of the same information exposed to the client, is still sealed in the service ticket. The content of that service ticket is not accessible to the client, because it is encrypted in the service's key (the key the service shares with the KDC), which is not known to the client. That prevents the client from tampering with the information in the ticket. The client typically places the ticket, along with the other ticket information, including the session key for that ticket, into a credentials cache for future use.

Client–Service Exchanges

Session keys play the same role in the client–service exchange as they do in the client–KDC exchanges. The authenticator constructed by the client as part of the application request (AP-REQ) message is encrypted using the session key associated with the service ticket. That same session key is accessible to the service when the service decrypts the service ticket using its own service key. That session key from the service ticket is then used to decrypt (and thus validate) the authenticator.

Cross-Real Authentication

A realm typically defines a collective trust, or common security domain. Obviously there are limits to the size of such a domain both in manageability and in the collective and common trust that domain represents. For example, collective or common trust usually drops precipitously at enterprise boundaries, and sometimes at organizational boundaries within an enterprise. However, it is often the case that those various domains, or realms, must still communicate securely.

Between realms, Kerberos provides cross-realm authentication services. Cross-realm authentication allows principals in one realm (e.g., clients) to authenticate with principals in another realm (e.g., services). Conceptually, cross-realm authentication treats each realm in the path between a client and a service as simply another service. The client's realm effectively issues a ticket for the ticket-granting service (TGS) in the service's realm; that ticket is referred to as a cross-realm or inter-realm TGT. For example, a client in realm X accessing a service in realm Y first goes to a KDC in realm X to obtain a cross-realm TGT for realm Y; that TGT is then presented to a KDC in realm Y in order to obtain a service ticket for the end, or "target" service.

Cross-realm authentication requires prior agreement between the administrators of the two realms in order to establish the keys on the respective KDCs. Those keys effectively allow one realm to issue cross-realm TGTs that will be honored by the other realm. As with other services, possession of a ticket does not ensure right of access; access is ultimately determined by the service and not the issuing realm or KDC. The trust established between realms for cross-realm authentication lies in the promise that the realms will not lie about the identity of their respective clients. The ability to issue a cross-realm TGT is not necessarily bilateral; this allows one-way cross-realm authentication, although this feature is rarely used.

The client may collect cross-realm TGTs obtained during cross-realm authentication, just as any other tickets, and hold them in its credential cache for reuse. Once the client obtains the cross-realm TGT for the target realm, the client can request tickets from the target realm's TGS directly, just as the client would request tickets directly from the TGS in its own realm. Once the client obtains the ticket for the target realm's TGS, the client–service authentication process is identical to the client–service authentication process within a single realm. Thus, cross-realm authentication between a client and any service in the other realm requires that the additional cross-realm authentication steps be performed only once. For example, given realms X and Y, where the realm administrators have previously established a cross-realm relationship, a client in realm X that wants to get to a service in realm Y must first obtain a cross-realm TGT from a KDC in realm X for realm Y. That

cross-realm TGT may then be used to get a ticket from a KDC in realm Y for a service in realm Y and the KDC in realm X does not participate in the latter step.

Any number of realms can have a direct, or pair-wise, cross-realm relationship, in which case a client goes directly between those realms as described above. Where many realms are involved, direct relationships between every pair of realms can be a significant management overhead for establishing all of the necessary cross-realm keys. For example, with ten realms, a direct relationship between every pair of realms requires that each realm maintain nine pairs of cross-realm keys (a key pair assumes a bilateral relationship), for a total of 90 cross-realm key pairs. Although this is manageable for a relatively small number of realms, such as one might find within an enterprise, it becomes unmanageable for a large number of realms. Note that this is the geometric trust complexity problem discussed earlier.

To reduce the complexity of cross-realm key management, realms may also be arranged in transitive relationships. This reduces the number of direct relationships that must be managed but may require a client to traverse, or transit, intermediate realms in order to get to the realm of the end service. For example, given realms X, Y, and Z, where X–Y has a direct relationship, Y–Z has a direct relationship, but X-Z does not have a direct relationship. In this case, X–Z has a transitive relationship through Y. In order for a client in X to get to a service in Z, the client must transit Y, because X and Z do not have a direct relationship. The client first obtains a cross-realm TGT from realm X to realm Y. That cross-realm TGT is then used to obtain a cross-realm TGT from realm Y to realm Z. The cross-realm process may be extended to as many steps as are necessary for a client to reach the target realm of a service. Each step in that process is identical and results in a cross-realm TGT for a realm that is "closer" to the realm of the service.

Within a collective, realms are typically organized as a tree, or "realm hierarchy," where each realm has a direct relationship with one parent and potentially several children. To get from one realm to another, the client may have to climb up the tree toward the root, and then down the tree to get to the desired service's realm, collecting inter-realm TGTs along the way. The tradeoff between direct and transitive realm structures is the key management overhead required for direct relationships vs. the network overhead required to transit intermediate realms. Both direct and transitive relationships can be used in combination. For example, the majority of realms may be arranged using transitive cross-realm relationships, as in a realm hierarchy. Where performance or trust is an issue for specific realms, those realms can also have direct cross-realm relationships, allowing clients to go directly to the target realm, thereby "short circuiting" the need to transit intermediate realms in the realm hierarchy.

Tickets issued as a result of cross-realm authentication have within them the names of the realms transited by the client within them. The list of transited realms is referred to as the "transited realms list." This allows a service (or any intermediate realm) to ensure that all the realms in the path that participated in cross-realm authentication can be trusted not to lie about the client's identity. However, in general, a realm will either be trusted or not. A trusted realm will be part of a cross-realm collective. Untrusted realms will be excluded from that collective or will not be placed in the path between critical clients and services. If principals or services must avoid the use of a less trusted realm due to the sensitivity of their work, direct relationships can be established between those realms, bypassing those less trusted realms.

Ticket Restrictions

If the client sends a credential — that is, a ticket and the associated session key — to another principal, the recipient's use of the client's identity is limited solely by the ticket's implicit restrictions. The lifetime of a ticket is one obvious implicit restriction that defines the time during which a ticket may be used. Another implicit restriction is the service name in the ticket; that service name is an implicit restriction on the use of the ticket. If the service name in that ticket is the ticket-granting service (TGS), and hence the ticket is a TGT, then the holder may obtain any other tickets. Obviously, handing over your TGT (along with the TGT's session key) to another principal requires a very high level of trust in that principal.

In some cases, the implicit restrictions in a ticket may be sufficient. For example, consider a client that wishes to print a file on a file server using a print server. If the client sufficiently trusts the print server, the client can simply send a credential (ticket and session key) for the file server to the print server. The print server can then use that credential to access the file server in the client's name. The service ticket (for the file server) in that credential only allows the print server to access the file server using the client's identity; it does not allow the print server to access any other services using the client's identity. However, the client must trust the print server sufficiently to allow the print server unrestricted use of the client's identity when accessing the

file server. If that trust is not warranted, authorization data can be used to further restrict the print server's use of the client's identity.

In many cases we would like to restrict certain common uses of a credential by another principal without having to first agree on the syntax or semantics of authorization data. There are several common forms of restrictions provided by Kerberos to deal with these cases. (Most if not all of these cases could use authorization data to restrict the ticket's use.) The codification of these restrictions by Kerberos is in large part recognition of common use. These restrictions also allow common constraints on ticket usage that are based on site policies that are enforced by the KDC.

Address Restrictions

A ticket's use may be limited to specific network addresses, such as the originating client work station. Those address restrictions may be used to help restrict the use of credentials sent to another principal and can also help to foil the use of stolen credentials. Multihomed systems (systems with more than one network address or interface) require special care to ensure that address restrictions include the appropriate addresses for the system. In some cases it may be appropriate to restrict use to a subset of the addresses or interfaces on the system (e.g., inbound or outbound interfaces on a firewall). In other cases there may be no control over, or any desire to control, which addresses or interfaces are used, such as on a high-performance server with many network interfaces. Address restrictions placed on a TGT are propagated to service tickets obtained with that TGT unless otherwise specified. Address restrictions may also be empty, in which case there are no restrictions on where a ticket may be used from. There are obvious security concerns with empty address restrictions. However, outside of a few uses, the use of address restrictions has fallen out of favor. This is due to the difficulty for clients and intermediaries to determine the addresses that a recipient may need.

Address restrictions provide the ability to restrict the use of credentials to a specific machine when those credentials are sent to an intermediary. It may also be desirable to restrict the intermediary's ability to propagate those credentials to other systems and services. (The term "propagation" used here means propagating the use of a credential; there is nothing that can be done to prohibit physical propagation of the ticket.) Ticket attributes known as "forwardable" and "proxiable" allow restricting the subsequent propagation of credentials by a recipient. Those restrictions are binary; they restrict further propagation of the credential by the recipient, or they do *not* restrict further propagation of the credential by the recipient. Finer-grained control must use restrictions in the authorization data. Sites may choose to limit the KDC's willingness to forward or proxy tickets. Similar indicators known as "forwarded" and "proxy" allow a service to determine if a ticket has been obtained in this manner. Services may modify their behavior based on the setting of those indicators. For example, a file server might choose to allow only read-access to certain files when presented with a ticket that has the proxy indicator set.

Proxiable

The proxiable attribute allows the holder of the ticket to ask the ticket-granting service (TGS) to modify the address or lifetime restrictions in the ticket. That results in another ticket with different address or lifetime restrictions. That resulting ticket always has the proxy attribute set. That proxy attribute may be checked by services to determine whether the ticket is from the original client or an intermediary. Proxiable tickets are used to restrict the use of a client's identity to a specific service; a proxiable ticket allows no changes to the ticket other than to the address restrictions. Sending a proxiable ticket to an intermediary allows that intermediary to propagate the ticket to other intermediaries.

For example, a client may provide an intermediary a service ticket for a file server where that ticket has the proxiable attribute set. This allows the intermediary to obtain another proxy or proxiable tickets for the file server and send that ticket to another intermediary, thus allowing other intermediaries access to the file server using the client's identity. Alternatively, the client may obtain a proxy ticket without the proxiable attribute set in the ticket. Lacking the proxiable attribute, that ticket can be used only by intermediaries that satisfy the address restrictions in the ticket. If there are no address restrictions in that ticket, there are effectively no restrictions on which intermediaries may use the ticket. However, what the ticket may be used for is still restricted implicitly by the ticket itself (e.g., the service name in the ticket). Client-specified authorization restrictions may further restrict the use of a credential (see below).

Forwardable

The forwardable attribute is similar to the proxiable attribute. The most significant difference is that the TGS will not issue another TGT based on a TGT with only the proxiable attribute set. A forwardable TGT effectively

allows the holder (assuming they also have the TGT's session key) unrestricted use of the identity in the TGT: forwardable and forwarded tickets — including other TGTs — can be obtained by anyone holding such a TGT. A TGT that is only proxiable does not allow the holder to obtain another TGT.

A forwardable TGT is typically sent if unrestricted use of the client's identity is desirable. One of the few cases where this is desirable is when a user logs into another computer system using, e.g., telnet. In that case the use is effectively establishing the same identity on another remote system. Although we could require the user to go through an initial authentication process again on that remote system (to obtain a TGT), that would provide little additional security and simply irritate the user. The difference in application between forwardable and proxiable tickets can be subtle, but important. In essence, there are three attributes that determine what requests the TGS will honor based on the ticket presented to it: forwardable, proxiable, and whether or not the ticket is a TGT.

Lifetime

A ticket's lifetime is an implied restriction. A proxiable or forwardable ticket's lifetime may be decreased but never increased.

Proxy Services

A proxy service is a service that performs a function on behalf of the client and that uses another end service in order to perform that function on behalf of the client (for example, a client wishing to print files using a print server where the files reside on a file server). The print server acts as a proxy for the client in order to access the files on the file server. The basic form of a proxy provides only implicit restrictions on the use of the client's identity by the intermediate service. This may be sufficient for some clients and services. In the previous example, the client must first obtain a proxy ticket for the print server. That ticket will show the requesting client as the client principal name, and the file server as the service principal name. That proxy ticket may be based on an existing service ticket the client holds for the file service, or it may be obtained directly using a TGT.

1. The client obtains a proxy service ticket for the file server. If the client possesses a ticket for the file server with the proxiable attribute set, that ticket may be used to request a proxy ticket from the TGS. The client sends the file server service ticket in its possession to the TGS, requesting a proxy ticket along with new address restrictions, if any. The TGS returns a service ticket for the file server with new address restrictions. That service ticket will, by default, have the proxiable attribute cleared and will always have the proxy indicator set.

   If the client does not possess a proxiable ticket for the file server, the client must obtain a proxy ticket for the file server using a TGT. That TGT must have the proxiable attribute set. This process is similar to the one described above, only it follows more typical TGS semantics.
2. The client authenticates to the print server using a conventional client–service authentication exchange. The client then sends the proxy credential (ticket and session key) obtained in the previous step to the print server. A variety of means may be used to send those credentials; the Kerberos "credentials" (CREDS) message is intended specifically for this purpose and ensures that the session key associated with the ticket is protected during the transfer of those credentials.
3. The print server uses the file server credential obtained in the previous step to authenticate to the file server, and obtain access to the file server, using the client's identity.

Note that when presented with such a ticket, the file server has no way of knowing that it is not really the client, but the print server, that is requesting access — the client name shown in the ticket is the originating client, not the print server. The file server may infer some information from the fact that the proxy indicator is set in the credential, for example. While useful, this does not provide very granular control and requires that the client must have an fairly high level of trust in the print server. Unless the file server places additional restrictions on access to files based on the setting of the proxy indicator, the print server has full access to any of the client's files. More granular restrictions require the use of client-provided authorization restrictions.

Authorization

Kerberos defines the rules for packaging authorization data elements in tickets and the semantics for placing those elements into tickets. Kerberos does not define the interpretation of those authorization data elements.

There are several points in time where authorization information may be provided or embedded into a ticket, ranging from the initial authentication exchange, to the client–service authentication exchange, and several points in between. There are also several possible sources of authorization information, including the client, as well as authorization services that may be a part of, or accessible to, the KDC. Authorization data provided by clients is referred to as restrictions, because the data restricts the authorized use of a client's identity. (Client-provided authorization data obviously should not be used to amplify the client's authorization, or clients could grant themselves any authority.)

Each authorization data element has a type associated with it. Kerberos defines the syntax of the type information, but does not generally define the interpretation of those types. Authorization data element types are application- or service-specific. Kerberos does not otherwise define the contents of the underlying authorization data elements, and KDCs generally do not interpret those elements, but treat them as opaque objects. Interpretation of authorization data elements is generally a function of each service. By convention or agreement, some elements may have meaning to a large number of services, and thus have a common syntax and interpretation for those services. In other cases, authorization data elements will be meaningful only to a single service, and thus the interpretation of those elements can be performed only by that service. Thus, the use of authorization data requires that the client and the end service (i.e., the applications) agree on the syntax and semantics of the authorization data.

In essence, Kerberos simply provides the ability to securely pass authorization data through intermediate services: the data is sealed (encrypted) in the ticket for the end service by the KDC using the end service's key; the data is unsealed (decrypted), by the end service using its service key. Because authorization data is sealed in a ticket, an intermediate service cannot tamper with that information. However, an intermediate service may be able to modify certain implicit restrictions or may add authorization information to the ticket, depending on ticket attributes.

During the initial authentication process between the client and the authentication service (AS), both the KDC and another authorization source may provide authorization data that is to be placed into the TGT. That data is generally propagated to all other tickets obtained using that TGT. That is, when the TGT is used to subsequently obtain a service ticket from the TGS, the authorization data in the TGT is copied to the service ticket as part of the service ticket construction by the TGS. KDC-supplied authorization data typically bounds the client's authorization. The authorization data placed into the TGT typically represents information that is widely applicable, and that would be of interest to most or all services. For example, KDC-supplied authorization data may include all of a client's group memberships.

The ticket-granting service (TGS) provides the same facilities as the AS for placing authorization data into a ticket. The KDC, or another authorization source, may provide authorization data that is to be placed into the service ticket. In addition, the client may also provide additional authorization data (i.e., restrictions) to be placed into the resulting ticket. That authorization data is in addition to the authorization data that is copied from the TGT used to obtain the service ticket. The authorization data placed into a service ticket as part of the TGS exchange typically represents information that is specific to a service; it may also represent information that is specific to a client–service pair.

Finally, the client–service authentication process provides an additional point at which the client can provide authorization data to the service. The client places additional authorization data into the authenticator that is part of the application request (AP-REQ) message. That authorization data represents restrictions that the client wishes to communicate to the service and that is specific to the session. Thus, at the point when a client authenticates to a service, the service has the sum of the authorization data and that is provided as part of the authenticator in the AP-REQ, the service ticket, and the TGT. That authorization data includes all client-specified restrictions.

Note that the AS does not define the ability for clients to specify authorization data (i.e., restrictions) in the authentication service request (AS-REQ) message, and thus place restrictions into the TGT. (The syntax of the AS-REQ allows this, but the semantics of the protocol preclude it, although it could be provided as preauthentication data if needed.) However, there is nothing that prevents a client from subsequently requesting a TGT from the TGS and placing restrictions into the resulting TGT at that time — for example, in the case of obtaining a proxy or forwarded TGT using an existing proxiable or forwardable TGT. The TGT is simply a ticket for the TGS, and there is nothing that precludes the TGS — or any service for that matter — from issuing a ticket for itself.

Capabilities and Delegation

A capability refers to a credential that has certain rights associated with its possession. Those rights may be both implicit in the fields of the associated ticket and explicit, using authorization data encapsulated in the ticket. A capability that has no address restrictions is sometimes referred to as a "bearer proxy," because it may be used by anyone (client or service) who possesses the credential.[14]

Anyone who possesses a credential with a ticket that is forwardable or proxiable can change or remove address restrictions from the ticket. Anyone who possesses a credential with a ticket that is forwardable or proxiable can also add to the authorization data. That authorization information should never be additive and thus allow the holder to amplify his privileges, thus the use of the term "restrictions" to refer to client-provided authorization information in such tickets. That is, it is acceptable for any holder to further restrict authorization by adding to the authorization data to the ticket; it is not acceptable for any holder to further amplify authorization by adding authorization data to the ticket.

To illustrate the use of capabilities, we again use the example of the client, print server, and file server. The approach illustrated in this example must be used carefully to guard against unwarranted amplification of privileges by intermediate services. For this example, we define authorization data with semantics that are similar to what one might find in an ACL with the triplet:

<id=principal><object=name><permissions=list>

In this triplet, "user" specifies who (a principal identifier); "object" specifies the name of the object to be acted on; and "permissions" specifies the allowable actions by the user on the object. If "id" is empty, then the implied ID is the client name listed in the associated ticket. An authorization data element is thus a triplet as defined above.

Once again, the client wishes to print a file using a print server (the intermediate, or proxy, service), where the file is on a file server (the end service). However, the client does not place a tremendous amount of trust in this print server, and therefore wants to restrict the print server's access. Specifically, the client wants to restrict the print server to read-access for a single file that is to be printed, and wants to restrict that access to a relatively short period of time. We assume that the client already has a service ticket for the print server and a proxiable service ticket for the file server.

1. The client requests a proxy ticket from the ticket-granting service (TGS) for the file server. In the TGS request, the client provides the proxiable service ticket for the file server that is already in the client's possession; requests a lifetime of 30 minutes; specifies the proxy attribute; and has cleared the proxiable and forwardable attributes. If the client wishes to restrict the ticket to the use of a specific print server with a known network address, then the address restrictions in the TGS request specify only the print server's network address. The client could leave the address restrictions empty if the network address of the print server was unknown, or enumerate a list of addresses if the print server is multihomed, or if any one of a pool of networked printers might be used to satisfy the request.

   The following element is specified in the authorization data field of the TGS request (or more accurately, the authorization data field of the AP-REQ that is part of the TGS request):

   <id=><object=/home/Hanley/thesis.ps><permissions=read>

   The interpretation of that triple is: id is null, and therefore interpreted as the client name in the ticket; object specifies the file "/home/Hanley/thesis.doc"; permissions specify read-access. The interpretation of that authorization is: "The client principal name specified in the ticket cannot perform any operation except to read the file '/home/Hanley/thesis.doc'."
2. The TGS constructs a new ticket and sends the new ticket back to the client. That new ticket is identical to the original proxiable service ticket for the file server (provided in the TGS request), except that the new ticket has the client-specified authorization data sealed within it; the proxy indicator set; the proxiable and forwardable attributes clear; and a lifetime of 30 minutes (the new ticket may also have different address restrictions). The new ticket also has a new session key.
3. The client authenticates to the print server using a client–service authentication exchange.
4. The client sends the proxy credential (ticket and session key) obtained in step 2 to the print server using a credentials (CREDS) message.

5. The print server authenticates to the file server using the proxy credential, obtained from the client in the previous step, using a conventional client–service authentication exchange. The print server is now communicating with the file server under the client's identity.
6. When the file server unseals the ticket received in the previous step, the authorization data in the ticket, placed there by the TGS in step 2, is exposed to the file server.

At this point, the print server and file server have authenticated, with the print server using the identity of the client. The file server has no knowledge of the fact that it is the print server actually acting on the client's behalf. However, the print server — through the authorization data in the ticket — knows that restrictions have been placed on the client's access and, we must assume, will enforce those restrictions. (If we cannot trust the file server to properly enforce access controls on its own files, then it is of questionable use for storing controlled information. We cannot solve that problem with Kerberos.) Also, because the ticket expires after 30 minutes, the print server will no longer be able to access the client's file on the print server after that time.

The conventions that control how authorization data is interpreted, the potential sources of that authorization data, and the ticket attributes used, are extremely important to ensure the integrity of this example. By convention, we have agreed that the presence of any authorization elements (i.e., authorization triples) in the authorization data implicitly restricts actions to those that are explicitly enumerated. While those enumerated elements are necessary, they are not sufficient for a complete and secure solution. If the ticket given to the print service had the proxiable or forwardable attribute set, the print service could go back to the TGS and obtain a new service ticket with different authorization. That would allow the print service to obtain access to any of the client's files. Note that this also implies that care should be exercised to ensure that no unwarranted authorization data is in the proxy ticket, as might be the case if the original (proxiable) ticket from which the proxy ticket was obtained had unwanted authorization information in it. Moreover, we cannot allow those tickets to be proxiable or forwardable, to eliminate the possibility of the print server amplifying its privileges by adding authorization data to a ticket.

Because the authorization data is created by the client, that authorization, while sufficient for the needs of the client, is not sufficient for the needs of the file server. The file server did not participate in the creation of the authorization data, and therefore should treat it as suspect. If the file server based all access control decisions only on the authorization data in the ticket, any client could grant itself any rights to any file. For example, there is nothing to stop the client from requesting a proxy with authorization data that specifies access to another user's files and using the resulting proxy ticket itself. This is one reason why proxiable and forwardable tickets should never be given out freely to untrusted intermediaries if authorization data could be used to amplify privileges.

If the file server blindly believed and obeyed the authorization data in the ticket, a client could use a proxy to gain access to any files. That would obviously not be very secure. Thus, this example is secure only if the file server has additional rules it applies to make authorization decisions, such as ACLs, to limit the authorization of the client. In other words, the file server must first check the authorization specified by its ACLs against the client's identity; with that as the authorized limits for the client, the file server can then determine if the authorization specified in the ticket is within those limits.

Note the temporal difference between capabilities and ACLs. To provide temporary, delegated access to a print server in an ACL-based system, the ACL on the file server would have to be modified temporarily to allow access by the file server. Constantly modifying ACLs could seriously degrade performance. However, there are practical limits to how much authorization data can be placed into a capability. This points to a need for both mechanisms: ACLs for long-lived and relatively static authorization information, and capabilities for more dynamic and context-specific information, as is found in delegation.

In the example above, the capability constructed by the client may be used by anyone who possesses the capability (subject to, for example, address restrictions). The client could also restrict the use of the capability to a specific principal using the "id" field in the authorization triplet. For example, by placing the print server's principal identifier into the ID field. This would require that the print server use two credentials to access the file server: the proxy credential provided by the client (showing the client identity in the ticket, and showing the print server's identity in the authorization data); and a credential for the print server itself (showing the print server's identity), to prove to the file server that the print server is the principal listed in the "id" field of the authorization triplet of the client proxy credential.

Identity-based restrictions, in conjunction with the other usage guidelines discussed above, would eliminate the possibility of the print server giving the client's proxy credential to another service, and of the other service subsequently using the credential to obtain unauthorized access to the client's files. This type of restriction

would be preferable to address restrictions and also provides the ability for the file server to audit and control access based on the identity of both the client and the intermediate service. This would allow the file server to, for example, enforce additional restrictions based on the identity of the intermediate server. For example, the file server may choose to prohibit write-access to files by print servers, regardless of what permissions are specified in the authorization data. Another example is to restrict access to certain files by "public" printers, regardless of the file specified in the authorization data.

Management

Management, performance, and operation are all reflections of one another. A system that makes many demands on the environment will require more resources to meet and maintain those demands, whether those demands be disk storage, CPU, network bandwidth, users, or support personnel. A system that makes many assumptions about the environment will require more resources to meet and maintain those assumptions. Those assumptions are simply implied demands the system places on its environment. Those demands have a direct influence on the cost of achieving an acceptable level of performance and the ability of the implementation to perform its intended function. The greater the demands, the higher the cost of operating and managing the system, or the supporting elements that the system depends on. If those demands are not satisfied, a system's performance and usability will suffer. In the extreme case, performance becomes so poor that the system cannot carry out its intended function.

The cost of satisfying demands and assumptions can rise very rapidly in a distributed environment. The more distributed an environment, the less likely that demands will be satisfied over a given number of systems, and the higher the cost of satisfying those demands. Of special concern is the ability of a system to function effectively in the face of changes in the environment. The more distributed an environment, the higher the probability that changes to the environment will occur over a given unit of time and that intervention will be required to compensate for those changes. Thus, the cost of maintaining assumptions increases.

Those problems are magnified in distributed security. The greater the demands placed on the environment by the security system, the more likely it is that performance problems will result and that the security system will fail to carry out its assigned function. The more assumptions that are made about the environment, the more likely it is that intervention will be required to compensate for those changes. Intervention increases the probability of errors, which can lead to security problems.

It is important to distinguish the demands made by Kerberos as a technology and the demands made by Kerberos as a security system. Kerberos technology makes modest demands on the environment, and satisfying those demands should be well within the means of most organizations. Kerberos as a security system can make very insignificant or very oppressive demands on the environment, depending on the level of security an organization needs or chooses to enforce. We use the term "appropriate" to describe that level of security and to qualify those elements that are outside the scope of Kerberos — or any security technology. If an organization decides that "appropriate security" means "very high security," then demands, assumptions, cost, and effort will all increase.

Users

One of the first concerns usually raised by network and system administrators is "What is this going to do to my users?" That is a justifiable concern, because any change that is visible to users will tend to produce a heavy influx of support calls. Kerberos can be virtually invisible and undemanding of users, or extremely visible and oppressive in its demands. That choice is a function of the level of security the site chooses to enforce using Kerberos. For the security needs of the vast majority of sites, Kerberos need not be visible to the user community.

Users are generally unaware of Kerberos, except during the initial authentication process (i.e., sign-on), when they must provide their Kerberos principal identifier and a password, or some other proof of identity. If the Kerberos sign-on is integrated into the host sign-on, Kerberos can be made invisible to the user. If the Kerberos sign-on is not integrated into the host sign-on, or the host has no concept of a sign-on, a separate Kerberos utility to allow the user to sign on and complete the initial authentication process is required.

The result of the Kerberos initial authentication is a ticket-granting ticket (TGT), which is placed into a credentials cache, and which applications may subsequently use for obtaining service tickets in order to authenticate to services. The process of obtaining service tickets using the TGT, and the subsequent authentication exchange between the client and the service, is invisible to the user. Kerberos utilities are typically

provided to view the tickets contained in the credentials cache. However, with the exception of diagnostics and troubleshooting, those utilities are typically not used and are unnecessary.

One of the few times a user might encounter different behavior due to Kerberos is if their TGT expires. All tickets, including the TGT, have a lifetime. Applications will automatically request a new ticket if the old one has expired. However, an application cannot request a new TGT without user involvement. That is, the user must go through the initial authentication process to obtain a TGT. Whether the user community ever encounters that behavior will depend on the lifetime chosen for TGTs. If that lifetime is longer than the average workday, most users will never see this behavior.

Assumptions

Kerberos makes certain assumptions about the environment and the security of the various systems and individuals that make up the Kerberos environment. When discussing these assumptions it is important to distinguish what is required for any distributed or network environment, what is required for any distributed security system, what requirements are specific to Kerberos, and what requirements are specific to a Kerberos implementation.

Minimal assumptions and requirements necessary for any distributed environment include:

- A functional network for clients and services to interact.
- A functional network directory service for clients and services to locate each other.
- A functional software distribution system to distribute software to computer systems that host clients and services.

Assumptions and requirements that are common to virtually all distributed security systems are negotiable and depend on acceptable cost and risk. These include:

- Appropriately secure systems for hosting clients and services
- Appropriately secure software distribution service
- Appropriate protection of identity information by individuals (passwords, smart cards, tokens, etc.)

Assumptions and requirements that are Kerberos-specific are negotiable and depend on acceptable cost and risk. These include:

- Appropriately secure systems for hosting KDCs
- Appropriately secure time service, with loosely synchronized clocks on all systems on which Kerberos operates

The following discussion provides security recommendations for the assumptions and requirements enumerated above. These recommendations are common to virtually all implementations. However, they do not account for budget or other organizational constraints, and actual requirements will depend on cost–risk tradeoffs, which will be different for each deployment.

Directory Service

Kerberos typically requires the Internet domain name service (DNS) to construct the names of service-based principals and locate those principals on the network. An ineffective DNS or an inconsistent naming structure can make this job more cumbersome. Although many network services depend on a network naming system to function, a compromised name service does not present a security threat to Kerberos, other than possibly a denial-of-service attack. Note that such a denial-of-service attack would likely affect many network services, and not just Kerberos.

Software Distribution Service

Any large distributed environment requires a software distribution service for cost-effectively distributing and installing software on physically remote systems. That distribution system should be secure to ensure that the integrity of the security software itself is not compromised.

Secure Time Service

Loosely synchronized clocks are typically required between the KDCs, and between KDCs and application servers (e.g., within five minutes). Implementations vary in their requirements for clock synchronization. Unsynchronized clocks primarily represent a security threat due to replay attacks. Depending on the Kerberos

implementation and the protocols used, clock synchronization may or may not be required. However, synchronized clocks are generally desirable in any large network, especially for auditing and network and system management to correlate activities and events across the network. If timestamps are used as the basis for replay protection, the time service used to synchronize clocks should be secure.

KDCs

Because the KDC is the trusted third party for all principals in the realms it serves, the KDC should be both logically and physically secure. Failure to secure the KDC can result in the compromise of an entire realm. The KDC should support no applications, users, or protocols other than Kerberos. (That is, everything except Kerberos has been removed from the machine.) Ideally, the system will not support remote network access except by means of the Kerberos services it offers. Remote administration of KDCs and principals is a fact of life in today's environment. Most modern Kerberos implementations provide a secure remote administration facility.

Services

Systems that host services, or "application servers," should be secured to the level required by the most sensitive application or data on that server. Failure to adequately secure the application servers may result in the compromise of services that operate on that application server, and their data. Note that a compromise of an application server compromises only those applications on the server and does not compromise any other principals.

Clients

Client systems should be secured to the level required by the most sensitive user of the client or the most sensitive application that is accessed from that client. Failure to adequately secure client systems may result in the compromise of any users of the client system or compromise of data accessed from the system. A compromised client puts all users of the client at risk. For example, a password grabber on a client compromises anyone who uses the client; a virus potentially compromises the data of any application accessed from that client. A compromised client does not compromise principals that do not use that client. However a client compromise could spread if one of the users of that client has elevated privileges, e.g., a Kerberos administrator. Kerberos administrators (or anyone with elevated privileges) should not use a client system unless they have an appropriate level of trust in that system.

Identity Information

Identity information, no matter what the form, requires appropriate protection of that information by individuals. If passwords are used, those passwords should be sufficiently strong. Most modern Kerberos implementations provide password policy enforcement to minimize the use of weak passwords. If public key credentials are used, protection of those credentials is as important as password protection. If additional security is required, technologies that provide two-factor authentication, such as token cards or smart cards, may be used; appropriate care in protecting those devices must still be exercised by the individual. Note that a compromise of an individual does not implicitly compromise any other Kerberos component or principal. However, as with any system, administrative personnel who have elevated privileges should be of special concern. For those individuals, two-factor authentication may be appropriate.

Operation

In terms of operational management, clients are by far the most important, with services a distant second, followed by KDCs. Implicit in that ranking are the associated infrastructure elements that are required for each Kerberos component to perform its function. That ranking obtains from the relative numbers of the components. Clients are typically the most numerous by orders of magnitude, and their sheer numbers magnify even the smallest manageability problem. That is not to say that management of KDCs is unimportant, but if given the choice between a few skilled people trained and dedicated to managing a few KDCs vs. 100,000 users and clients, the choice should be obvious.

Clients

Other than installation, the primary manageability concern with clients is locating KDCs and services (discussed later in this chapter).

Servers

The primary management overhead associated with service principals is the maintenance of the key table. As previously discussed, the key table holds a service principal's key. Communication of the key should be done securely, which means either manually communicating the key out-of-band or pulling the key from the KDC using a key management utility on the system on which the service operates. The latter method of pulling the key from the KDC is preferable.

For example, once Kerberos client software is installed on the application server, a key management utility can be used by an administrator to access the KDC, establish a secure session, generate the service key, and place the service key into the service's key table. The administrator effectively provides the secure channel for securely communicating the initial service key. Once the initial keys are established, secure key update, or "key rollover," can be automated. That key rollover can be initiated on the server to pull a new key from the KDC to the server, or a KDC can push a new key to the server. Implementations vary in the sophistication of the key management utilities available and the facilities for automating the key rollover process.

KDCs

A fully equipped KDC generally includes a variety of services for administration and management, database propagation, password change, etc. Some of those services can be quite complex. However, the main services provided by a KDC are for authentication and are quite simple. Those services do not, as a rule, maintain state or require write-access to the principal database.

Most implementations differentiate between "primary" and "secondary" (or "master" and "slave") KDCs depending on the services they provide. A primary KDC typically provides a reference copy of the principal database, as well as hosting services that require write-access to the database. Secondary KDCs typically maintain read-only copies of the database. Implementations vary tremendously in the mechanisms used to propagate information from primary to secondary KDCs. In the most primitive mechanisms, a bulk propagation of the entire database is performed at fixed intervals. More sophisticated mechanisms incrementally propagate only those database records that change in real time. The issues associated with periodic bulk propagation are numerous and significant. Incremental propagation is a prerequisite for any large-scale production implementation.

Services that require write access to the principal database include those required for day-to-day administration of the principal database, such as adding, deleting, and changing principals. Administrative functions are generally performed using a special administrative tool, either locally on the KDC, or remotely. Password-change operations also require write access to the principal database. Password-change is typically the only operation in which the general client population requires access to a service on the primary KDC — that is, a service that has write-access to the principal database. Although implementations vary, the inability of clients to access the primary KDC will typically preclude password-change operations. That argues for a primary KDC configuration that provides system and network redundancy and automatic failover. Beyond the administrative functions associated with principals, there is little additional work involved in managing a KDC.

The primary services used by clients — the authentication service (AS) and ticket-granting service (TGS) — do not generally require write-access to the database. Thus, secondary KDCs should, as a rule, be the client's first selection when locating a KDC to provide those services. It is not unusual for all AS and TGS requests to be serviced by secondary KDCs, and to dedicate the primary KDC to administrative services. This allows the resources of the primary KDC to be dedicated to services that only the primary KDC can provide, which allows it to serve a much larger client community.

Each entry in the principal database is typically encrypted in a "master key" that is defined when the database is created. That master key prevents compromise of the realm should a backup of the principal database be inadvertently released, for example. However, for unattended restart of the KDC and unattended operation of services that must manipulate the database, the master key must be kept in persistent storage. If unattended KDC restart is not required, the master key can be typed in on the console when the KDC starts. However, that typically does not make the master key available to other services that may require access to the database, such as administrative services. Because of those issues, virtually all implementations use a master key that is kept in persistent storage, such as a disk file. Obviously, keeping the master key secure is of paramount importance, and any backups should exclude storage containing a copy of the master key.

Realms

Most of the issues involved in the use of multiple realms revolve around the client's ability to locate KDCs and services in a realm. The ease or difficulty with which clients can perform those functions, and the associated management overhead, are usually the determining factors in whether or not an organization uses multiple realms.

If multiple realms are used, cross-realm keys must be established between realms, and appropriate entries placed into the principal database. Key generation and creation of the principal database entries require very little effort. However, those cross-realm keys must be communicated between realms in a secure fashion. Unless a secure channel already exists between realms, those keys should be communicated using a secure, out-of-band mechanism, such as physical mail. Once those initial keys are established, a secure channel can be formed to change the keys periodically.

Note that a user can have identities in multiple realms. For example, the same physical individual may have a principal identity in multiple realms. Although those two identities may represent the same individual, Kerberos does not make that association. By the same token, there is nothing that prevents a client computer system from being used for authenticating an individual to any realm or accessing a service in any realm. That situation would not be unusual in an environment with multiple realms and a roving user community. Although it is typical for client systems to define a default realm as a convenience for users, that default realm is only a convenience and, unless otherwise constrained, does not limit the use of the client by individuals in a single realm.

A service, or more precisely, the instantiation of an application on a host computer system, may also operate in multiple realms. While it is unusual, and there are security implications that must be considered, there is nothing that prevents one system from hosting applications that have identities in multiple realms. Nor is there anything that prevents the same application on the same system from having an identity in multiple realms. Having a common system or application that has an identity in multiple realms may be an alternative to cross-realm authentication. For example, consider a database that is shared between two groups in different realms. The database service can be placed into one realm, with the other group using cross-realm authentication to access it. Alternatively, the database can have an identity in both realms, with each group accessing the database as a service in their own realm, thus eliminating the need for cross-realm authentication. Again, there are security implications in such an approach that must be taken into account. Specifically, management of the service keys must be carefully considered.

Principals

Management of principals is similar to that of any system that maintains identity information. Principals must be added, removed, and modified. A principal identifier should not be reused until all services that may have local copies of the principal identifier have been notified. For example, if a service uses a principal identifier in a local access control list (ACL), the ACL must be updated before the principal identifier is reused to ensure that the new entity does not have unwarranted access to that service.

All implementations provide tools to perform administrative functions. For large-scale deployments, it may also be desirable to couple Kerberos administration to an enterprise administrative system. As with any system that uses passwords, resetting passwords is probably the most common administrative function performed in Kerberos. Some implementations allow administrative functions to be tightly constrained (for example, limiting help desk personnel to performing password resets and not allowing them to perform other administrative functions, such as adding, removing, or otherwise examining or modifying principal entries).

Key Strength and Rollover

As mentioned above, there are a number of keys that should be rolled over periodically. Those keys are generally randomly generated bit strings and are very resistant to any attack short of an exhaustive key search. Thus, the strength of the keys and the required rollover frequency depend almost entirely on the key length used. This suggests that the strongest possible key strength, such as triple-DES, should be used for critical keys. An exhaustive search of the triple-DES key space is well beyond the means of any organization today or for the foreseeable future, with the possible exception of a few government intelligence agencies.

As for all services, the key strength and rollover frequency for a service should be appropriate for the sensitivity of the service. One service stands out as demanding the highest possible level of protection: the

ticket-granting service (TGS). All ticket-granting tickets (TGTs) received by clients are sealed in the key of the TGS, and all authentication with services is ultimately rooted in that TGT. If the TGS' key is compromised, the TGS can be impersonated, and with it the entire realm. Obviously, protecting the TGS's key is of paramount importance. Close behind the TGS in importance are the keys used for administrative services and cross-realm authentication.

Automation of the key-rollover process should eliminate virtually all management overhead associated with key rollover. For remote systems, rollover can be initiated from the KDC and pushed to the service, or it may be initiated by the service and pulled from the KDC. However it is done, automation of the rollover process for services on remote systems implies that an existing key is used to establish the secure channel for key rollover. If shared secrets and symmetric key cryptography are used as the basis for establishing that secure channel, the rollover process should strive to camouflage the key rollover sequence. That minimizes the probability of an attacker recording the sequence containing the new key and the subsequent compromise of the new key based on an old key.

Names and Locations

The majority of the management and operational issues with Kerberos revolve around names, the association of those names with physical or logical entities, and the location of those entities in the network. The naming and location issues faced by Kerberos are not unique to Kerberos and are faced by virtually all distributed environments.

Historically, services have been tied to machines, and those machines have a name that people know and understand, and the network software can be used to connect a client to that machine and implicitly to a service. In many environments, a single system or service might be known by many names, and as long as the client is able to connect to the service, no one much cares. When a system such as Kerberos is introduced that relies on names to identify and authenticate unique entities, names start to matter much more. All of a sudden, the name may be used not only for location, but authentication, and the client, the service, and Kerberos must all agree on what those names are attached to, and the network naming or directory service must also agree with where they are located.

Name services such as DNS provide solutions to the simple client–server connection problem. However, as the coupling between physical systems and services becomes more tenuous, we are left with the problem of finding an instance of the service (i.e., a system on which the service is operating) somewhere in the network. That service name may or may not have any relationship to a computer system's network name. Although there are many solutions to this problem, as of this writing there are no solutions that an implementation can rely on in most environments.

Name Spaces

Kerberos defines a name space consisting of realms and principals. Other than their own principal name, most users will have little or no knowledge of other Kerberos principal names, especially those associated with services. Thus it is left up to the Kerberos software and the environment to somehow map the names that people are familiar with to the corresponding Kerberos principal identities and locate those entities in the network. If Kerberos names are associated with an existing name space, such as DNS, and a name in one name space can be mapped trivially to another, most of the issues become relatively innocuous. If the names in the Kerberos name space are not associated with an existing name space, management effort and the probability of errors goes up significantly, as should be obvious from the discussion below.

Services

Services typically use an "instance" in the principal name to help distinguish different instances of the same service, e.g., name/instance@REALM. For example, the instance may distinguish the same service operating on different computer systems. Although it is generally the case that the same principal name would imply similar functions across different instances, that is by convention only. Different principal identifiers — the concatenation of the name, instance, and realm — are treated as completely different entities by Kerberos.

The instance is used by virtually all Kerberos implementations to locate the service on the network. For service principals, Kerberos clients by convention use the fully qualified DNS domain name of the host computer system on which a service operates as the instance. For example, wadmin/www.z.com@Z.COM might be a Web administrative service application on the system www.z.com. Other services may also be present

on the same system, and each of those services could have its own name with the same instance. For example, ccare/www.z.com@Z.COM might be a customer care service application running on the same system.

By convention, there is a generic host principal used for authentication to generic host services, such as telnet. By convention, those generic services share the principal name "host." For example, telnet clients would use the service principal name host/y.z.com@Z.COM to access to a telnet server running on system y.z.com. The principal identifier host/x.z.com@Z.COM represents the same principal name (host) with a different instance (x.z.com). Although host/y.z.com@Z.COM and host/x.z.com@Z.COM may imply a common service (i.e., a common function) on different systems, Kerberos makes no such implication. From the perspective of Kerberos, those principal identifiers are different, and therefore represent different entities; any implied similarity is by convention only.

Note that there is an implied relationship between the instance and the location of the service, and a client must know both in order to use a service. To establish a connection with the service (regardless of whether Kerberos is used), the location must be known, and the principal name must be known for the client to form the correct service name for that service and obtain the correct service ticket. This implied relationship can be either a great convenience or a great pain, depending on whether the relationship holds true.

Within a single realm, the principal names used for services and the manner in which a client forms the identifier of a service principal have a significant effect on the usability of the implementation. Services that use the common and generic "host" principal name are well defined and not a problem. For other services, those services' principal identifiers must be defined and known to the client. The instance name used for service principals can also present a problem for the client. Although the Kerberos convention is to use the fully qualified DNS domain name, or "long form," for the instance in the principal identifier, some DNS implementations return the "short form." This can present problems if one system uses the short form and another system uses the long form. From the perspective of Kerberos, those two identifiers are different, and hence different principals. Both of those identifiers must have a principal entry and an entry in the key table for the service — which increases management overhead — or an error will result when a client uses the wrong principal identifier to attempt to access the service.

KDCs

Before a client can do anything with Kerberos, it must locate a KDC in order to authenticate and obtain tickets for the individual using the client. Note that unlike service principals, which generally use the instance portion of the principal name to also locate the machine on which the service is operating, there is no implied KDC location based in the realm name. The only inference one can make from a realm name is that a KDC is operating on a system somewhere in the corresponding domain. For example, we can infer that a KDC for the realm Z.COM is probably located on a system somewhere in domain z.com.

If multiple KDCs are used for availability or performance, there must also be some means of directing the client to the appropriate KDC, or for the client to automatically locate a KDC should the first choices be unavailable. For systems that use primary and secondary KDCs, the client will also need to know how to locate the primary KDC for a realm for password-change operations.

Different individuals in different realms may use the same client. It is unrealistic to expect those individuals to know the names or addresses of KDCs in their realm, and therefore the job of locating a KDC falls to the Kerberos client software. Applications on the client may also access different services in different realms. As with individual principals, it is unrealistic for those applications to have embedded within them knowledge as to the location of KDCs in different realms, and again that job falls to the Kerberos client software.

Traversing multiple realms can also present problems for the client. Kerberos defines a standard mechanism for traversing realms that are arranged in a hierarchy. For other realm structures, there is no defined mechanism. Moreover, the client must know the realm in which a service resides. If a service is in a different realm, the client must perform cross-realm authentication to get to that service. In order to perform that cross-realm authentication, the client again must locate a KDC in each of the realms it must traverse.

The basic KDC-realm location problem has a variety of solutions, and implementations vary in how they solve the problem. The simplest and most primitive solution is to use a configuration file on the client. Typically, that configuration file defines a default realm and KDC, which the client uses unless told otherwise. That solution is sufficient for basic implementations. That configuration file may also enumerate a list of alternate KDCs and realms, and the primary KDC for each realm. Thus, changes to the environment may require that configuration file to be updated on many clients. For a relatively static environment, that may be acceptable. For even a moderately dynamic environment, that is unacceptable.

To solve the KDC realm location problem in an effective manner, as much static configuration information as possible must be removed from the client. Solutions that address the problem may make use of naming conventions for KDCs and may include the use of DNS aliases, rotaries, and informational records. Other solutions may use "referrals" or "redirection" to direct the client to the appropriate source. This solution requires only that the client be able to contact at least one KDC; that KDC is assumed to have the knowledge of how to get to other KDCs and realms, and can refer or redirect the client as needed.

Interoperability

The Kerberos 5 protocol defines what is necessary for implementations to be "wire-level" interoperable, and different implementations tend to be quite good about wire-level interoperability. However, the Kerberos standard does not address many of the host-specific or environmental issues that every functional Kerberos implementation must deal with, and there is no guarantee that two implementations will deal with the same issue the same way. *De facto* standards have typically developed on different platforms to address these issues. If a platform vendor provides a Kerberos implementation, that vendor will generally set the standard on their platform. Thus, while these issues are generally not significant, they are worth noting.

- Locating a KDC within a realm may be done in different ways. This can result in duplicate management effort in order to maintain consistency between two different representations of that information.
- Credentials cache locations and formats may vary. The primary concern is the ability for applications to access the TGT for obtaining service tickets. Unless applications use a common credentials cache to hold the TGT, the user may be forced to go through an additional sign-on.

The most significant interoperability issues between KDCs and clients are not a function of the Kerberos protocol, but specific features that KDCs or clients may require or support. This usually manifests itself in the types of preauthentication mechanisms supported, such as token cards, public key X.509 certificates, etc.

Although the standard defines client–KDC interactions, no standards, neither formal nor *de facto*, define KDC propagation mechanisms and administrative interfaces. Thus, those propagation mechanisms and administrative interfaces tend to be vendor-specific. The result is that, although it is quite feasible to use a mixture of clients and KDCs from different vendors, all KDCs within a realm must typically come from the same vendor. Between realms, cross-realm authentication couples the KDCs in those realms (not database propagation). Because cross-realm authentication is defined by the Kerberos standard, KDCs from different vendors in different realms should have no trouble interoperating.

Performance

Performance is the degree to which Kerberos can perform its intended function with a given level of resources. Kerberos will consume some resources, and the efficiency of Kerberos can be gauged by how effectively it uses those resources. Resources take the form of network bandwidth, and disk and CPU on clients, servers, KDCs, and personnel.

For performance, the KDC is typically the most important component, with services a distant second and clients third. That order obtains from the relative concentration of work performed by each of those components and the effects of inefficiencies or failure on other components. An inefficient KDC can affect a large number of clients and services, whereas an inefficient client generally affects only that client. Implicit in that ranking are the infrastructure elements needed to support each component. The efficiency of a KDC, by any measure, makes little difference if the network or directory service needed for clients to communicate with the KDC is inefficient or inoperable.

Encryption

One of the first concerns that usually comes to mind with any security system that uses encryption is the additional CPU and network overhead. In Kerberos, the use of encryption for authentication in the authentication service (AS), ticket-granting service (TGS), and application (AP) messages is intentionally limited, and the resulting cryptographic overhead is minor.

For applications that encrypt and decrypt data, the overhead may be very noticeable (whether or not those applications use Kerberos). That overhead depends on the amount of data that is encrypted, the encryption algorithms used, the efficiency of the implementation's algorithms, and the availability and use of hardware

cryptographic acceleration by the implementation. Data encryption and decryption overhead is generally not an issue on clients, as even moderately efficient software cryptographic implementations on today's client platforms are normally faster than the network. However, for servers the situation may be reversed, as those servers are typically the focal points for many clients. That is, the cost of encryption and decryption is spread over many clients, and a much smaller number of servers. Those servers may justify the investment in hardware cryptographic accelerators if performance is an issue.

Encryption of application data adds no measurable overhead to the network. The sole exception to this are protocols that exchange a very small amount of information in each message and that use a block cipher such as DES. This causes messages that are shorter than the block size of the cipher to be padded out to the block size of the cipher. For example, DES is a block cipher with a block size of eight bytes; encrypting a single byte results in an output that is eight bytes. However, the additional overhead added by Kerberos in this case will likely be unnoticeable, as it will be dwarfed by the overhead of the message envelope. Simply put, any protocol that transmits a few bytes of data in each message is, by definition, horribly inefficient at moving data — encrypted or not — and encryption will cause a very minor increase in that inefficiency.

Network

The demands Kerberos places on a network are modest and rarely an issue. Network demands will depend on several factors, including the behavioral pattern of clients, network topology, and the location of KDCs within the network. The KDC can communicate with clients using either UDP or TCP. Because of its greater efficiency, UDP is the preferred method. However, if firewalls are placed between clients and KDCs, UDP may not be feasible; for those clients, TCP may be used.

The additional network traffic produced by the Kerberos authentication process is simple to determine:

- *Initial authentication*. A single exchange between the client and a KDC at the beginning of the workday (AS-REQ and AS-REP). This exchange may involve more than one message in each direction, depending on the technology used for initial authentication. For example, a challenge–response token card typically requires an additional exchange between the client and a KDC.
- *Obtaining a service ticket*. A single exchange between the client and a KDC the first time an application service is accessed during the workday (TGS-REQ and TGS-REP). Different services require different service tickets, and thus each time a service is accessed the first time during the workday, this exchange will occur.
- *Client-to-service authentication*. A single message from the client to the service (AP-REQ). If the client requests mutual authentication, there is one additional message from the service to the client (AP-REP). The Kerberos authentication exchange between the client and service may be embedded in the application's session establishment messages and will not show up as an additional message, but rather as a nominal increase in size of the standard session establishment messages.

The size of the messages varies depending on various options and the amount of authorization information embedded in tickets. Assuming no authorization information, message sizes range from approximately 100 to 500 bytes.

KDCs

KDC performance is rarely an issue. The primary services provided by a KDC — those that are most used and have the greatest effect on performance — are the authentication service (AS) and ticket-granting service (TGS). The AS and TGS typically do not require local state, and typically require only read-access to the principal database. This allows liberal placement of KDCs within the network and eliminates the need to bind clients to specific KDCs. Moreover, because of the very simple and symmetric message exchanges and the reuse of common syntax and semantics in the protocol, KDC implementations tend to be quite compact and very efficient in their use of memory and CPU. Rates in excess of 20 AS and TGS exchanges per second for a KDC on a small system are not unusual.

The limiting factor on KDC performance is usually the I/O associated with the principal database. CPU overhead for encryption and decryption is usually a distant second (assuming that symmetric-key cryptography is being used), owing to the relatively small size of the messages processed by the KDC and the limited use of encryption for those messages. Disk resource requirements depend on the database used and the number of principals in the database; although requirements vary, a rule of thumb is 1 Kb of disk for each principal in the database.

Clients and Services

Implementations vary in what they require of systems that host clients and services. Generally, the additional overhead imposed on clients, services, and the additional network overhead for an application is unobtrusive. Disk and memory usage on those systems is typically quite small; the primary variation and resource consumption is typically not in the implementation of the Kerberos protocol, but in ancillary facilities such as graphical user interfaces. Again, although the basic Kerberos authentication process is typically unobtrusive, applications that encrypt large amounts of data may see very visible effects on performance.

Provisioning

As discussed previously, the inherent demands Kerberos places on the network are quite modest. Most modern networks should have little or no trouble with the additional network traffic. However, the network topology, KDC placement, and the location of clients and servers relative to each other and KDCs can have either an insignificant or a very significant effect on the network. Most network operations groups have the knowledge and experience to properly provision and locate KDCs in the network, and those groups should be consulted when determining provisioning requirements.

Key Services

Many modern networks have the concept of "key services," which are required for the proper functioning of a modern enterprise network. Key services typically include naming services, such as DNS, and may include time services, such as NTP. The systems that host those services are typically located in facilities at key points in the network, and those facilities are intended to ensure the availability of key services to all users in the face of network outages and other failures.

Those key service facilities will typically have a higher level of physical security than many other facilities. Key services facilities will usually define the location of KDCs in the network, as well as secure time services, if used. Those key service facilities also provide a baseline for the physical security of the KDCs. That security may or may not be sufficient.

Primary KDC

The primary KDC should be dedicated to administrative functions and data distribution. The primary KDC should use a high-availability platform with no single point of failure. The number of secondary KDCs and their propagation requirements obviously contributes to sizing of the primary KDC. The most significant effect on sizing the primary KDC is client password-change frequency. For example, for a user population of 100,000, with a password expiration of three months (approximately 60 working days), the system will be required to handle an average of approximately 1700 password-change operations per day. Virtually all of those password changes will occur at sign-on (when the expiration is detected and the user is forced to change his password), and most will center on a narrow band at 8 AM in any time zone. That can present a potentially significant load on the primary KDC. Network connectivity should be appropriate for that load. This also points out the need to distribute password expiration as evenly as possible when loading the principal database.

Secondary KDCs

Secondary KDCs should perform the vast majority of the day-to-day work: providing the authentication and ticket-granting services most used by clients. There is a great deal of freedom in the sizing and location of secondary KDCs. User communities of 5,000 to 20,000 are within the performance range of a small to moderate-sized secondary KDC. Availability, not performance requirements, will be the major factor in determining secondary KDC provisioning. Clients should, as a rule, always be directed to a nearby secondary KDC as their first choice. This argues for a greater number of smaller secondary KDCs placed closer to clients.

If availability is a concern, large subnets, campuses, or other major user communities that may be separated by a network failure should have two secondary KDCs, in order to eliminate a single point of failure. Exact physical placement of that secondary pair will be determined by network topology. For example, the pair may be physically distant from each other and still provide a high level of redundancy and availability, depending on the network topology. On the other hand, placing both secondary KDCs on a single network segment that may fail increases cost and does little for redundancy.

If Kerberos is used for local work station access control, availability to the client is critical. If clients and application servers are separated, and if access to those application servers is the predominant factor, then

secondary KDCs should be close to the application servers, and not to the clients. Simply put, if the network between the client and the application server is inoperable, a secondary KDC local to the client will not do much good if the objective is to allow the client to securely communicate with the application server.

Clients and Servers

Client and server platforms will not, as a rule, require any additional resources for Kerberos. However, if large amounts of application data are encrypted, servers may require additional CPU capability or hardware cryptographic accelerators. Encryption of application data does not add any measurable overhead to the network. Additional CPU requirements should scale linearly with the amount of data and will depend on the strength of the cryptographic algorithm, and the key size used. Thus, the additional CPU required to meet the demands of the application can be determined with simple timing tests. If hardware cryptographic accelerators are used, scheduling overhead and key setup time for the accelerator may put an upper bound on performance for small messages. Simple metrics such as the number of bytes per second that can be encrypted or decrypted are not sufficient to determine the real-world performance of hardware accelerators.

Deployment

The appropriate deployment strategy for Kerberos depends both on the intended application and the infrastructure that is in place. Typically, the application will define what demands are placed on Kerberos, and that will, in turn, define the demands on the organization and infrastructure. Other than client software distribution and configuration, those organizational and infrastructure demands are typically the gating factor in any Kerberos deployment. For narrowly focused applications, deployment is generally not an issue and is driven exclusively by the application requirements, with Kerberos simply a component embedded in, and deployed with, that application. For broad-based applications, such as secure single sign-on or enterprise access control, the deployment strategy is typically much more complex. That complexity arises not so much from the technology, but from the more complex and varied organizational and environmental requirements of those deployments.

Deployment stakeholders typically include the user community, security groups, network operations groups, and user administration groups, among others. All will be affected by any large-scale deployment, and all will have a say, directly or indirectly, in a deployment. The introduction of a broad-based security system will, by definition, cross organizational and functional boundaries, and friction is usually the result. If pushed too far and too fast, that deployment friction can generate heat sufficient to incinerate even a well-oiled machine. Unless the organization has a demonstrated need and desire to take big steps, small steps should be the rule. That applies to all security systems.

Successful large-scale deployments tend to be done in two phases: partial infrastructure deployment, followed by incremental client deployment, along with any incremental requirements in the supporting infrastructure. Supporting infrastructure, including any KDCs required for availability and performance, can occur in tandem with deployment of pockets of clients. Alternatively, a KDC "backbone" can be deployed prior to any client deployments.

DNS

The identifier space for DNS should be a concern. Although rationalizing the DNS structure for many organizations was an issue five years ago, it tends to be a much smaller issue now. Because of the growth in TCP/IP and intranets, most organizations have already been forced to deal with that issue over the past years. That said, if the DNS machine name space is chaotic, the DNS structure should be rationalized.

The DNS subdomains that are rationalized must consider the relative locations of clients and services and their interaction. Putting Kerberos into two different subdomains — where clients and servers cross between those subdomains — without first rationalizing the name space in both domains will usually result in problems. Again, this is usually best done incrementally, one subdomain at a time, with rationalization preceding deployment within a subdomain. However, it is not unusual to find that rationalizing one subdomain causes unexpected problems elsewhere. It would be wise to let those perturbations settle before embarking on a Kerberos deployment.

Identities

Typically, the most significant problem encountered in large-scale deployments is rationalizing the identifier spaces for people. Everyone in most organizations has at least one, and typically many more than one, ID.

Rationalizing those spaces in the form of secure single sign-on can itself be the justification for a Kerberos deployment. However, no technology provides a solution to the fundamental problem: people are known by different identities within different and discrete name spaces within the enterprise, and the binding of those multiple identities to a specific individual cannot be known. That problem is the result of years of evolution. Binding of multiple identities to a specific individual can be inferred in some cases. The cost and effort of solving this problem, and level of trust in the resulting environment, depend on the level of assurance provided by that inference.

If there is at least one identifier that is relatively universal, and that identity can be trusted, or there are discrete sets of identifiers with little or no overlap, then the job is much easier. If, on the other hand, the identifier space is chaotic, then more time and energy will be required to rationalize IDs. That time and energy can be due to several factors, including the need to change some names; the need to gain user acceptance when names are changed; and the need to rectify any problems caused by name changes (e.g., systems or applications that are hard-wired with specific names or groups). The actual implementation of the solution is best performed incrementally. This implies an extended deployment, or at least an extended period over which the system is enabled and visible to users. While possible, changing even a relatively small fraction of 100,000 user or system identifiers all at once will likely result in chaos and mass hysteria.

The problem is not eliminated if identity mapping is used to map local identifiers (e.g., a local host or application user ID) to a more uniform identifier, such as a Kerberos principal identifier. Identity mapping may obscure or hide that uniform identifier from users, and thus obviate at least some of the issues with changing identifiers. However, although this approach has an intuitive appeal, it does not eliminate the need for someone or something to go through and map identifiers between different name spaces (the uniform name space being one of those). Building such an "identity map" can be a labor-intensive, time-consuming, and error-prone process. The cost and effort of such a solution should be weighed against the cost and effort in promoting a visible uniform identifier before an approach is selected. Note that Kerberos does not provide implicit capabilities for identifier mapping. Using multiple realms may help but can bring additional issues. Also note that when mapping identities, more-trusted identities should always be used to derive less-trusted identities; less-trusted identities should never be used to derive more-trusted identities.

Enrollment

Even with a rational identifier space, users must still be enrolled in the Kerberos database. That is, the principal database must be populated with the names and the passwords of users. There are several ways of populating the principal database depending on what information is available from existing sources, such as legacy user databases, and the form of that information. Depending on what is available, initially populating the principal database can be either a very trivial or a very significant effort.

If a legacy database exists with IDs and passwords, that legacy database can be used to bulk-load the principal database. That database must have clear-text passwords, or keys that are based on an algorithm that is compatible with Kerberos. If clear-text passwords exist in the legacy database, bulk loading is a simple and straightforward process. If the password algorithm used for the legacy database is incompatible with Kerberos, the keys must be transformed to an algorithm that is acceptable to Kerberos, which can be difficult or impossible, depending on the legacy algorithm used.

If keys that use a standard Kerberos algorithm are unavailable, an alternative is to add support for the legacy algorithms to Kerberos, specifically for the purpose of deployment or initially loading the principal database. This requires creating local-use encryption types within the Kerberos implementation (which the protocol allows for). The Kerberos principal database is then loaded with the existing password values from the legacy databases. Those principal entries would also be flagged to require a change-password operation the first time the user logs in. As part of that change-password operation, the new password would be used to update the principal database entry using a standard Kerberos algorithm. After all users have been registered in this manner, support for the legacy algorithm should be removed.

The use of a legacy algorithm as the basis for initial authentication can reduce the security of the system, and thus its use should be limited to enrollment or deployment. Although this approach may expose a weak derivation of the password on the network, that exposure is limited. Moreover, if clear-text passwords or a weak derivation is currently being used and transmitted across the network, this approach does not make the situation any worse and allows us to rapidly improve the situation. If no legacy databases exist, an existing interface (e.g., the existing login process) can be modified to capture and use passwords to enroll those users

and populate the principal database with their passwords. As a last resort, new passwords/keys can be issued to users.

Realm Design

Other than environmental factors and provisioning requirements discussed previously, the greatest effect on the operation and deployment of a Kerberos implementation will depend on realm design. As always, the rule should be to keep it simple. Unless there is a reason for multiple realms, a single realm should be used. The reasons for using multiple realms might include separation of duties or trust between realms, or the need to distribute the number of primary KDCs (one per realm) for availability of administrative services.

The ability of clients to automatically determine the realm of a service, locate a KDC within a realm, and traverse realms will determine the additional management overhead of a multiple-realm design. If services are available to automate those client needs, multiple realms will not add measurable management overhead. Performance issues due to additional cross-realm authentication operations may also affect the design, but that is usually a distant second behind management overhead. DNS informational records and redirection and referral capability by KDCs can be used to significantly reduce the management overhead of multiple realms. The following discussion assumes that those facilities are unavailable to, or unused by, the Kerberos implementation.

If automated services are not available to mitigate client realm issues, multiple realms should be arranged in a hierarchy, or tree, and that tree should follow the organization's existing DNS domain structure in order to simplify the association of a service name with, or locating a KDC within, a realm. This argues for realms that map directly to each and every subdomain that provides services that clients in other domains (and hence realms) access. This also implies that when a new subdomain is created, a new realm is created as well. This typically implies a large number of realms, which may not be feasible due to the number of KDCs required. An implementation that allows multiple realms to be serviced by a single KDC can mitigate KDC provisioning issues but does not address separation of security or trust, or the availability of a primary KDC.

The key to the success of this strategy is maintaining congruency between realms and DNS domains to whatever depth of the DNS hierarchy is appropriate. This is required in order to minimize the amount of information required by clients and to maximize the amount of information that can be inferred by clients. For example, if congruency to first-level subdomains is appropriate, then each and every first-level subdomain must have a realm; if congruency to second-level subdomains is appropriate, then each and every second-level subdomain must also have a realm. This also implies that creation or removal of a subdomain implies creation or removal of the corresponding realm.

Maintaining realm–domain congruency allows clients to infer a realm implicitly given a DNS name; the client would have to be explicitly told to what depth the realm–domain structure is congruent (e.g., first, second, etc., level of subdomains). Note that this does not provide any information as to the name of a KDC within a realm. KDC-location by clients can be handled using appropriate naming conventions. For example, using KDC's with names such as "kerberos.sub.domain" might be used to locate KDCs within "sub.domain," and implicitly "sub.realm." If secondary KDCs are used, a DNS rotary can be used, or additional conventions such as "kerberos*n*.sub.domain" (where *n* denotes secondary KDCs).

Ongoing Development

This section give\s a snapshot of ongoing development efforts surrounding Kerberos and related technologies. Given the rapid development of security technology today, this discussion can only be illustrative and is by no means complete or definitive.

Standards

This section provides an overview of standards efforts relating to Kerberos. Some of these efforts are ongoing and have not yet been approved by the IETF.

Authorization

Ongoing standards efforts are intended to define commonly used authorization data types for identifying the source of authorization information[15] (for example, to distinguish between client- and KDC-supplied autho-

rization information). This effort is also aimed at standardizing the behavior of servers in the presence, or absence, of certain authorization information.

PKINIT

The Public Key Initial Authentication (PKINIT) effort is designed to standardize the use of Public Key credentials (certificates and key pairs) and asymmetric-key cryptography for authentication as part of the Kerberos initial authentication exchange.[16] Using PKINIT, users with Public Key credentials can gain access to Kerberos services within the enterprise. Simple public–private key pairs, without credentials (i.e., issued by a CA), may also be used. PKINIT uses the preauthentication facility of the initial authentication process to incorporate public key capabilities.

PKCROSS

The Public Key Cross-Realm (PKCROSS) effort is based on the PKINIT effort and is designed to standardize the use of Public Key credentials and asymmetric-key cryptography for cross-realm authentication.[17] PKCROSS allows *ad hoc* and direct trust relationships to be established between different realms, thus eliminating the key management required of current implementations, as well as minimizing trust issues associated with transited realms for clients. This minimizes the need for clients or transited realms to have information about realm topology or relationships.

PKTAPP

Public Key Utilizing Tickets for Application Servers (PKTAPP) allows the use of the Kerberos ticketing mechanism without the requirement for a central KDC.[18] PKTAPP proposes a variation of the PKINIT mechanism for allowing application servers to issue tickets for themselves, instead of having the tickets issued by a KDC.

Related Technologies

These technologies are related to Kerberos or are commonly integrated with, or interact with, Kerberos implementations. As of this writing, all of these technologies have ongoing Kerberos-related development efforts associated with them, either within the standards community or by specific vendors.

Public Key

Public key may describe a system that uses certificates or the underlying public key (i.e., asymmetric-key) cryptography on which such a system is based, or both. A public key system implies asymmetric-key cryptography; asymmetric-key cryptography does not imply a public key system. (By the same token, Kerberos implies support for DES, whereas DES does not imply Kerberos.)

In the traditional public key (PK) model, clients are issued credentials, or "certificates," by a "Certificate Authority" (CA). The CA is a trusted third party. PK certificates contain the user's name, the expiration date of the certificate, etc. The most prevalent certificate format is X.509, which is an international standard. PK certificates typically have lifetimes measured in months or years. Because of the long-lived nature of PK certificates, certificate revocation is a key element in PK infrastructures (PKIs). The authentication process in PK authentication systems also provides the information necessary for a client and server to establish a session key for subsequent data encryption (that is, encryption of application data).

PK credentials, in the form of certificates and public–private key pairs, can provide a strong, distributed authentication system. The private key, which is the most important secret possessed by an individual, runs to hundreds or thousands of bits in length. Thus, a persistent storage system is required to hold the private key, and access to this storage must be protected using a more mundane and conventional mechanism, such as a password. Conventional PK systems still suffer from lack of tools and techniques for managing client credentials. Smart cards hold some promise for secure and mobile private key storage. However, that technology is still relatively new and expensive to deploy on any but a limited scale. Lower-cost solutions, which store the credentials on a local (e.g., work station) disk file, have mobility or security issues. Revocation of PK credentials is still a problem, and standard, scalable and efficient solutions have yet to be provided.

The Kerberos and PK trust models are very similar. A Kerberos ticket is analogous to a PK certificate. However, Kerberos tickets usually have lifetimes measured in hours or days, instead of months or years. Because of their relatively short lifetime, Kerberos tickets are typically allowed to expire instead of being explicitly revoked. The Kerberos session key is analogous to the private key associated with the public key contained in a PK certificate. Possession of the private key is required to prove the authenticity of the sender in a PK system.

That is typically done by signing, or encrypting, information with the private key. That signed or encrypted information, along with the certificate, allows a receiver to verify the association between that information and the certificate. As with Kerberos, the trust the receiver places in the identity of the sender is a function of the trust the receiver places in the issuing authority. In the public key systems, that issuing authority is the certificate authority (CA); in Kerberos, that issuing authority is the KDC.

The use of authentication mechanisms such as public key has the potential for minimizing the need for a central online authentication service such as Kerberos. However, authentication is only one of the functions required of an enterprise security service, and the removal of authentication is unlikely to affect Kerberos' role in supporting access control, authorization, and delegation. Moreover, applications where the performance of asymmetric-key cryptography is unacceptable will still require the use of a system that can provide robust services based on symmetric-key cryptography. Advances in cryptography, such as optimizations of elliptic curve algorithms and hardware acceleration, promise improvements in the performance and cost-effectiveness of asymmetric-key cryptography. When the cost will reach a level that allows wide-scale adoption is unclear. In any case, Kerberos can incorporate that technology today for those who can afford it.

PK systems have been integrated into Kerberos using the preauthentication facility of the initial authentication exchange. For example, the client can provide a signed message, with or without an X.509 certificate, as a preauthentication element in the request to the Kerberos authentication service. The result of that exchange is a standard Kerberos 5 credential.

OSF DCE

The Open Software Foundation, Distributed Computing Environment (OSF DCE) uses Kerberos 5 as the underlying security mechanism.[19] DCE extends the basic Kerberos credential to include other information, such as authorization, and defines an authorization system that is separate but typically co-located with the authentication and ticket-granting services on the DCE security server. DCE clients also use RPC (Remote Procedure Call) as their basic communication mechanism, which requires that both client and server utilize the same secure RPC to be interoperable; the RPC is secured using Kerberos 5.

DCE applications are not interoperable with Kerberos 5 applications. However, many DCE implementations also provide support for standard Kerberos 5 clients. That is, the DCE security server may also provide a standard Kerberos 5 authentication service (AS) and ticket-granting service (TGS). That support for standard Kerberos 5 clients does not make DCE and Kerberos 5 applications interoperable; authorization and RPC transport are still barriers to interoperability between applications. As the term "computing environment" implies, DCE requires additional infrastructure components beyond the basic security service, such as a cell directory service, time service, etc.

Kerberos 4

Kerberos 4 is the predecessor of Kerberos 5. Kerberos 5 addresses many Kerberos 4 security issues, as well as other scalability and portability issues associated with Kerberos 4. Although conceptually similar, Kerberos 5 and Kerberos 4 are quite different. Kerberos 4 has seen fairly extensive use in educational and commercial environments, and in a few key applications. One of the most widely used applications is AFS (Andrew File System), which is a secure distributed file system (similar to the OSF DCE distributed file service, DFS).

Kerberos 5 and Kerberos 4 applications are not interoperable. Some Kerberos 5 implementations also include support for Kerberos 4 and provide facilities to improve interoperation between Kerberos 4 and Kerberos 5 environments. Interoperation may be achieved by direct support for Kerberos 4 authentication and ticket-granting services by the KDC, or by allowing a Kerberos 4 ticket to be used to obtain a Kerberos 5 ticket (or vice versa).

GSS-API

The Generic Security Service Applications Programming Interface (GSS-API) is a standard that provides applications with a standard API for using different security mechanisms. The objective of the GSS-API is to shield applications from variations in the underlying security mechanisms. In its simplest form, the GSS-API is a thin veneer that sits above an underlying mechanism; that mechanism, such as Kerberos 5, provides the actual security services. Although applications are shielded from the underlying mechanism, the infrastructure for each security mechanism is still required.

The original GSS-API specification is referred to as V1.[20] V1 of the GSS-API does not support mechanism negotiation. V2 of the GSS-API specification provides the ability for implementations to support multiple mechanisms.[21] As an API, the GSS-API must define specific language bindings, and there are separate standards

for each language binding, such as Java.[22] As of this writing, only "C" language bindings are standardized.[23] GSS-API mechanism specifications may also encapsulate existing mechanisms, in which case a protocol, and not just an API, is defined as part of the GSS-API mechanism standard.

Kerberos 5 was one of the first mechanisms implemented under the GSS-API. Several other mechanisms have also been implemented, including SPKM[24] (Simple Public Key Mechanism) and IDUP[25] (Independent Data Unit Protocol). Two GSS-API applications are compatible only if the underlying GSS-API mechanisms are compatible. GSS-API applications using a Kerberos 5 mechanism and "native" Kerberos 5 applications are not interoperable, because the GSS-API defines not only an API, but a protocol as well.[26] Although the GSS-API Kerberos 5 mechanism uses messages that are the same as Kerberos 5, those messages are encapsulated in a protocol that is different from Kerberos 5.

Microsoft SSPI

The Microsoft Security Service Provider Interface (SSPI) is the Microsoft equivalent of the GSS-API.[27] A mechanism such as Kerberos 5 is a "security provider," and applications use security providers through the "provider interface" (the API). The SSPI Kerberos 5 mechanism is wire-level compatible with the GSS-API Kerberos 5 mechanism. The SSPI API is not compatible with the GSS-API. Thus, although the APIs differ, clients and servers written to use either SSPI or GSS-API can interoperate using a common Kerberos 5 mechanism.

SNEGO

The Simple and Protected GSS-API Negotiation Mechanism (SNEGO), is a special GSS-API mechanism that allows the secure negotiation of the mechanism to be used by two different GSS-API implementations.[28] In essence, SNEGO defines a universal but separate mechanism, solely for the purpose of negotiating the use of other security mechanisms. SNEGO itself does not define or provide authentication or data protection, although it can allow negotiators to determine if the negotiation has been subverted, once a mechanism is established. GSS-API implementations that do not support SNEGO cannot negotiate, and therefore the client and server must agree *a priori* what mechanism or mechanisms will be used.

SSL

Secure Sockets Layer (SSL), and the related Transport Layer Security (TLS), are secure point-to-point protocols that define both authentication and message confidentiality protection.[29] SSL uses public key authentication. Because SSL is point-to-point, it is suitable only as a low-level transport protocol. An SSL authentication exchange results in the establishment of a shared secret key on both the client and server. That key, and conventional symmetric-key cryptography, is used to provide message confidentiality protection.

SSL has also been used to provide an initial authentication exchange between a client and a Kerberos KDC. In essence, SSL is used to replace the standard Kerberos initial authentication exchange, and a special authentication service (AS) is used on the KDC. SSL authentication is used in place of the client's initial authentication request, which may or may not involve the use of a password by the client. SSL is then used to securely transport the TGT back to the client. SSL is presently one of the few protocols that do not have a standard way of integrating Kerberos authentication to provide message integrity and confidentiality, although such integration has been proposed.[30]

SASL

Simple Authentication and Security Layer (SASL) is a framework for negotiating a security mechanism for session-oriented protocols.[31] SASL specifies a naming convention for registered mechanisms, as well as profile information required for clients and servers to use a mechanism to protect a specific protocol. Registered SASL mechanisms include Kerberos 4 and GSS-API, among others.

IPSec

Internet Protocol Security (IPSec), provides integrity or confidentiality services at the network layer.[32] All data protection is performed using symmetric-key cryptography. Establishment of the session keys for data protection is also defined by IPSec, and may use both symmetric- and asymmetric-key cryptography.

Although IPSec provides data protection, it does not provide the key management infrastructure necessary for a large number of IPSec systems to authenticate and establish the session keys needed for data protection. As a network layer protection service, IPSec is targeted primarily at machine-to-machine security; authentication of individuals and applications is outside the scope of IPSec, and depends entirely on the key manage-

ment infrastructure used, and the integration of that key management infrastructure with the IPSec implementation.

Kerberos can provide key management for IPSec implementations, and this has been proposed through the use of the GSS-API mechanism.[33] In essence, the Kerberos principals are simply machines, or more accurately, the service on each machine that provides IPSec network layer protection. Kerberos can also provide the key management for binding individuals and applications to IPSec implementations.

RADIUS

The Remote Authentication Dial-In User Service (RADIUS) allows a RADIUS client (typically a network access device, such as a terminal server), to authenticate a user on a remote computer and control that user's access to the network.[34] The RADIUS client uses the RADIUS protocol to talk to a RADIUS server to authenticate the user. The RADIUS server may contain a simple database containing IDs and passwords, or may use another server to authenticate the client, such as a token card server, or a Kerberos KDC. RADIUS has gained significant acceptance among network and token card vendors.

RADIUS protects the communication between a RADIUS client (e.g., a terminal server), and a RADIUS server. RADIUS does not protect the communications between a remote client and a RADIUS client. Thus, information passed between the remote client (e.g., a laptop computer) and the RADIUS client is unprotected. RADIUS does not have the concept of a credential, and the result of authentication using RADIUS is a yes–no answer. Thus, RADIUS is primarily used as a simple access control mechanism. DIAMETER, part of the AAA (Authentication, Authorization, and Accounting) effort in the IETF, is working to address some of the limitations of RADIUS.[35]

RADIUS has been integrated with Kerberos by using the RADIUS server as a surrogate Kerberos client. That is, the RADIUS server acts as a client to verify an ID and password against a KDC; that ID and password come from the end user at the remote computer system. Although the RADIUS server obtains a Kerberos credential as the result of that authentication, there is no way to send that credential back to the end client through the RADIUS client. The benefit of using RADIUS in this manner is that a single authentication database can be used (the KDC's principal database), even though the result of authentication does not provide the client a credential. Note that RADIUS does not protect the user's password between the end client and the RADIUS, and the RADIUS client and server have access to the user's Kerberos ID and password. Thus, use of RADIUS as part of a Kerberos implementation should ensure that the resulting exposure is acceptable.

CDSA

Common Data Security Architecture (CDSA) provides a standard API for many security services, including encryption, authentication, and credential storage and management.[36] CDSA also defines standard methods for incorporating a variety of security service providers, both hardware and software, and a variety of mechanisms, including public key and biometrics. CDSA is similar to Microsoft's Cryptographic API (MS CAPI) in purpose. CDSA was originally developed by Intel and has now been adopted by the Open Group.[37]

Token Cards

Token cards are an example of a very simple trusted third party authentication system. A user, in possession of a token, keys in information from the token. That information is then sent to the application, which verifies the information with a token card server (the trusted third party) provided by the token card vendor. Typically, the value presented by the token is usable only once (to prevent replays) or has a very limited life, and is generated using a key contained within the token card (which is tamper-proof) and a key known to the vendor's token card server.

Token cards secure only the authentication to the application and do not provide any security for the application's data. That is, no information in the authentication process is available for establishing a session key for subsequently encrypting application data. Moreover, token cards must be used for authentication to each application, just as a password is. While the user is not required to remember passwords — the token card in effect generates the passwords — the user must still key a "password" in for each application authentication.

There are three basic types of token cards: challenge–response, time synchronous, and event synchronous. Regardless of type, all have a common attribute: the card is (or should be) tamper-proof, and the card contains a secret key shared between the card and the security server. Use of the card typically requires both physical possession of the card (something you have) and a PIN (something you know). The requirement that those two factors be present for authentication to succeed is the basis for the term "two-factor authentication."

Software may also be used to achieve the same effect as a hardware token card. Obviously a software "token card" does not provide the two factors provided by a hardware token.

A variety of token card systems have been integrated into Kerberos using the preauthentication facility of the initial authentication service. The KDC then contacts the token card server, instead of the client contacting the token card server. This allows a mix of token card technologies to be used. The result of the initial authentication exchange is a standard Kerberos 5 credential.

Smart Cards

Smart cards are so named because they have processing intelligence on a card that is the same form factor as a credit card. The processing power and memory capacity varies depending on the card. Smart cards have received prominent attention recently, primarily because of the promise they hold for addressing public key client credential management and security issues, by holding the user's private key in tamper-proof storage, and performing cryptographic operations on the card. Thus, the user's private key never leaves the card.

Smart card costs are dropping rapidly. However, a wide-scale smart card deployment requires not only cards, but also readers. As of this writing, cards with the necessary processing power and storage, and the associated readers, are still too expensive for wide-scale deployment. Although smart cards are most often associated with public key systems, smart cards are also used to provide symmetric-key cryptography. Symmetric-key smart cards may provide secure key storage and associated cryptographic functions for use as challenge–response devices, for example.

Public key smart cards have been integrated into Kerberos using the preauthentication mechanism. This allows users with smart cards to authenticate to the Kerberos authentication service using the public key credentials on a smart card.

Encryption Algorithms

The two broad classifications of cryptographic systems are symmetric-key and asymmetric-key. Both Kerberos and public key systems (as well as other authentication systems) may incorporate one or both cryptographic systems. Common symmetric-key systems include DES (Data Encryption Standard), and the triple-DES variant.[38] Common asymmetric-key systems include ECC[39] (elliptic curve) and RSA[40] (Rivest–Shamir–Adleman). The strength of these different systems is difficult to compare and is only one element that determines their application. For example, based on exhaustive key search, a triple-DES (112-bit) key is approximately equal to a 1792-bit RSA key (i.e., key modulus);[41] and a 1024-bit RSA key is approximately equal to a 160-bit ECC key.[42]

The distinguishing characteristic of these systems is the symmetry of the keys used for encryption and decryption. Symmetric-key systems use the same key for encryption and decryption. Thus, two parties must share the same key (presumably secret) in order to encrypt and decrypt information. Asymmetric-key systems use different, but related, keys for encryption and decryption: information encrypted with one key can only be decrypted with the other key. That key pair is typically referred to as a public–private key pair. One of the keys is public and known to many people; the other key is private (presumably secret) and known to only one person.

Another distinguishing characteristic of these systems is the CPU speed or hardware complexity for encryption and decryption operations. Symmetric-key systems tend to be quite fast. Asymmetric-key systems tend to be CPU intensive and are typically used only for encrypting small amounts of data — typically only that needed for authentication (as with digital signatures). Because of its speed advantages, symmetric key cryptography is still used by all security systems for encrypting application data. Symmetric- and asymmetric-key are often used together. For example, asymmetric-key is used to establish a session key for symmetric-key by encrypting a symmetric session key (that symmetric-key usually being a very a small amount of data). Higher-performance symmetric-key is then used to encrypt and decrypt the application data. The speed of cryptographic operations in symmetric-key systems is typically symmetric. That is, encrypt and decrypt speeds are generally the same (for the same implementation running on the same hardware). The speed of cryptographic operations in asymmetric-key systems is typically asymmetric, and depends on what function is being performed.

Cryptographic systems alone do not constitute a secure authentication system. Kerberos and public key are secure, distributed, authentication systems that use cryptographic systems, define the rules of how cryptography is used, and that define the syntax and semantics for various protocol messages and data formats. Although the rules and protocols for different authentication systems tend to be very different, the problems that must be solved to build a practical, secure, distributed, authentication system are largely invariant.

Kerberos defines the use of symmetric-key cryptography, including both DES and triple-DES, for both authentication and data encryption. Asymmetric-key cryptography has also been integrated into Kerberos using the preauthentication facility of the initial authentication service.

Secure Hash Algorithms

Secure distributed authentication systems require secure hash functions and not just encryption and decryption, although secure hash functions are often built using a cryptographic algorithm. A secure hash function takes a large amount of data and hashes it down to a small amount of data (e.g., 128 bits), or the "hash value." The attributes of a secure hash function are no two inputs should produce the same output ("collision proof"), and you cannot work backwards from the hash value to the input. Think of the secure hash value as a fingerprint: the hash value uniquely defines the input but does not tell you anything about the input. Note that a simple checksum, such as CRC32, is not a secure hash function — too many inputs produce the same output. A secure hash is sometimes referred to as a message digest or cryptographic checksum.

A secure hash is typically used to provide integrity protection and is also used in digital signature applications. The hash value of a document is generated, and that value is encrypted using an individual's key. Encrypting only the hash value, or signature, eliminates the need to encrypt the entire document for integrity protection. That encrypted value is also the digital signature of the individual applied to a document. Verifying the signature against the document simply regenerates the hash value of the document, decrypts the encrypted hash value, and compares the two. If someone changes either the signature or the document, the hash will change, and verification will fail. The most common hash functions are MD5[43] (Message Digest 5) and SHA-1[44] (Secure Hash Algorithm 1).

Kerberos defines the use of several secure hash functions, including DES and triple-DES message authentication code (MAC) hashing functions, as well as MD5 and SHA-1.

Lessons Learned

As discussed in previous sections, most of the technical issues surrounding the implementation and deployment of Kerberos are tractable, and when properly understood, those issues should not present serious problems. The significant technical issues that remain — such as fragmented or dysfunctional namespaces — and their solutions are dependent on the environment. Various methods can minimize those issues, but there is little that Kerberos, or any security system, can do to fix the underlying problems. And as with all security systems, the primary obstacles to success are not technical, but fundamental to the role of information security in today's business and organizational environments. Kerberos does what it can technically by providing a robust and cost-effective distributed security system. The rest is up to us.

Risk, Fear, and Value

Kerberos is fundamentally a strong distributed authentication system. It can be used for a single application within a single group or a set of applications that span an enterprise. Whatever the use, successful deployments usually address applications that can benefit from what Kerberos has to offer. That applies whether Kerberos is being used for a single application or to implement enterprise wide secure single sign-on. As obvious as it may seem, the security that Kerberos brings with it must be perceived to be of value to the organization. Although security practitioners may appreciate the intrinsic value of strong authentication, the broader community within most organizations generally does not perceive that value. Without perceived value, cost and effort will be viewed as wasted. To put it another way, without perceived value, any deployment problems will be magnified, and the probability of success will rapidly approach zero.

Applications that can benefit from a distributed security system such as Kerberos are growing more common than in the past. However, the fundamentals still hold true. As enterprises move to more distributed environments, services are often pushed out toward the consumer. For example, providing on-demand access to human resources data (typically some of the most sensitive information in an organization) by employees from individual desktops. Such "self-service" applications require a strong, distributed authentication system that can also provide data encryption, and provide those capabilities at reasonable cost. The cost of the security infrastructure can often be justified by the cost savings obtained by removing the "human firewall" of clerks that typically guard access to those applications' data.

Because the intrinsic value of a system such as Kerberos is not always appreciated, it is up to security practitioners to identify the applications that can benefit. That requires more than an understanding of security. It also requires understanding the application, and the business needs that surround the application. It requires knowledge sufficient to make the benefits of security intrinsically obvious to the application owners, or sufficient knowledge to quantify the risks and costs to the application owners. Risk and cost are a business decision. Making an informed decision requires understanding both. Risk is often difficult to quantify, and unquantified risk, in the form of fear, can sometimes be a great motivator. However, decisions based on fear are often subject to reversal and second-guessing, and are poor substitutes for informed decision making.

Security based on value and informed decisions will find a more accepting audience, and much easier deployment, than those based on fear.

Distributed Security

The rules that a security system enforces represent demands and assumptions made of the environment. If those rules are too onerous, the security implementation will fail as predictably, and for the same reasons, as any technology that makes unrealistic assumptions or resource demands on its environment. As a security *technology*, Kerberos provides very good performance and makes relatively modest demands and assumptions on its environment. As a security *system*, the demands and assumptions made by Kerberos are entirely dependent on an organization's definition of acceptable security.

The tradeoff between acceptable security and what is practical in an organization, is the first question that the security practitioner must answer. The answer to that question varies from organization to organization, and technology generally plays a minor role in the equation. Moreover, the organic nature of most distributed environments is not receptive to the introduction of a broad-based security system. Introduction of such a system into those environments — with implicitly greater uniformity and rigidity — will cause friction. If Kerberos is used to enforce draconian security measures in environments that have previously had very informal or isolated security practices, problems are very likely to occur. Technology cannot solve those problems.

The very nature of distributed environments increases diversity and indeterminacy. That introduces a greater degree of uncertainty into the security equation. That uncertainty is something the security community has historically been very uncomfortable with. Probabilistic models of security require quantification and analysis. Today, that quantification and analysis are extremely difficult at best, impossible at worst, and so rare as to be nonexistent. Thus we are left to make a value judgment, and for most it is far easier to retreat into the absolutes of the past than to risk uncertainty. After all, risk reduction and aversion is what security is all about.

While the level of certainty that we are historically accustomed to is achievable in distributed environments, it is not achievable at a cost that any organization can afford. That is extremely unlikely to change. Diversity and indeterminacy are increasing with every passing day. Successful distributed security implementations recognize and embrace those changes, making incremental improvements as organizations and technology adapt and converge on an acceptable paradigm. Unsuccessful distributed security implementations shun those changes and attempt to impose unrealistic demands based on time-worn assumptions about what is feasible, necessary, or desirable.

The one lesson that stands out from years of Kerberos implementations is that uncertainty is a fact of life in distributed security. Learn to deal with it.

Notes

1. Project Athena is a model of "next-generation distributed computing" in the academic environment. It began in 1993 as an eight-year project with DEC and IBM as its major industrial) sponsors. Their pioneering model is based on client–server technology and it includes such innovations as authentication based on Kerberos and X Windows. An excellent reference — George Champine, *MIT Project Athena, A Model for Distributed Campus Computing*, Digital Press, 1991. Other definitive works on Kerberos include B. Methods of Attacking and Defending Cryptosystems

Joost Houwen, CISSP

Encryption technologies have been used for thousands of years and, thus, being able read the secrets they are protecting has always been of great interest. As the value of our secrets have increased, so have the technological innovations used to protect them. One of the key goals of those who want to keep secrets is to keep ahead of techniques used by their attackers. For today's IT systems, there is increased interest in safeguarding company and personal information, and therefore the use of cryptography is growing. Many software vendors have responded to these demands and are providing encryption functions, software, and hardware. Unfortunately, many of these products may not be providing the protection that the vendors are claiming or customers are expecting. Also, as with most crypto usage throughout history, people tend to defeat much of the protection afforded by the technology through misuse or inappropriate use. Therefore, the use of cryptography must be appropriate to the required goals and this strategy must be constantly reassessed. To use cryptography correctly, the weaknesses of systems must be understood.

This chapter reviews various historical, theoretical, and modern methods of attacking cryptographic systems. Although some technical discussion is provided, this chapter is intended for a general information technology and security audience.

Cryptography Overview

A brief overview of definitions and basic concepts is in order at this point. Generally, *cryptography* refers to the study of the techniques and methods used to hide data, and *encryption* is the process of disguising a message so that its meaning is not obvious. Similarly, decryption is the reverse process of encryption. The original data is called *cleartext* or *plaintext,* and the encrypted data is called *ciphertext*. Sometimes, the words *encode*/*encipher* and *decode*/*decipher* are used in the place of *encrypt* and *decrypt*. A cryptographic algorithm is commonly called a *cipher*. *Cryptanalysis* is the science of breaking cryptography, thereby gaining knowledge about the plaintext. The amount of work required to break an encrypted message or mechanism is call the *work factor*. *Cryptology* refers to the combined disciplines of cryptography and cryptanalysis.

Cryptography is one of the tools used in information security to assist in ensuring the primary goals of confidentiality, integrity, authentication, and non-repudiation.

Some of the things a cryptanalyst needs to be successful are:

- Enough ciphertext
- Full or partial plaintext
- Known algorithm
- Strong mathematical background
- Creativity

- Time, time, and more time for analysis
- Large amounts of computing power

Motivations for a cryptanalyst to attack a cryptosystem include:

- Financial gain, including credit card and banking information
- Political or espionage
- Interception or modification of e-mail
- Covering up another attack
- Revenge
- Embarrassment of vendor (potentially to get them to fix problems)
- Peer or open-source review
- Fun/education (cryptographers learn from others' and their own mistakes)

It is important to review the basic types of commonly used ciphers and some historical examples of cryptosystems. The reader is strongly encouraged to review cryptography books, but especially Bruce Schneier's essential *Applied Cryptography*[1] and *Cryptography and Network Security*[2] by William Stallings.

Cipher Types

Substitution Ciphers

A simple yet highly effective technique for hiding text is the use of substitution cipher, where each character is switched with another. There are several of these types of ciphers with which the reader should be familiar.

Monoalphabetic Ciphers

One way to create a substitution cipher is to switch around the alphabet used in the plaintext message. This could involve shifting the alphabet used by a few positions or something more complex. Perhaps the most famous example of such a cipher is the Caesar cipher, used by Julius Caesar to send secret messages. This cipher involves shifting each letter in the alphabet by three positions, so that "A" becomes "D," and "B" is replaced by "E," etc. Although this may seems simple today, it is believed to have been very successful in ancient Rome. This is probably due, in large part, to the fact the even the ability to read was uncommon, and therefore writing was probably a code in itself.

A more modern example of the use of this type of cipher is the UNIX *crypt* utility, which uses the ROT13 algorithm. ROT13 shifts the alphabet 13 places, so that "A" is replaced by "N," "B" by "M," etc. Obviously, this cipher provides little protection and is mostly used for obscuration rather than encryption, although with a utility named *crypt*, some users may assume there is actually some real protection in place. Note that this utility should not be confused with the UNIX *crypt( )* software routine that is used in the encryption of passwords in the password file. This routine uses the repeated application of the DES algorithm to make decrypting these passwords extremely difficult.[3]

Polyalphabetic Ciphers

By using more than one substitution cipher (alphabet), one can obtain improved protection from a frequency analysis attack. These types of ciphers were successfully used in the American Civil War[4] and have been used in commercial word-processing software. Another example of this type of cipher is the Vigenère cipher, which uses 26 Caesar ciphers that are shifted. This cipher is interesting as well because it uses a keyword to encode and decode the text.

One-Time Pad

In 1917, Joseph Mauborgne and Gilbert Vernam invented the unbreakable cipher called a one-time pad. The concept is quite effective, yet really simple. Using a random set of characters as long as the message, it is possible to generate ciphertext that is also random and therefore unbreakable even by brute-force attacks. In practice, having — and protecting — shared suitably random data is difficult to manage but this technique has been

successfully used for a variety of applications. It should be understood by the reader that a true, and thus unbreakable, one-time pad encryption scheme is essentially a theoretical concept as it is dependent on true random data, which is very difficult to obtain.

Transposition Cipher

This technique generates ciphertext by performing some form of permutation on plaintext characters. One example of this technique is to arrange the plaintext into a matrix and perform permutations on the columns. The effectiveness of this technique is greatly enhanced by applying it multiple times.

Stream Cipher

When large amounts of data need to enciphered, a cipher must be used multiple times. To efficiently encode this data, a stream is required. A stream cipher uses a secret key and then accepts a stream of plaintext producing the required ciphertext.

Rotor Machines

Large numbers of computations using ciphers can be time-consuming and prone to errors. Therefore, in the 1920s, mechanical devices called rotors were developed. The rotors were mechanical wheels that performed the required substitutions automatically. One example of a rotor machine is the Enigma used by the Germans during World War II. The initial designs used three rotors and an operator plugboard. After the early models were broken by Polish cryptanalysts, the Germans improved the system only to have it broken by the British.

RC4

Another popular stream cipher is the Rivest Cipher #4 (RC4) developed by Ron Rivest for RSA.

Block Cipher

A block cipher takes a block of plaintext, a key, and produces a block of ciphertext. Current block ciphers produce ciphertext blocks that are the same size as the corresponding plaintext block.

DES

The Data Encryption Standard (DES) was developed by IBM for the National Institute of Standards and Technology (NIST) as Federal Information Processing Standard (FIPS) 46. Data is encrypted using a 56-bit key and 8 parity bits with 64-bit blocks.

3DES

To improve the strength of DES-encrypted data, the algorithm can be applied in the triple-DES form. In this algorithm, the DES algorithm is applied three times, either using two keys (112-bit) encrypt-decrypt-encrypt, or using three keys (168-bit) encrypt-encrypt-encrypt modes. Both forms of 3DES are considered much stronger than single DES. There have been no reports of breaking 3DES.

IDEA

The International Data Encryption Algorithm (IDEA) is another block cipher developed in Europe. This algorithm uses 128-bit keys to encrypt 64-bit data blocks. IDEA is used in Pretty Good Privacy (PGP) for data encryption.

Types of Keys

Most algorithms use some form of secret key to perform encryption functions. There are some differences in these keys that should be discussed.

1. *Private/Symmetric.* A private, or symmetric, key is a secret key that is shared between the sender and receiver of the messages. This key is usually the only key that can decipher the message.
2. *Public/Asymmetric.* A public, or asymmetric, key is one that is made publicly available and can be used to encrypt data that only the holder of the uniquely and mathematically related private key can decrypt.

3. *Data/Session.* A symmetric key, which may or may not be random or reused, is used for encrypting data. This key is often negotiated using standard protocols or sent in a protected manner using secret public or private keys.
4. *Key Encrypting.* Keys that are used to protect data encrypting keys. These keys are usually used only for key updates and not data encryption.
5. *Split Keys.* To protect against intentional or unintentional key disclosure, it is possible to create and distribute parts of larger keys which only together can be used for encryption or decryption.

Symmetric Key Cryptography

Symmetric key cryptography refers to the use of a shared secret key that is used to encrypt and decrypt the plaintext. Hence, this method is sometimes referred to as secret key cryptography. In practice, this method is obviously dependent on the "secret" remaining so. In most cases, there needs to be a way that new and updated secret keys can be transferred. Some examples of symmetric key cryptography include DES, IDEA, and RC4.

Asymmetric Key Cryptography

Asymmetric key cryptography refers to the use of public and private key pairs, and hence this method is commonly referred to as public key encryption. The public and private keys are mathematically related so that only the private key can be used to decrypt data encrypted with the public key. The public key can also be used to validate cryptographic signatures generated using the corresponding private key.

Examples of Public Key Cryptography

RSA

This algorithm was named after its inventors, Ron Rivest, Adi Shamir, and Leonard Adleman, and based on the difficulty in factoring large prime numbers. RSA is currently the most popular public key encryption algorithm and has been extensively cryptanalyzed. The algorithm can be used for both data encryption and digital signatures.

Elliptic Curve Cryptography (ECC)

ECC utilizes the unique mathematical properties of elliptic curves to generate a unique key pair. To break the ECC cryptography, one must attack the "elliptic curve discrete logarithm problem." Some of the potential benefits of ECC are that it uses significantly shorter key lengths and that is well-suited for low bandwidth/CPU systems.

Hash Algorithms

Hash or digest functions generate a fixed-length hash value from arbitrary-length data. This is usually a one-way process, so that it impossible to reconstruct the original data from the hash. More importantly, it is, in general, extremely difficult to obtain the same hash from two different data sources. Therefore, these types of functions are extremely useful for integrity checking and the creation of electronic signatures or fingerprints.

MD5

The Message Digest (MD) format is probably the most common hash function in use today. This function was developed by Ron Rivest at RSA, and is commonly used as a data integrity checking tool, such as in Tripwire and other products. MD5 generates a 128-bit hash.

SHA

The Secure Hash Algorithm (SHA) was developed by the NSA. The algorithm is used by PGP, and other products, to generate digital signatures. SHA produces a 160-bit hash.

Steganography

Steganography is the practice used to conceal the existence of messages. That is different from encryption, which seeks to make the messages unintelligible to others.[5]

A detailed discussion of this topic is outside the scope of this chapter, but the reader should be aware that there are many techniques and software packages available that can be used to hide information in a variety of digital data.

Key Distribution

One of the fundamental problems with encryption technology is the distribution of keys. In the case of symmetric cryptography, a shared secret key must be securely transmitted to users. Even in the case of public key cryptography, getting private keys to users and keeping public keys up-to-date and protected remain difficult problems. There are a variety of key distribution and exchange methods that can be used. These range from manual paper delivery to fully automated key exchanges. The reader is advised to consult the references for further information.

Key Management

Another important issue for information security professionals to consider is the need for proper key management. This is an area of cryptography that is often overlooked and there are many historical precedents in North America and other parts of the world. If an attacker can easily, or inexpensively, obtain cryptographic keys through people or unprotected systems, there is no need to break the cryptography the hard way.

Public versus Proprietary Algorithms and Systems

It is generally an accepted fact among cryptography experts that closed or proprietary cryptographic systems do not provide good security. The reason for this is that creating good cryptography is very difficult and even seasoned experts make mistakes. It is therefore believed that algorithms that have undergone intense public and expert scrutiny are far superior to proprietary ones.

Classic Attacks

Attacks on cryptographic systems can be classified under the following threats:

- Interception
- Modification
- Fabrication
- Interruption

Also, there are both passive and active attacks. Passive attacks involve the listening-in, eavesdropping, or monitoring of information, which may lead to interception of unintended information or traffic analysis where information is inferred. This type of attack is usually difficult if not impossible to detect. However, active attacks involve actual modification of the information flow. This may include[6]:

- Masquerade
- Replay
- Modification of messages
- Denial of service

There are many historical precedents of great value to any security professional considering the use of cryptography. The reader is strongly encouraged to consult many of the excellent books listed in the bibliography, but especially the classic, *The Codebreakers: The Story of Secret Writing*, by David Kahn.[7]

Standard Cryptanalysis

Cryptanalysis strives to break the encryption used to protect information, and to this end there are many techniques available to the modern cryptographer.

Reverse Engineering

Arguably, one of the simplest forms of attack on cryptographic systems is reverse engineering, whereby an encryption device (method, machine, or software) is obtained through other means and then deconstructed to learn how best to extract plaintext. In theory, if a well-designed crypto hardware system is obtained and even its algorithms are learned, it may still be impossible to obtain enough information to freely decrypt any other ciphertext.[8] During World War II, efforts to break the German Enigma encryption device were greatly aided when one of the units was obtained. Also, today when many software encryption packages that claim to be foolproof are analyzed by cryptographers and security professionals, they are frequently found to have serious bugs that undermine the system.

Guessing

Some encryption methods may be trivial for a trained cryptanalyst to decipher. Examples of this include simple substitutions or obfuscation techniques that are masquerading as encryption. A common example of this is the use of the logical XOR function, which when applied to some data will output seemingly random data, but in fact the plaintext is easily obtained. Another example of this is the Caesar cipher, where each letter of the alphabet is shifted by three places so that A becomes D, B becomes E, etc. These are types of cryptograms that commonly present in newspapers and puzzle books.

The *Principle of Easiest Work* states that one cannot expect the interceptor to choose the hard way to do something.[9]

Frequency Analysis

Many languages, especially English, contain words that repeatedly use the same patterns of letters. There have been numerous English letter frequency studies done that give an attacker a good starting point for attacking much ciphertext. For example, by knowing that the letters E, T, and R appear the most frequently in English text, an attacker can fairly quickly decrypt the ciphertext of most monoalphabetic and polyalphabetic substitution ciphers. Of course, critical to this type of attack is the ready supply of sufficient amounts of ciphertext from which to work. These types of frequency and patterns also appear in many other languages, but English appears particularly vulnerable. Monoalphabetic ciphers, such as the Caesar cipher, directly transpose the frequency distribution of the underlying message.

Brute Force

The process of repeatedly trying different keys to obtain the plaintext are referred to as brute-force techniques. Early ciphers were made stronger and stronger in order to prevent human "computers" from decoding secrets; but with the introduction of mechanical and electronic computing devices, many ciphers became no longer usable. Today, as computing power grows daily, it has become a race to improve the resistance, or work factor, to these types of attacks. This of course introduces a problem for applications that may need to protect data that may be of value for many years.

Ciphertext-Only Attack

The cryptanalyst is presented only with the unintelligible ciphertext, from which she tries to extract the plaintext. For example, by examining only the output of a simple substitution cipher, one is able to deduce patterns and ultimately the entire original plaintext message. This type of attack is aided when the attacker has multiple pieces of ciphertext generated from the same key.

Known Plaintext Attack

The cryptanalyst knows all or part of the contents of the ciphertext's original plaintext. For example, the format of an electronic funds transfer might be known except for the amount and account numbers. Therefore, the work factor to extract the desired information from the ciphertext is significantly reduced.

Chosen Plaintext Attack

In this type of attack, the cryptanalyst can generate ciphertext from arbitrary plaintext. This scenario occurs if the encryption algorithm is known. A good cryptographic algorithm will be resistant even to this type of attack.

Birthday Attack

One-way hash functions are used to generate unique output, although it is possible that another message could generate an identical hash. This instance is called a collision. Therefore, an attacker can dramatically reduce the work factor to duplicate the hash by simply searching for these "birthday" pairs.

Factoring Attacks

One of the possible attacks against RSA cryptography is to attempt to use the public key and factor the private key. The security of RSA depends on this being a difficult problem, and therefore takes significant computation. Obviously, the greater the key length used, the more difficult the factoring becomes.

Replay Attack

An attacker may be able to intercept an encrypted "secret" message, such as a financial transaction, but may not be able to readily decrypt the message. If the systems are not providing adequate protection or validation, the attacker can now simply send the message again, and it will be processed again.

Man-in-the-Middle Attack

By interjecting oneself into the path of secure communications or key exchange, it possible to initiate a number of attacks. An example that is often given is the case of an online transaction. A customer connects to what is thought to be an online bookstore; but in fact, the attacker has hijacked the connection to monitor and interact with the data stream. The customer connects normally because the attacker simply forwards the data onto the bookstore, thereby intercepting all the desired data. Also, changes to the data stream can be made to suit the attacker's needs.

In the context of key exchange, this situation is potentially even more serious. If an attacker is able to intercept the key exchange, he may be able to use the key at will (if it is unprotected) or substitute his own key.

Dictionary Attacks

A special type of known-plaintext and brute-force attack can be used to guess the passwords on UNIX systems. UNIX systems generally use the *crypt( )* function to generate theoretically irreversible encrypted password hashes. The problem is that some users choose weak passwords that are based on real words. It is possible to use dictionaries containing thousands of words and to use this well-known function until there is a match with the encoded password. This technique has proved immensely successful in attacking and compromising UNIX systems. Unfortunately, Windows NT systems are not immune from this type of attack. This is accomplished by obtaining a copy of the NT SAM file, which contains the encrypted passwords, and as in the case of UNIX, comparing combinations of dictionary words until a match is found. Again, this is a popular technique for attacking this kind of system.

Attacking Random Number Generators

Many encryption algorithms utilize random data to ensure that an attacker cannot easily recognize patterns to aid in cryptanalysis. Some examples of this include the generation of initialization vectors or SSL sessions. However, if these random number generators are not truly random, they are subject to attack. Furthermore, if the random number generation process or function is known, it may be possible to find weaknesses in its implementation. Many encryption implementations utilize pseudorandom number generators (PRNGs), which as the name the name suggests, attempt to generate numbers that are practically impossible to predict. The basis of these PRNGs is the initial random seed values, which obviously must be selected properly. In 1995, early versions of the Netscape Navigator software were found to have problems with the SSL communication security.[10] The graduate students who reverse engineered the browser software determined that there was a problem with the seeding process used by the random number generator. This problem was corrected in later versions of the browser.

Inference

A simple and potential low-tech attack on encrypted communication can be via simple inference. Although the data being sent back and forth is unreadable to the interceptor, it is possible that the mere fact of this communication may mean there is some significant activity. A common example of this is the communication between military troops, where the sudden increase in traffic, although completely unreadable, may signal the start of an invasion or major campaign. Therefore, these types of communications are often padded so as not to show any increases or decreases in traffic. This example can easily be extended to the business world by considering a pending merger between two companies. The mere fact of increased traffic back and forth may signal the event to an attacker. Also, consider the case of encrypted electronic mail. Although the message data is well encrypted, the sender and recipient are usually plainly visible in the mail headers and message. In fact, the subject line of the message (e.g., "merger proposal") may say it all.

Modern Attacks

Although classical attacks still apply and are highly effective against modern ciphers, there have been a number of recent cases of new and old cryptosystems failing.

Bypass

Perhaps one of the simplest attacks that has emerged, and arguably is not new, is to simply go around any crypto controls. This may be as simple as coercion of someone with access to the unencrypted data or by exploiting a flaw in the way the cipher is used. There are currently a number of PC encryption products on the market and the majority of these have been found to have bugs. The real difference in these products has been the ways in which the vendor has fixed the problem (or not). A number of these products have been found to improperly save passwords for convenience or have backdoor recovery mechanisms installed. These bugs were mostly exposed by curious users exploring how the programs work. Vendor responses have ranged from immediately issuing fixes to denying there is a problem.

Another common example is the case of a user who is using some type of encryption software that may be protecting valuable information or communication. An attacker could trick the user into running a Trojan horse program, which secretly installs a backdoor program, such as BackOrifice on PCs. On a UNIX system, this attack may occur via an altered installation script run by the administrator. The administrator can now capture any information used on this system, including the crypto keys and passphrases. There have been several demonstrations of these types of attacks where the target was home finance software or PGP keyrings. The author believes that this form of attack will greatly increase as many more users begin regularly using e-mail encryption and Internet banking.

Operating System Flaws

The operating system running the crypto function can itself be the cause of problems. Most operating systems use some form of virtual memory to improve performance. This "memory" is usually stored on the system's hard disk in files that may be accessible. Encryption software may cache keys and plaintext while running, and

this data may remain in the system's virtual memory. An attacker could remotely or physically obtain access to these files and therefore may have access to crypto keys and possibly even plaintext.

Memory Residue

Even if the crypto functions are not cached in virtual memory or on disk, many products still keep sensitive keys in the system memory. An attacker may be able to dump the system memory or force the system to crash, leaving data from memory exposed. Hard disks and other media may also have residual data that may reside on the system long after use.

Temporary Files

Many encryption software packages generate temporary files during processing and may accidentally leave plaintext on the system. Also, application packages such as word processors leave many temporary files on the system, which may mean that even if the sensitive file is encrypted and there are no plaintext versions of the file, the application may have created plaintext temporary files. Even if temporary files have been removed, they usually can be easily recovered from the system disks.

Differential Power Analysis

In 1997, Anderson and Kuhn proposed inexpensive attacks against through which knowledgeable insiders and funded organizations could compromise the security of supposed tamper-resistant devices such as smart cards.[11] While technically not a crypto attack, these types of devices are routinely used to store and process cryptographic keys and provide other forms of assurance. Further work in this field has been done by Paul Kocher and Cryptographic Research, Inc. Basically, the problem is that statistical data may "leak" through the electrical activity of the device, which could compromise secret keys or PINs protected by it. The cost of mounting such an attack appears to be relatively low but it does require a high technical skill level. This excellent research teaches security professionals that new forms of high-security storage devices are highly effective but have to be used appropriately and that they do not provide *absolute* protection.

Parallel Computing

Modern personal computers, workstations, and servers are very powerful and are formidable cracking devices. For example, in *Internet Cryptography*,[12] Smith writes that a single workstation will break a 40-bit export crypto key, as those used by Web browsers, in about ten months. However, when 50 workstations are applied to this problem processing in parallel, the work factor is reduced to about six days. This type of attack was demonstrated in 1995 when students using a number of idle workstations managed to obtain the plaintext of an encrypted Web transaction.

Another example of this type of processing is *Crack* software, which can be used to brute-force guess UNIX passwords. The software can be enabled on multiple systems that will work cooperatively to guess the passwords.

Parallel computing has also become very popular in the scientific community due the fact that one can build a supercomputer using off-the-shelf hardware and software. For example, Sandia National Labs has constructed a massively parallel system called Cplant, which was ranked the 44th fastest among the world's 500 fastest supercomputers (http://www.wired.com/ news/technology/0,1282,32706,00.html). Parallel computing techniques mean that even a moderately funded attacker, with sufficient time, can launch very effective and low-tech brute-force attacks against medium to high value ciphertext.

Distributed Computing

For a number of years, RSA Security has proposed a series of increasingly difficult computation problems. Most of the problems require the extraction of RSA encrypted messages and there is usually a small monetary award. Various developers of elliptic curve cryptography (ECC) have also organized such contests. The primary reason for holding these competitions is to test current minimum key lengths and obtain a sense of the "real-world" work factor.

Perhaps the most aggressive efforts have come from the Distributed.Net group, which has taken up many such challenges. The Distributed team consists of thousands of PCs, midrange, and high-end systems that

collaboratively work on these computation problems. Other Internet groups have also formed and have spawned distributed computing rivalries. These coordinated efforts show that even inexpensive computing equipment can be used in a distributed or collaborative manner to decipher ciphertext.

DES Cracker

In 1977, Whitfield Diffie and Martin Hellman proposed the construction of a DES-cracking machine that could crack 56-bit DES keys in 20 hours. Although the cost of such a device is high, it seemed well within the budgets of determined attackers. Then in 1994, Michael Weiner proposed a design for a device built from existing technology which could crack 56-bit DES keys in under four hours for a cost of $1 million. The cost of this theoretical device would of course be much less today if one considers the advances in the computer industry.

At the RSA Conferences held in 1997 and 1998, there were contests held to crack DES-encrypted messages. Both contests were won by distributed computing efforts. In 1998, the DES message was cracked in 39 days. Adding to these efforts was increased pressure from a variety of groups in the United States to lift restrictive crypto export regulations. The Electronic Freedom Foundation (EFF) sponsored a project to build a DES cracker. The intention of the project was to determine how cheap or how expensive it would be to build a DES cracker.

In the summer of 1998, the EFF DES cracker was completed, costing $210,000 and taking only 18 months to design, test, and build. The performance of the cracker was estimated at about five days per key. In July 1998, EFF announced to the world that it had easily won the RSA Security "DES Challenge II," taking less than three days to recover the secret message. In January 1999, EFF announced that in a collaboration with Distributed.Net, it had won the RSA Security "DES Challenge III," taking 22 hours to recover the plaintext. EFF announced that this "put the final nail into the Data Encryption Standard's coffin." EFF published detailed chip design, software, and implementation details and provided this information freely on the Internet.

RSA-155 (512bit) Factorization

In August 1999, researchers completed the factorization of the 155-digit (512-bit) RSA Challenge Number. The total time taken to complete the solution was around five to seven months without dedicating hardware. By comparison, RSA-140 was solved in nine weeks. The implications of this achievement in relatively short time may put RSA keys at risk from a determined adversary. In general, it means that 768- or 1024-bit RSA keys should be used as a minimum.

TWINKLE RSA Cracker

In summer 1999, Adi Shamir, co-inventor of the RSA algorithm, presented a design for The Weizmann Institute Key Locating Engine (TWINKLE), which processes the "sieving" required for factoring large numbers. The device would cost about $5000 and provide processing equivalent to 100 to 1000 PCs. If built, this device could be used similarly to the EFF DES Cracker device. This device is targeted at 512-bit RSA keys, so it reinforces the benefits of using of 768- or 1024-bit, or greater keys.

Key Recovery and Escrow

Organizations implementing cryptographic systems usually require some way to recover data encrypted with keys that have been lost. A common example of this type of system is a public key infrastructure, where each private (and public) key is stored on the Certificate Authority, which is protected by a root key(s). Obviously, access to such a system has to be tightly controlled and monitored to prevent a compromise of all the organization's keys. Usually, only the private data encrypting, but not signing, keys are "escrowed."

In many nations, governments are concerned about the use of cryptography for illegal purposes. Traditional surveillance becomes difficult when the targets are using encryption to protect communications. To this end, some nations have attempted to pursue strict crypto regulation, including requirements for key escrow for law enforcement.

In general, key recovery and escrow implementations could cause problems because they are there to allow access to all encrypted data. Although a more thorough discussion of this topic is beyond the scope of this chapter, the reader is encouraged to consult the report entitled "The Risks of Key Recovery, Key Escrow, and

Trusted Third Party Encryption," which was published in 1997 by an *ad hoc* group of cryptographers and computer scientists. Also, Whitfield Diffie and Susan Landau's *Privacy on the Line* is essential reading on the topic.

Protecting Cryptosystems

Creating effective cryptographic systems requires balancing business protection needs with technical constraints. It is critical that these technologies be included as part of an effective and holistic protection solution. It is not enough to simply implement encryption and assume all risks have been addressed. For example, just because an e-mail system is using message encryption, it does not necessarily mean that e-mail is secure, or even any better than plaintext. When considering a protection system, not only must one look at and test the underlying processes, but one must also look for ways around the solutions and address these risks appropriately. It is vital to understand that crypto solutions can be dangerous because they can easily lead to a false sense of information security.

Design, Analysis, and Testing

Fundamental to the successful implementation of a cryptosystem are thorough design, analysis, and testing methodologies. The implementation cryptography is probably one of the most difficult and most poorly understood IT fields. Information technology and security professionals must fully understand that cryptographic solutions that are simply dropped into place are doomed to failure.

It is generally recommended that proprietary cryptographic systems are problematic and usually end up being not quite what they appear to be. The best algorithms are those that have undergone rigorous public scrutiny by crypto experts. Just because a cryptographer cannot break his or her own algorithm, this does not mean that this is a safe algorithm. As Bruce Schneier points out in "Security Pitfalls in Cryptography," the output from a poor cryptographic system is very difficult to differentiate from a good one.

Smith[13] suggests that preferred crypto algorithms should have the following properties:

- No reliance on algorithm secrecy
- Explicitly designed for encryption
- Available for analysis
- Subject to analysis
- No practical weaknesses

When designing systems that use cryptography, it is also important to build in proper redundancies and compensating controls, because it is entirely possible that the algorithms or implementation may fail at some point in the future or at the hands of a determined attacker.

Selecting Appropriate Key Lengths

Although proper design, algorithm selection, and implementation are critical factors for a cryptosystem, the selection of key lengths is also very important. Security professionals and their IT peers often associate the number of "bits" a product uses with the measure of its level of protection. As Bruce Schneier so precisely puts it in his paper "Security Pitfalls in Cryptography": "…reality isn't that simple. Longer keys don't always mean more security."[14] As stated earlier, the cryptographic functions are but part of the security strategy. Once all the components and vulnerabilities of a encryption strategy have been reviewed and addressed, one can start to consider key lengths.

In theory, the greater the key length, the more difficult the encryption is to break. However, in practice, there are performance and practical concerns that limit the key lengths to be used. In general, the following factors will determine what key sizes are used:

- Value of the asset it is protecting (compare to cost to break it)
- Length of time it needs protecting (minutes, hours, years, centuries)
- Determination of attacker (individual, corporate, government)
- Performance criteria (seconds versus minutes to encrypt/decrypt)

Therefore, high value data that needs to protected for a long time, such as trade secrets, requires long key lengths. Whereas, a stock transaction may only be of value for a few seconds, and therefore is well protected with shorter key lengths. Obviously, it is usually better to err toward longer key sizes than shorter. It is fairly common to see recommendations of symmetric key lengths, such as for 3DES or IDEA, of 112 to 128 bits, while 1024- to 2048-bit lengths are common for asymmetric keys, such as for RSA encryption.

Random Number Generators

As discussed earlier, random number generators are critical to effective cryptosystems. Hardware-based RNG are generally believed to be the best, but more costly form of implementation. These devices are generally based on random physical events, and therefore should generate data that is nearly impossible to predict.

Software RNGs obviously require additional operating system protection, but also protection from covert channel analysis. For example, systems that use system clocks may allow an attacker access to this information via other means, such as remote system statistics or network time protocols. Bruce Schneier has identified software random number generators as being a common vulnerability among crypto implementations [SOURCE], and to that end has made an excellent free PRNG available, with source code, to anyone. This PRNG has undergone rigorous independent review.

Source Code Review

Even if standard and publicly scrutinized algorithms and methods are used in an application, this does not guarantee that the application will work as expected. Even open-source algorithms are difficult to implement correctly because there are many nuances (e.g., cipher modes in DES and proper random number generation) that the programmer may not understand. Also, as discussed in previous sections, many commercial encryption packages have sloppy coding errors such as leaving plaintext temporary files unprotected. Cryptographic application source code should be independently reviewed to ensure that it actually does what is expected.

Vendor Assurances

Vendor assurances are easy to find. Many products claim that their data or communications are encrypted or are secure; however, unless they provide any specific details, it usually turns out that this protection is not really there or is really just "obfuscation" at work. There are some industry evaluations and standards that may assist in selecting a product. Some examples are the Federal Information Processing Standards (FIPS), the Common Criteria evaluations, ICSA, and some information security publications.

New Algorithms

Advanced Encryption Algorithm (AES)

A new robust encryption algorithm was needed to replace the aging Data Encryption Standard (FIPS 46-3), which had been developed in the 1970s. In September 1997, NIST issued a Federal Register notice soliciting an unclassified, publicly disclosed encryption algorithm that would be available royalty-free, worldwide. Following the submission of 15 candidate algorithms and three publicly held conferences to discuss and analyze the candidates, the field was narrowed to five candidates:

- MARS (IBM)
- RC6TM (RSA Laboratories)
- RIJNDAEL (Joan Daemen, Vincent Rijmen)
- Serpent (Ross Anderson, Eli Biham, Lars Knudsen)
- Twofish (Bruce Schneier, John Kelsey, Doug Whiting, David Wagner, Chris Hall, Niels Ferguson)

NIST continued to study all available information and analyses about the candidate algorithms, and selected one of the algorithms, the Rijndael algorithm, to propose for the AES. The Secretary of Commerce approved FIPS 197, Advanced Encryption Standard (AES), which, effective May 26, 2002, makes it compulsory and binding on federal agencies for the protection of sensitive, unclassified information. The development and public review process has proven very interesting, showing the power of public review of cryptographic algorithms.

Conclusion

The appropriate use of cryptography is critical to modern information security, but it has been shown that even the best defenses can fail. It is critical to understand that cryptography, while providing excellent protection, can also lead to serious problems if the whole system is not considered. Ultimately, practitioners must understand not only the details of the crypto products they are using, but what they are in fact protecting, why these controls are necessary, and who they are protecting these assets against.

Domain 6 Enterprise Security Architecture

The Enterprise Security Architecture Domain contains the concepts, principles, structures, and standards used to design, implement, monitor, and secure operating systems, equipment, networks, applications, and those controls used to enforce various levels of confidentiality, integrity, and availability.

Building an information system requires a balance among various requirements, such as capability, flexibility, performance, ease of use, cost, business requirements, and security. Security should be considered a requirement from the beginning — it is simply another feature that needs to be included. Attempting to retrofit the required and desired security controls after the fact can lead to user frustration, a lowered security posture, and significantly increased implementation costs. Based on the importance of each requirement, various trade-offs may be necessary during the design of the system. Thus, it is important to identify what security features must be included. Then if a performance or flexibility requirement means downgrading or not including a security feature, the architecture designers can keep the primary goals of the system in check and make compromises on the nonessential points.

Security architecture is simply a view of an overall system architecture from a security perspective. It provides some insight into the security services, mechanisms, technologies, and features that can be used to satisfy system security requirements. It provides recommendations on where, within the context of the overall system architecture, security mechanisms should be placed. The security view of a system architecture focuses on the system security services and high-level mechanisms, allocation of security-related functionality, and identified interdependencies among security related components, services, mechanisms, and technologies, and at the same time reconciling any conflict among them. The security architecture is only one aspect of the enterprise or system architecture, which may also include network architecture or physical connectivity architecture.

Security architecture describes how the system is put together to satisfy the security requirements. It is not a description of the functions of the system; it is more of a design overview, describing at an abstract level the relationships between key elements of the hardware, operating systems, applications, network, and other required components to protect the organization's interests. It should also describe how the functions in the system development process follow the security requirements. For example, if the security requirements specify that the system must have a given level of assurance as to the correctness of the security controls, the security architecture must prescribe these specifications in the development process.

Security requirements are not added steps to the development process; instead, the specifications or guidelines of the security architecture provide an influence during all development processes. During the beginning stages, the security architecture should outline high-level security issues, such as the system security policy, the level of assurance required, and any potential impacts security could have on the design process. As the system is developed, the security architecture should evolve in parallel, and may even need to be slightly ahead of the development process so that the security requirements will guide the development process.

The chapters presented here provide the necessary breadth to address the challenges of developing a security architecture and the insight to evaluate the existing or legacy architecture of an organization.

Contents

Enterprise Security Architecture

William Hugh Murray

INTRODUCTION

Sometime during the 1980s we crossed a line from a world in which the majority of computer users were users of multi-user systems to one in which the majority were users of single-user systems. We are now in the process of connecting all computers in the world into the most complex mechanism that humans have ever built. While for many purposes we may be able to do this on an ad hoc basis, for purposes of security, audit, and control it is essential that we have a rigorous and timely design. We will not achieve effective, much less efficient, security without an enterprise-wide design and a coherent management system.

Enterprise

If you look in the dictionary for the definitions of enterprise, you will find that an enterprise is a project, a task, or an undertaking; or, the readiness for such, the motivation, or the moving forward of that undertaking. The dictionary does not contain the definition of the enterprise as we are using it here. For our purposes here, the enterprise is defined as the largest unit of business organization, that unit of business organization that is associated with ownership. If the institution is a government institution, then it is the smallest unit headed by an elected official. What we need to understand is that it is a large, coordinated, and independent organization.

ENTERPRISE SECURITY IN THE 1990s

Because the scale of the computer has changed from one scaled to the enterprise to one scaled to the application or the individual, the computer security requirements of the enterprise have changed. The new requirement can best be met by an architecture or a design.

We do not do design merely for the fun of it or even because it is the "right" thing to do. Rather, we do it in response to a problem or a set of requirements. While the requirements for a particular design will be those

for a specific enterprise, there are some requirements that are so pervasive as to be typical of many, if not most, enterprises. This section describes a set of observations by the author to which current designs should respond.

Inadequate expression of management intent — One of these is that there is an inadequate expression of management's intent. Many enterprises have no written policy at all. Of those that do, many offer inadequate guidance for the decisions that must be made. Many say little more than "do good things." They fail to tell managers and staff how much risk general management is prepared or intends to accept. Many fail to adequately assign responsibility or duties or fix the discretion to say who can use what resources. This results in inconsistent risk and inefficient security, i.e., some resources are overprotected and others are underprotected.

Multiple sign-ons, IDs, and passwords — Users are spending tens of minutes per day logging on and logging off. They may have to log on to several processes in tandem in order to access an application. They may have to log off of one application in order to do another. They may be required to remember multiple user identifiers and coordinate many passwords. Users are often forced into insecure or inefficient behavior in futile attempts to compensate for these security measures. For example, they may write down or otherwise record identifiers and passwords. They may even automate their use in macros. They may postpone, or even forget tasks so as not to have to quit one application in order to do another. This situation is often not obvious to system managers. They tend to view the user only in the context of the systems that they manage rather in the context of the systems he uses. He may also see this cost as "soft money," not easily reclaimed by him. On the other hand, it is very real money to the enterprise which may have thousands of such users and which might be able to get by with fewer if they were not engaged in such activity. Said another way, information technology management overlooks what general management sees as an opportunity.

Multiple points of control — Contrary to what we had hoped and worked for in the 1980s, data are proliferating and spreading throughout the enterprise. We did not succeed in bringing all enterprise data under a single access control system. Management is forced to rely upon multiple processes to control access to data. This often results in inconsistent and incomplete control. Inconsistent control is usually inefficient. It means that management is spending too much or too little for protection. Incomplete control is ineffective. It means that some data are completely unprotected and unreliable.

Unsafe defaults — In order to provide for ease of installation and avoid deadlocks, systems are frequently shipped with security mechanisms set to the unsafe conditions by default. The designers are concerned that even

before the system is completely installed, management may lose control. The administrator might accidentally lock himself out of his own system with no remedy but to start over from scratch. Therefore, the system may be shipped with controls defaulted to their most open settings. The intent is that after the systems are configured and otherwise stable, the administrator will reset the controls to the safe condition. However, in practice and so as not to interfere with running systems, administrators are often reluctant to alter these settings. This may be complicated by the fact that systems which are not securely configured are, by definition, unstable. The manager has learned that changes to an already unstable system tend to aggravate the instability.

Complex administration — The number of controls, relations between them, and the amount of special knowledge required to use them may overwhelm the training of the administrator. For example, in order to properly configure the password controls for a Novell server, the administrator may have to set four different controls. The setting of one requires not only knowledge of how the others are set but how they relate to each other. The administrator's training is often focused on the functionality of the systems rather than on security and control. The documentation tends to focus on the function of the controls while remaining silent on their use to achieve a particular objective or their relationship to other controls.

Late recognition of problems — In part because of the absence of systematic measurement and monitoring systems, many problems are being detected and corrected late. Errors that are not detected or corrected may be repeated. Attacks are permitted to go on long enough to succeed. If permitted to continue for a sufficient length of time without corrective action, any attack will succeed. The cost of these problems is greater than it would be if they were detected on a more timely basis.

Increasing use, users, uses, and importance — Most important for our purposes here, security requirements arise in the enterprise as the result of increasing use of computers, increasing numbers of users, increasing numbers of uses and applications, and increasing importance of those applications and uses to the enterprise. All of these things can be seen to be growing at a rate that dwarfs our poor efforts to improve security. The result is that relative security is diminishing to the point that we are approaching chaos.

ARCHITECTURE DEFINED

In response to these things we must increase not only the effectiveness of our efforts but also their efficiency. Because we are working on the scale of the enterprise, ad hoc and individual efforts are not likely to be successful. Success will require that we coordinate the collective efforts of the enterprise according to a plan, design, or architecture.

Architecture can be defined as that part of design that deals with what things look like, what they do, where they are, and what they are made of. That is, it deals with appearance, function, location, and materials. It is used to agree on what is to be done and what results are to be produced so that multiple people can work on the project in a collaborative and cooperative manner and so that we can agree when we are through and the results are as expected.

The design is usually reflected in a picture, model, or prototype; in a list of specified materials; and possibly in procedures to be followed in achieving the intended result. When dealing in common materials, the design usually references standard specifications. When using novel materials the design must describe these materials in detail.

In information technology we borrow the term from the building and construction industry. However, unlike this industry, we do not have 10,000 years of tradition, conventions, and standards behind us. Neither do we share the rigor and discipline that characterize them.

TRADITIONAL IT ENVIRONMENT

Computing environments can be characterized as traditional and modern. Each has its own security requirements but, in general and all other things being equal, the traditional environment is easier to secure than its modern equivalent.

Closed — Traditional IT systems and networks are closed. Only named parties can send messages. The nodes and links are known in advance. The insertion of new ones requires the anticipation and cooperation of others. They are closed in the sense that their uses or applications are determined in advance by their design, and late changes are resisted.

Hierarchical — Traditional IT can be described as hierarchical. Systems are organized and controlled top down, usually in a hierarchical or tree structure. Messages and controls flow vertically better than they do horizontally. Such horizontal traffic as exists is mediated by the node at the top of the tree, for example, a mainframe.

Point-to-point — Traffic tends to flow directly from point to point along nodes and links which, at least temporarily, are dedicated to the traffic. Traffic flows directly from one point to another; what goes in at node A will come out only at node B.

Connection switched — The resources that make up the connection between two nodes are dedicated to that connection for the life of the communication. When either is to talk to another, the connection is torn down and a new one is created. The advantage is in speed of communication and security, but capacity may not be used efficiently.

Host-dependent workstations — In traditional computing, workstations are incapable of performing independent applications. They are dependent upon cooperation with a host or master in order to be able to perform any useful work.

Homogeneous components — In traditional networks and architectures, there is a limited number of different component types from a limited number of vendors. Components are designed to work together in a limited number of ways. That is to say part of the design may be dictated by the components chosen.

MODERN IT ENVIRONMENT

Open — By contrast, modern computing environments are open. Like the postal system, for the price of a stamp anyone may send a message. For the price of an accommodation address, anyone can get an answer back. For not much more, anyone can open his own post office. Modern networks are open in the sense that nodes can be added late and without the permission or cooperation of others. They are open in the sense that their applications are not predetermined.

Flat — The modern network is flat. Traffic flows with equal ease between any two points in the network. It flows horizontally as well as it does vertically. Traffic flows directly and without any mediation. If one were to measure the bandwidth between any two points in the network, chosen arbitrarily, it would be approximately equal to that between any other two points chosen the same way. While traffic my flow faster between two points that are close to each other, taken across the collection of all pairs, it flows with the same speed.

Broadcast — Modern networks are broadcast. While orderly nodes accept only that traffic which is intended for them, traffic will be seen by multiple nodes in addition to the one for which it is intended. Thus, confidentiality may depend in part upon the fact that a large number of otherwise unreliable devices all behave in an orderly manner.

Packet-switched — Modern networks are packet-switched rather than circuit-switched. In part this means that the messages are broken into packets and each packet is sent independent of the others. Two packets sent from the same origin to the same destination may not follow the same path and may not arrive at the destination in the same order that they were sent. The sender cannot rely upon the safety of the path or the arrival of the message at the destination and the receiver cannot rely upon the return address. In part, it means that a packet may be broadcast to multiple nodes, even to all nodes, in an attempt to speed it to its destination. By design it will be heard by many nodes other than the ones for which it is intended.

Intelligent workstations — In modern environments, the workstations are intelligent, independently programmable, and capable of performing independent work or applications. They are also vulnerable both to the leakage of sensitive information and to the insertion of malicious programs. These malicious programs may be untargeted viruses or they may be password grabbers that are aimed at specific workstations, perhaps those used by privileged users.

Heterogeneousness — The modern network is composed of a variety of nodes and links from many different vendors. There may be dozens of different workstations, servers, and operating systems. The links may be of many speeds and employ many different kinds of signaling. This makes it difficult to employ an architecture that relies upon the control or behavior of the components.

OTHER SECURITY ARCHITECTURE REQUIREMENTS

IT architecture — The information security architecture is derivative of and subordinate to the information technology architecture. It is not independent. One cannot do a security architecture except in the context of and in response to an IT architecture. An information technology architecture describes the appearance, function, location, and materials for the use of information technology. Often one finds that the IT architecture is not sufficiently well thought out or documented to support the development of the security architecture. That is to say, it describes fewer than all four of the things that an architecture must describe. Where it is documented at all, one can expect to find that it describes the materials but not appearance, location, or function.

Policy or management intent — The security architecture must document and respond to a policy or an expression of the level of risk that management is prepared to take. This will influence materials chosen, the roles assigned, the number of people involved in sensitive duties, etc.

Industry and institutional culture — The architecture must document and respond to the industry and institutional culture. The design that is appropriate to a bank will not work for a hospital, university, or auto plant.

Other — Likewise, it must respond to the management style — authoritarian or permissive, prescriptive or reactive — of the institution, to law and regulation, to duties owed to constituents, and to good practice.

SECURITY ARCHITECTURE

The security architecture describes the appearance of the security functions, what is to be done with them, where they will be located within the

organization, its systems, and its networks, and what materials will be used to craft them. Among other things, it will describe the following.

Duties, roles, and responsibilities — It will describe who is to do what. It specifies who management relies upon and for what. For every choice or degree of freedom within the system, the architecture will identify who will exercise it.

How objects will be named — It will describe how objects are named. Specifically, it will describe how users are named, identified or referred to. Likewise it will describe how information resources are to be named within the enterprise.

What authentication will look like — It must describe how management gains sufficient confidence in these names or identifiers. How does it know that a user is who he says he is and that the data returned for a name are the expected data? Specifically, the architecture describes what evidence the user will present to demonstrate her identity. For example, if the user is to be authenticated based upon something that he knows, what are the properties (length and character set) of that knowledge?

Where it will be done — Similarly, the architecture will describe where the instant data are to be collected, where the reference data will be stored, and what process will reconcile the two.

What the object of control will be — The architecture must describe what it is that will be controlled. In the traditional IT architecture this was usually a file or a dataset, or sometimes a procedure such as a program or a transaction type. In modern systems it is more likely to be a data base object such as a table or a view.

Where access will be controlled — The architecture will describe where, i.e., what processes, will exercise control over the objects. In the traditional IT architecture we tried to centralize all access control in a single process, scaled to the enterprise. In more modern systems access will be controlled in a large number of places. These places will be scaled to departments, applications, and other ways of organizing resources. They may be exclusive or they may overlap. How they are related and where they are located is the subject of the design.

Generation and distribution of warnings and alarms — Finally, the design must specify what events or combinations of events require corrective action, what process will detect them, who is responsible for the action, and how the warning will be communicated from the detecting process to the party responsible for the correction.

POLICY

A Statement of Management's Intent

Among other things, a policy is a statement of management's intent. Among other things, a security policy describes how much risk management intends to take. This statement must be adequate for managers to be able to figure out what to do in a given set of circumstances. It should be sufficiently complete that two managers will read it the same way, reach similar conclusions, and behave in similar ways.

It should speak to how much risk management is prepared to take. For example, management expects to take normal business risk, or acceptable and accepted risk. Alternately or in addition, management can specify the intended level of control. For example, management can say that controls must be such that multiple people must be involved in sensitive duties or material fraud.

The policy should state what management intends to achieve, for example, data integrity, availability, and confidentiality, and how it intends to do it. It should clearly state who is to be responsible for what. It should state who is to have access to what information. Where such access is to be restricted or discretionary, then the policy should state who will exercise the discretion.

The policy should be such that it can be translated into an access control policy. For example, it might say that read access to confidential data must be restricted to those authorized by the owner of the data. The architecture will describe how a given platform or a network of platforms will be used to implement that policy.

IMPORTANT SECURITY SERVICES

The architecture will describe the security mechanisms and services that will be used to implement the access control policy. These will include but not be limited to the following.

User name service — The user name service is used for assigning unique names to users and to resolve aliases where necessary. It can be thought of as a data base, data base application, or data base service. The server can encode and decode user names into user identifiers. For the distinguished user name it returns a system user identifier or identifiers. For the system user identifier it returns a distinguished user name. It can be used to store information about the user. It is often used to store other descriptive data about the user. It may store office location, telephone number, department name, and manager's name.

Group name service — The group name service is used for assigning unique group names and for associating users with those groups. It

permits the naming of any arbitrary but useful group such as member of department m, employees, vendors, consultants, users of system 1, users of application A, etc. It can also be used to name groups of one, such as the payroll manager. For the group name, it returns the names, identifiers, or aliases of members of the group. For a user name, it returns a list of the groups of which that user is a member. A complete list of the groups of which a user is a member is a description of his role or relationship to the enterprise. Administrative activity can be minimized by assigning authority, capabilities, and privileges to groups and assigning users to the groups. While this is indirect it is also usually efficient.

Authentication server — The authentication server reconciles evidence of identity. Users are enrolled along with the expectation, i.e., the reference data, for authenticating their identity. For a user identifier and an instance of authenticating data, the server returns *true* if the data meets its expectation, i.e., matches the reference data, and *false* if it does not. If *true*, the server will vouch to its clients for the identity of the user. The authentication server must be trusted by its client and the architecture must provide the basis for that trust. The server may be attached to its client by a trusted path or it may give its client a counterfeit-resistant voucher (ticket or encryption-based logical token).

Authentication service products — A number or authentication services are available off the shelf. These include Kerberos, SESAME, NetSP, and Open Software Foundation Distributed Computing Environment (OSF/DCE). These products can meet some architectural requirements in whole or in part.

Single point of administration — One implication of multiple points of control is that there may be multiple controls that must be administered. The more such controls there are, the more desirable it becomes to minimize the points of administration. Such points of administration may simply provide for a common interface to the controls or may provide for a single data base of its own. There are a number of standard architectures that are useful here. These include SESAME and the Open Software Foundation Distributed Computing Environment.

RECOMMENDED ENTERPRISE SECURITY ARCHITECTURE

This section makes some recommendations about enterprise security architecture. It describes those choices which, all other things equal, are to be preferred over others.

Single-user name space for the enterprise — Prefer a single-user name space across all systems. Alternatively, have an enterprise name server that relates all of a user's aliases to his distinguished name. This server

should be the single point of name assignment. In other words it is a data base application or server for assigning names.

Prefer strong authentication — Strong authentication should be preferred by all enterprises of interest. Strong authentication is characterized by two kinds of evidence, at least one of which is resistant to replay. Users should be authenticated using two kinds of evidence. Evidence can be something that only one person knows, has, is, or can do. The most common form of strong authentication is something that the user knows such as a password, pass-phrase, or personal identification number (PIN), plus something that they carry such as a token. The token generates a one-time password that is a function of time or a challenge. Other forms in use include a token plus palm geometry or a PIN plus the way the user speaks.

Prefer single sign-on — Prefer single sign-on. A user should have to log on only once per workstation per enterprise per day. A user should not be surprised that if he changes workstations, crosses an enterprise boundary, or leaves for the day, that he should have to log on again. However, he should not have to log off one application to log on to another or log on to multiple processes to use one application.

Application or service as point of control — Prefer the application or service as the point of control. The first applicable principle is that the closer to the data that the control is, the fewer instances of it that there will be, the less subject it will be to user interference, the more difficult it will be to bypass, and consequently, the more reliable it will be. This principle can be easily understood by contrasting it to the worst case — the one where the control is on the desktop. Multiple copies must be controlled, they are very vulnerable to user interference, not to say complete abrogation, and the more people there are who are already behind the control. The second principle is that application objects are both specific, i.e., their behavior is intuitive, predictable from their name, and obvious as to their intended use. Contrast "update name and address of customer" to "write to customer data base." One implication of the application as the point of control is that there will be more than one point of control. However, there will be fewer than if the control were even closer to the user.

Multiple points of control — Each server or service should be responsible for control of access to all of its dynamically allocated resources. Prefer that all such resources be of the same resource type. To make its access decision, the server may use local knowledge or data or it may use a common service that is sufficiently abstract to include its rules. One implication of the server or service as the point of control is that there will be multiple points of control. That is to say, there are multiple repositories of data and multiple mechanisms that management must manipulate to exercise control. This may increase the requirement for special knowledge, communication, and coordination.

Limited points of administration — Therefore, prefer a limited number of points of administration that operate across a number of points of control. These may be relatively centralized to respond to a requirement for a great deal of special knowledge about the control mechanism. Alternatively it can be relatively decentralized to meet a requirement for special knowledge about the users, their duties, and responsibilities.

Single resource name space for enterprise data — Prefer a single name space for all enterprise data. Limit this naming scheme to enterprise data; i.e., data that are used and meaningful across business functions or that are related to the business strategy. It is not necessary to include all business functional data, project data, departmental data, or personal data.

Object, table, or view as unit of control — Prefer capabilities, objects, tables, views, rows, columns, and files, in that order as objects of control. This is the order in which the data are most obvious as to meaning and intended use.

Arbitrary group names with group-name service — It is useful to be able to organize people into affinity groups. These may include functions, departments, projects, and other units of organization. They may also include such arbitrary groups as employees, nonemployees, vendors, consultants, contractors, etc. The architecture should deal only with enterprise-wide groups. It should permit the creation of groups which are strictly local to a single organizational unit or system. Enterprise group names should be assigned and group affinities should be managed by a single service across the enterprise and across all applications and systems. This service may run as part of the user name service. Within reasonable bounds any user should be able to define a group for which he is prepared to assume ownership and responsibility. Group owners should be able to manage group membership or delegate it. For example, the human resources manager might wish to restrict the ability to add members to the group *payroll department* while permitting any manager to add users to the group *employee* or the group *nonemployee*.

Rules-based (as opposed to list-based) access control — Prefer rules-based to list-based access control. For example, prefer "access to data labelled confidential is limited to employees" should be preferred to "user A can access dataset 1." While the latter is more granular and specific, the former covers more data in a single rule. The latter will require much more administrative activity to accomplish the same result as the former. Similarly, it can be expressed in far less data. While the latter may permit only a few good things to happen, the former forbids a large number of bad things. This recommendation is counterintuitive to those of us who are part of the tradition of "least possible privilege." This rule implies that a user should be given access to only those resources required to do their job and that all access should be explicit. The rule of least privilege worked

well in a world in which the number of users, data objects, and relations between them was small. It begins to break down rapidly in the modern world of tens of millions of users and billions of resources.

Data-based rules — Access control rules should be expressed in terms of the name and other labels of the data rather than in terms of the procedure to be performed. They should be independent of the procedures used to access the data or the environment in which they are stored. That is, it is better to say that a user has *read* access to *filename* than to say that he has *execute* access to *word.exe*. It makes little sense to say that a user is restricted to a procedure that can perform arbitrary operations on an unbounded set of objects. This is an accommodation to the increase in the number of data objects and the decreasing granularity of the procedures.

Prefer single authentication service — Evidence of user identity should be authenticated by a single central process for the entire enterprise and across all systems and applications. These systems and applications can be clients of the authentication server or the server can issue trusted credentials to the user that can be recognized and honored by the using systems and applications.

Prefer a single standard interface for invoking security services — All applications, services, and systems should invoke authentication, access control, monitoring, and logging services via the same programming interface. The generalized system security application programming interface (GSSAPI) is preferred in the absence of any other overriding considerations. Using a single interface permits the replacement or enhancement of the security services with a minimum of disruption.

Encryption services — Standard encryption services should be available on every platform. These will include encryption, decryption, key management, and certificate management services. The Data Encryption Standard algorithm should be preferred for all applications save key management, where RSA is preferred. A public key server should be available in the network. This service will permit a user or an application to find the public key of any other.

Automate and hide all key management functions — All key management should be automated and hidden from users. No keys should ever appear in the clear or be transcribed by a user. Users should reference keys only by name. Prefer dedicated hardware for the storage of keys. Prefer smart cards, tokens, PCMCIA cards, other removable media, laptops, or access-controlled single user desktops in that order. Only keys belonging to the system manager should be stored on a multi-user system.

Use firewalls to localize and raise the cost of attacks — The network should be compartmented with firewalls. These will localize attacks, prevent them from spreading, increase their cost, and reduce the value of success.

Firewalls should resist attack traffic in both directions. That is, each subnetwork should use a firewall to connect to any other. A subnet manager should be responsible for protecting both his own net and connecting nets from any attack traffic. A conservative firewall policy is indicated. That is, firewalls should permit only that traffic which is necessary for the intended applications and should hide all information about one net from the other.

Access control begins on the desktop — Access control should begin on the desktop and be composed up rather than begin on the mainframe and spread down. The issue here is to prevent the insertion of malicious programs more than to prevent the leakage of sensitive data.

APPENDIX I

PRINCIPLES OF GOOD DESIGN

Prefer broad solutions to point solutions — Prefer broad security solutions which work across the enterprise, multiple applications, multiple resources, and against multiple hazards to those which are limited to or specific to one of these. Such practices are almost always more efficient than a collection of mechanisms that are specific to applications, resources, or hazards.

Prefer end-to-end solutions to point-by-point solutions — Similarly, prefer encryption-based end-to-end security solutions that are independent of the network. The more sensitive the application and the more hostile the network, the greater this preference. Such solutions are more robust and more efficient than those that attempt to identify and fix all of the vulnerabilities between the ends of the path.

Design top-down, implement bottom up — Design by functional decomposition and successive refinement. Implement by composition from the bottom. Prefer early deployment of those services and servers which will be required over the long haul.

Do it right the first time — When building infrastructure, build for the ages. Do it right the first time. This strategy is more effective and more efficient than the "assess and patch" strategy that has been the approach to security in the past.

Prefer planning to fixing — Similarly, work by plan and design rather than by experimentation. Necessary experimentation should be carefully identified, contained, and controlled.

Prefer long term to short — Applications are becoming more sensitive and the environment more hostile. While one may consent to a plan that permits an early deployment of an application with a plan to deploy the

agreed upon security function by a date certain, do not take a "wait and see" approach.

Justify across the enterprise and time — Security measures must be justified across the entire enterprise and across the life of the application or the mechanism. By definition, security prefers predictable, regular, prevention costs to unpredictable, irregular, remedial costs. They should be justified across a time frame that is consistent with the normal frequency of the events that it addresses. Security measures are relatively easy to justify in this manner and difficult to justify locally or in the short term. In justifying security measures, weight should be given to the fact that applications are becoming more sensitive, more interoperable, and more important, and that the environment in which they operate is becoming less reliable and more hostile.

Provide economy of safe use — Using the system safely should require as little user effort as possible. For example, a user should have to log on only once per enterprise, per workstation, per day.

Provide consistent presentation and appearance — Security should look the same across the enterprise, i.e., applications, systems, and platforms.

Make control predictable and intuitive — Systems should be supportive. They should encapsulate the special knowledge required by the manager and user to operate them. They should make this information available to the manager and user at the time of use.

Provide ease of safe use — Design in such a way that it is easy to do the right thing. Penalties should be associated with doing the wrong thing (e.g., economy of log-on, user should have to log on only once per workstation, per enterprise, per day.)

Prefer mechanisms that are obvious as to their intent — Avoid mechanisms which are complex or obscure, which might cause error, or be used to conceal malice. For example, prefer online transactions, EDI, secure formatted E-mail, formatted E-mail, E-mail, and file transfer in that order. The online transaction is always obvious and predictable; for a given set of inputs one can predict the outputs. While the intent of a file transfer may be obvious, it is not necessarily so.

Encapsulate necessary special knowledge — Necessary special knowledge should be included in documentation or programs.

Prefer simplicity; hide complexity — For example, all other things being equal, simple mechanisms should be preferred to complex ones. Prefer a single mechanism to two, a single instance of a mechanism should be preferred to multiple ones. For example, prefer a single appearance of administration, like CA Unicenter Star to the appearance of all the systems

which may be hidden by it. Similarly, prefer a single point of administration such as SAM or RAS to Unicenter Star.

Place controls close to the resource — As a rule and all other things being equal, controls should be as close to the resource as possible. The closer to the resource, the more reliable the control, the more resistant to interference, and the more resistant to bypass. Controls should be server-based, rather than client-based.

Place operation of the control as close as possible to where the knowledge is and where the effect can be observed — For example, prefer controls operated by the owner of the resource, the manager of the group, the manager of the system, and the manager of the user rather than by a surrogate such as a security administrator. While a surrogate has the necessary special knowledge to operate the control, he knows less about the intent and the effect of the control. He cannot observe the effect and take corrective action. Surrogates are often compensation for a missing, complex, or poorly designed control.

Prefer localized control and data — As a general rule and all other things being equal, prefer solutions that place reliance on as few controls in as few places as possible. Not only are such solutions more effective and efficient but they are also more easily apprehended, comprehended, and demonstrated. Distribute function and data as required or indicated for performance, reliability, availability, and use or control.

APPENDIX III

GLOSSARY

Architecture — That part of design that deals with appearance, function, location, and materials.

Authentication — The testing or reconciliation of evidence; reconciliation of evidence of user identity

Cryptography — The art of secret writing; the translation of information from a public code to a secret one and back again for the purpose of limiting access to it to a select few.

Distinguished User Name — User's full name so qualified as to be unique within a population. Qualifiers may include such things as enterprise name, organization unit, date of birth, etc.

Enterprise — The largest unit of organization; usually associated with ownership. (In government it is associated with sovereignty or democratic election.)

Enterprise Data — Data which are defined, meaningful, and used across business functions or for the strategic purposes of the enterprise.

Name Space — All of the possible names in a domain, whether used or not.

PIN — Personal Identification Number; evidence of personal identity when used with another form.

APPENDIX IV

PRODUCTS OF INTEREST

Secure authentication products — A number of clients and servers share a protocol for secure authentication. These include Novell Netware, Windows NT and Oracle Secure Network Services. A choice of these may meet some of the architectural requirements.

Single sign-on products — Likewise, there are a number of products on the market that meet some or all of the requirements for limited or single sign-on. These include SSO DACS from Mergent International, NetView Access Services from IBM, and NetSP.

- SSO DACS (Mergent International) (see http://www.pilgrim.umass.edu/pub/security/mergent.html)
- NetView Access Services (IBM) (see http://www.can.ibm.com/mainframe/software/sysman/p32.html)
- SuperSession (see http://www.candle.com/product_info/solutions/SOLCL.HTM)
- NetSP (IBM) (see http://www.raleigh.ibm.com/dce/dcesso.html)

Authentication services — A number of standard services are available for authenticating evidence of user identity. These include:

- Ace Server (see http://www.securid.com/ID188.100543212874/Security/ACEdata.html)
- TACACS (see http://sunsite.auc.dk/RFC/rfc/rfc1492.html)
- Radius (see http://www.tribe.com/support/TribeLink/RADIUS/RADIUSpaper.html)

Administrative services — There are a number of products that are intended for creating and maintaining access control data across a distributed computing environment. These include:

- Security Administration Manager (SAM) (Schumann, AG) (see http://www.schumann-ag.de/deutsch/sam/sam.html)
- RAS (Technologic) (see http://www.technologic.com/RAS/rashome.html)
- Omniguard Enterprise Security Manager (Axent) (http://www.axent.com:80/axent/products/products.html)
- Mergent Domain DACS (http://www.mergent.com/html/products.html)
- RYO (“Roll yer own”)

Security Infrastructure: Basics of Intrusion Detection Systems

Ken M. Shaurette, CISSP, CISA, NSA, IAM

An intrusion detection system (IDS) inspects all inbound and outbound network activity. Using signature and system configuration, it can be set up to identify suspicious patterns that may indicate a network or system attack. Unusual patterns, or patterns that are known to generally be attack signatures, can signify someone attempting to break into or compromise a system. The IDS can be a hardware- or software-based security service that monitors and analyzes system events for the purpose of finding and providing real-time or near-real-time warning of events that are identified by the configuration to be attempts to access system resources in an unauthorized manner (see Exhibit 120.1).

There are many ways that an IDS can be categorized:

- *Misuse detection.* In misuse detection, the IDS analyzes the information it gathers and compares it to databases of attack signatures. To be effective, this type of IDS depends on attacks that have already been documented. Like many virus detection systems, misuse detection software is only as good as the databases of attack signatures that it can use to compare packets.
- *Anomaly detection.* In anomaly detection, a baseline, or normal, is established. This consists of things such as the state of the network's traffic load, breakdown, protocol, and typical packet size. With anomaly detection, sensors monitor network segments to compare their present state against the baseline in order to identify anomalies.
- *Network-based system.* In a network-based system, or NIDS, the IDS sensors evaluate the individual packets that are flowing through a network. The NIDS detects malicious packets that are designed by an attacker to be overlooked by the simplistic filtering rules of many firewalls.
- *Host-based system.* In a host-based system, the IDS examines the activity on each individual computer or host. The kinds of items that are evaluated include modifications to important system files, abnormal or excessive CPU activity, and misuse of root or administrative rights.
- *Passive system.* In a passive system, the IDS detects a potential security breach, logs the information, and signals an alert. No direct action is taken by the system.
- *Reactive system.* In a reactive system, the IDS can respond in several ways to the suspicious activity such as by logging a user off the system, closing down the connection, or even reprogramming the firewall to block network traffic from the suspected malicious source.

Defense-in-Depth

Hacking is so prevalent that it is wrong to assume that it will not happen. Similar to insurance statistics, "the longer we go without being compromised, the closer we are to an incident." You do not buy flood insurance

EXHIBIT 120.1 Definitions

To better understand the requirements and benefits of an intrusion detection system, it is important to understand and be able to differentiate between some key terms. Some of that terminology is outlined below.

Anomaly — This is a technique used for identifying intrusion. It consists of determining deviations from normal operations. First, normal activity is established that can be compared to current activity. When current activity varies sufficiently from previously set normal activity, an intrusion is assumed.

Audit Logs — Most operating systems can generate logs of activity, often referred to as audit logs. These logs can be used to obtain information about authorized and unauthorized activity on the system. Some systems generate insufficient or difficult-to-obtain information in their audit logs and are supplemented with third-party tools and utilities (i.e., Top Secret for MVS). The term *audit* as it pertains to these logs is generally associated with the process to assess the activity contained in the logs. Procedures should exist to archive the logs for future review, as well as review security violations in the logs for appropriateness. As it pertains to intrusion detection, an audit approach to detection is usually based on batch processing of after-the-fact data.

False Negative/Positive — These are the alerts that may not be desired. Not identifying an activity when it actually was an intrusion is classified as a false negative. Crying wolf on activity that is not an actual intrusion is a false positive.

File Integrity Checking (FIC) — File integrity checking employs a cryptographic mechanism to create a signature of each file to be monitored. The signature is stored for further use for matching against future signatures of the same file. When a mismatch occurs, the file has been modified or deleted; and it must be determined whether intrusive activity has occurred. FIC is valuable for establishing a "golden" unmodified version of critical software releases or system files.

Hackers — The popular press has established this term to refer to individuals who gain unauthorized access to computer systems for the purpose of stealing and corrupting data. It is used to describe a person who misuses someone else's computer or communications technology. Hackers maintain that the proper term for such individuals is *cracker*, and they reserve the term *hacker* for people who look around computer systems to learn with no intent to damage or disrupt.

Honeypot — A honeypot is a system or file designed to look like a real system or file. It is designed to be attractive to the attacker to learn their tools and methods. It can also be used to help track the hacker to determine their identity and to help find out vulnerabilities. It is used to help keep an attacker off of the real production systems.

Intrusion Detection Systems — By definition, an intrusion detection system consists of the process of detecting unauthorized use of, or attack on, a computer or network. An IDS is software or hardware that can detect such misuse. Attacks can come from the Internet, authorized insiders who misuse privileges, and insiders attempting to gain unauthorized privileges. There are basically two kinds of intrusion detection — host-based and network-based — described below. Some products have become hybrids that combine features of both types of intrusion detection.

IDS System Types

Host Based — This intrusion detection involves installing pieces of software on the host to be monitored. The software uses log files and system auditing agents as sources of data. It looks for potential malicious activity on a specific computer in which it is installed. It involves not only watching traffic in and out of the system but also integrity checking of the files and watching for suspicious processes and activity. There are two major types: application specific and OS specific.

OS Specific — Based on monitoring OS log files and audit trails.

Application Specific — Designed to monitor a specific application server such as a database server or Web server.

Network Based — This form of intrusion detection monitors and captures traffic (packets) on the network. It uses the traffic on the network segment as its data source. It involves monitoring the packets on the network as they pass by the intrusion detection sensor. A network-based IDS usually consists of several single-purpose hosts that "sniff" or capture network traffic at various points in the network and report on the attacks based on attack signatures.

Incident Response Plan — This is the plan that has been set up to identify what is to be done when a system is suspected of being compromised. It includes the formation of a team that will provide the follow-up on the incident and the processes that are necessary to capture forensic evidence for potential prosecution of any criminal activity.

Penetration Testing — Penetration testing is the act of exploiting known vulnerabilities of systems and users. It focuses on the security architecture, system configuration, and policies of a system. Penetration tests are often purchased as a service from third-party vendors to regularly test the environment and report findings. Companies can purchase the equivalent software used by these service organizations to perform the penetration tests themselves. Penetration testing and vulnerability analysis (see below) are often confused and used by people to mean the same thing, differentiated technically by whether you are attempting to penetrate (access) vs. simply reporting on vulnerabilities (test, for existence) such as the presence or absence of security-related patches. Some penetration test software can identify an apparent vulnerability and provide the option of attempting to exploit it for verification.

Vulnerability Scanner — This tool collects data and identifies potential problems on hosts and network components. Scanners are the tools often used to do a vulnerability analysis and detect system and network exposures. A scanner can identify such things as systems that do not have current patch levels, software and installation bugs, or poor configuration topology and protocols. A scanner does not enforce policy or fix exposures; it purely identifies and reports on them.

Vulnerability Analysis (also called vulnerability assessment) — Vulnerability analysis is the act of checking networks or hosts to determine if they are susceptible to attack, not attempting to exploit the vulnerability. The process consists of scanning servers or networks for known vulnerabilities or attack signatures to determine whether security mechanisms have been implemented with proper security configuration, or if poor security design can be identified. A form of vulnerability assessment is to use a product to scan sets of servers for exposures that it can detect.

in the 99th year before the 100-year flood. Although keeping hackers away from your company data is virtually impossible, much can be done to reduce vulnerabilities. Hacker have the easiest task; they need find only one open door. As the defenders, a company must check every lock, monitor every hallway. A company will implement a variety of sound security mechanisms such as authentication, firewalls, and access control; but there is still the potential that systems are unknowingly exposed to threats from employees and nonemployees (from inside and from outside). Layering security or using generally accepted practices for what is today often called a *defense-in-depth* requires more.

The complexity of the overall corporate environment and disparity of knowledge for security professionals subject implemented protection mechanisms to improper configuration, poor security design, or malicious misuse by trusted employees or vendor/contract personnel. Today's intrusions are attacks that exploit the vulnerabilities that are inherent in operating systems such as NT or UNIX. Vulnerabilities in network protocols and operating system utilities (i.e., telnet, FTP, traceroute, SNMP, SMTP, etc.) are used to perform unauthorized actions such as gaining system privileges, obtaining access to unauthorized accounts, or rerouting network traffic.

The hacker preys on systems that:

- Do not lock out users after unsuccessful log-in attempts
- Allow users to assign dictionary words as passwords
- Lack basic password content controls
- Define generic user IDs and assign password defaults that do not get changed
- Do not enforce password aging

Two-factor authentication is still expensive and slow to gain widespread adoption in large organizations. Using two factors — something you have and something you know — is one of the best methods to improve basic access control and thwart many simple intrusions.

A company that does not have a comprehensive view of where its network and system infrastructure stands in terms of security lacks the essentials to make informed decisions. This is something that should be resolved with the cooperation and support of all a company's IS technology areas. A baseline identifying gaps or places for improvement must be created. An IDS requirements proposal or any other security improvement proposal will require coordination with all infrastructure technicians to be effective. Companies need to have a dynamic information security infrastructure.

Although no organization relishes the idea of a system intrusion, there is some comfort that, with the right tools, it is possible to reduce exposures and vulnerabilities — but not necessarily eliminate all of the threats. There will always be some exposure in the environment. It is virtually impossible to remove them all and still have a functional system. However, measures to reduce impact of compromise can be put in place, such as incident response (what to do when), redundancy, traps (honeypots), prosecution (forensic evidence), and identification (logging). In order for it to be easier to track a hacker's activity, proper tools are needed to spot and plug vulnerabilities as well as to capture forensic evidence that can be used to prosecute the intruder. Intrusion detection systems are complex to implement, especially in a large environment. They can generate enormous quantities of data and require significant commitments in time to configure and manage properly. As such, an IDS has limitations that must be considered when undertaking selection and deployment. Even so, intrusion detection is a critical addition to an organization's security framework; but do not bother without also planning at least rudimentary incident response.

What to Look for in an IDS

Vendors are searching for the next generation, a predictive IDS — an IDS that can flag an attack without being burdened by the weight of its own logs and can operate worry-free with minimal false alarms. There are many shapes, sizes, and ways to implement an IDS. A rule-based model relies on preset rules and attack signatures to identify what to alert on and review. Anomaly-based systems build their own baselines over time by generating a database of usage patterns: when usage is outside the identified norm, an alert or alarm is set off. In addition, placement of an IDS is important especially when it comes to determining host- or network-based or the need for both.

A typical weakness in rule-based systems is that they require frequent updates and risk missing new or yet-unidentified attack patterns. An anomaly system attempts to solve this but tends to be plagued by false alarms. Often, companies install and maintain the host-based IDS on only production systems. Test hosts are often

the entry point for an attacker and, as such, require monitoring for intrusion as well. The next generation of IDS will correlate the fact that an intrusion has occurred, is occurring, or is likely to occur. It will use indicators and warnings, network monitoring and management data, known vulnerabilities, and threats to arrive at a recommended recovery process.

Some intrusion detection systems introduce the ability to have a real-time eye on what is happening on the network and operating systems. Many of the leading products offer similar features, so the choice of product can boil down to the fine details of how well the product will integrate into a company's environment as well as meet the company's incident response procedures. For example, one vendor's product may be a good fit for network detection in a switched network, but does not provide any host intrusion detection, or it misses traffic on other segments of the network.

For intrusion detection to be a useful tool, the network and all of the hosts under watch should have a known security state. A company must be first willing to apply patches for known vulnerabilities. Most of the vulnerability assessment tools can find the vulnerabilities, and these are what the intrusion detection tools monitor for exploitation. The anomaly-based system relies on the fact that most attacks fit a known profile. Usually this means that by the time the IDS system can detect an attack, the attack is preventable and patches are available. Security patches are a high priority among most if not all product vendors, and they appear rapidly if they are actively exploited. Therefore, it might be more effective to first discover the security posture of the network and hosts, bring them up to a base level of security, and identify maintenance procedures to stay at that desired level of security. Once that is accomplished, IDS can more effectively contribute to the overall security of the environment. It becomes a layer of the defense that has value.

Getting Ready

Although many organizations are not aware of them, there are laws to address intrusion and hacking. There are an even greater number of organizations that are not prepared to take advantage of the laws. For example, the Federal Computer Fraud and Abuse Act was updated in 1996 to reflect problems such as viruses sent via e-mail (Melissa, Bubble-Boy). In fact, the law was used to help prosecute the Melissa virus author. In addition, this same law addresses crimes of unauthorized access to any computer system, which would include nonvirus-related intrusions. DoS (denial-of-service) attacks have become very common, but they are no joking matter. In the United States, they can be a serious federal crime under the National Infrastructure Protection Act of 1996 with penalties that include years of imprisonment. Many countries have similar laws. For more information on computer crimes, refer to www.usdoj.gov/criminal/cybercrime/compcrime.html.

Laws are of little help if a company is unable to recognize an event is occurring, react to it, and produce forensic evidence of the crime. Forensic computer evidence is required for prosecution of a crime. Not every system log is appropriate as forensic evidence. Logs must maintain very specific qualities and should document system activity and log-in/log-out type activity for all computers on the network. These allow a prosecutor to identify who has accessed what and when. Also important is the process for gathering and protecting any collected information (the chain of custody) in order for the information to retain forensic value. This process should be part of a comprehensive incident response plan. IDS without intrusion response, including an incident response plan, essentially reduces its value. The IDS effectively becomes merely another set of unused log data.

Even more important than prosecution as a reason for maintaining forensic data, the company's network technicians can use the forensic evidence to determine how a hacker gained access in order to close the hole. The data can also be necessary to determine what was done when the attacker was inside the network. It can be used to help mitigate the damage. In many cases, companies are still rarely interested in the expense, effort, and publicity involved in prosecution.

A company must perform a thorough requirements analysis before selecting an intrusion detection system strategy and product. A return on investment (ROI) can be difficult to calculate; but in any case, costs and benefits need to be identified and weighted. Refer to Exhibit 120.2 for a discussion on cost/benefit analyses (CBA) and ROI. A solution must be compatible with the organization's network infrastructure, host servers, and overall security philosophy and security policies. There can be a big variance of resource (especially human) requirements among the different tools and methodologies. Both network and server teams must work together to analyze the status of an organization's security posture. (i.e., systems not patched for known vulnerabilities, weak password schemes for access control, poor control over root or administrative access). There may be

EXHIBIT 120.2 Cost/Benefit Analysis — Return on Investment

Risk Management to Improve Enterprise Security Infrastructure

Effective protection of information assets identifies the information used by an area and assigns primary responsibility for its protection to the management of the respective functional area that the data supports. These functional area managers can accept the risk to data that belongs to them, but they cannot accept exposures that put the data of other managers at risk.

Every asset has value. Performing an analysis of business assets — and the impact of any loss or damage resulting from the loss — is necessary to determine the benefits of any actual dollar or human time expenditures to improve the security infrastructure. A formal quantitative risk analysis is not necessary, but generally assessing the risks and taking actions to manage them can pay dividends. It will never be possible to eliminate all risks; the trick is to manage them. Sometimes it may be desirable to accept the risks, but it is a must to identify acceptance criteria. The most difficult part of any quantifiable risk management is assigning value and annual loss expectancy (ALE) to intangible assets like a customer's lost confidence, potential embarrassment to the company, or various legal liabilities. To provide a risk analysis, a company must consider two primary questions.

1. What is the probability that something will go wrong (*probability* of one event)?
2. What is the cost if something does go wrong (the *exposure* of one event)?

Risk is determined by getting answers to the above questions for various vulnerabilities and assessing the probability and impact of the vulnerability on each risk.

A quantifiable way to determine the risk and justify the cost associated with purchase of an IDS or any other security software or costs associated with mitigating risks is as follows:

- Risk becomes the probability times the exposure (risk = probability × exposure). Cost justification becomes the risk minus the cost to mitigate the vulnerabilities (justification = risk minus cost of security solution). If the justification is a positive number, then it is costjustified. For example, if the potential loss (exposure) on a system is $100,000, and the chance that the loss will be realized (probability) is about once in every ten years, the annual frequency rate (AFR) would be 1/10 (0.10). The risk (ALE) would be $100,000 × 0.10 = $10,000 per year. If the cost is $5000 to minimize the risk by purchasing security software, the cost justification would be $10,000 less $5000 = $5000, or payback in six months.
- Using a less quantifiable method, it would be possible to assign baseline security measures used in other similar sized companies, including other companies in the same industry. Setting levels of due diligence that are accepted in the industry would then require implementation of controls that are already proven, generally used, and founded on the "standard of due care." For example, for illustration purposes, say that 70 percent of other companies the size of your company are implementing intrusion detection systems and creating incident response teams. Management would be expected to provide similar controls as a "standard of due care." Unless it can be clearly proven that implementation costs of such measures are above the company's expected risks and loss expectancies, management would be expected to provide due diligence in purchasing and implementing similar controls.

many areas of basic information security infrastructure that require attention before IDS cost can be justified. The evaluations could indicate that simply selecting and implementing another security technology (IDS) is wasted money. A company may already own technologies that are not fully implemented or properly supported that could provide compensating controls and for which cost could be more easily justified.

When it comes to a comprehensive IDS, integration between server and network environments is critical. A simple decision such as whether the same tool should provide both network and host IDS is critical in the selection process and eliminates many tools from consideration that are unable to provide both. Even simply identifying integration requirements between operating systems will place limitations and requirements on technology selection. Does a company want to simply detect an intrusion, or is it desirable to also track the activity such as in a honeypot? Honeypots are designed to be compromised by an attacker. Once compromised, they can be used for a variety of purposes, such as an alert, an intrusion detection mechanism, or as a deception. Honeypots were first discussed in a couple of very good books: Cliff Stoll's *Cuckoo's Egg*[1] and Bill Cheswick's *An Evening with Berferd*.[2] These two reviews used a capture-type technology to gather an intruder's sessions. The sessions were then monitored in detail to determine what the intruder was doing.

Steps for Protecting Systems

To continue improving the process of protecting the company systems, three fundamental actions are required.

Action 1

The company must demonstrate a willingness to commit resources (money, people, and time) to patching the basic vulnerabilities in current systems and networks as well as prioritize security for networks and hosts.

Making use of an IDS goes way beyond simply installing the software and configuring the sensors and monitors. It means having necessary resources, both technical and human, to customize, react, monitor, and correct. Nearly all systems should meet basic levels of security protection. Simple standards such as password aging, improved content controls, and elimination of accounts with fixed passwords or default passwords are a step in that direction. It is also critical that all network and operating systems have current security patches installed to address known vulnerabilities and that maintenance procedures exist to keep systems updated as new alerts and vulnerabilities are found.

Action 2

All systems and network administrators must demonstrate the security skills and focus to eliminate basic vulnerabilities by maintaining and designing basic secure systems — which, poorly done, account for the majority of attacks.

Nearly all system and network administrators want to know how to secure their systems, but in many cases they have never received actual security training or been given security as a priority in their system design. Often, security is never identified as a critical part of job responsibility. It should be included in employee job descriptions and referenced during employee performance reviews. However, before this can be used as a performance review measurement, management must provide staff with opportunity (time away from office) and the priority to make security training part of job position expectations. Training should be made available in such topics as system security exposures, vulnerability testing, common attacks and solutions, firewall design and configuration, as well as other general security skills. For example, the effectiveness of any selected IDS tool is dependent on who monitors the console — a skilled security expert or an inexperienced computer operator. Even a fairly seasoned security expert may not know how to respond to every alert.

Action 3

Once security expectations are in place, tasks must be given proper emphasis. Staff members must recognize that security is part of their job and that they must remain properly trained in security. Security training should receive the same attention as the training they receive on the system and network technologies they support. Security must be given similar time and resources as other aspects of the job, especially defining and following maintenance procedures so that systems remain updated and secure.

Network and system administrators will need to stay current with the technology they support. Often they will attend training to stay current, but not to understand security because it is not sufficiently recognized as important to their job responsibilities.

These tasks will not stop all attacks but they will make a company a lot less inviting to any criminal looking for easy pickings. Typical attackers first case their target. When they come knocking, encourage them to go knocking on your neighbor's door — someone who has not put security measures in place. Putting the fundamentals in place to monitor and maintain the systems will discourage and prevent common external intrusion attempts as well as reduce internal incidents.

Types of Intrusion

Intrusions can be categorized into two main classes:

1. *Misuse intrusions* are well-defined attacks on known weak points of a system. They can be detected by watching for certain actions performed on certain objects. A set of rules determines what is considered misuse.

2. *Anomaly intrusions* are based on the observation of the deviation from normal system activity. An anomaly is detected by building a profile of the system monitored, followed by using some methodology for detecting significant deviations from this profile.

Misuse intrusions can be detected by doing pattern matching on audit-trail information because they follow well-defined patterns. For example, examining log messages of password failures can catch an attempt to log on or set user ID to root from unauthorized accounts or addresses.

Anomalous intrusions are a bit more difficult to identify. The first difficulty is identifying what is considered normal system activity. The best IDS is able to learn system and network traffic and correlate it to the time of day, day of week, and recognize changes. Exploitation of a system's vulnerabilities usually involves the hacker performing abnormal use of the system; therefore, certain kinds of system activity would be detected from normal patterns of system usage and flagged as potential intrusion situations. To detect an anomaly intrusion, it is necessary to observe significant deviations from the normal system behavior from the baseline set in a *profile*. A quantitative measure of normal activity can be identified over a period of time by measuring the daily activity of a system or network. For example, the average or a range of normal CPU activity can be measured and matched against daily activity. Significant variations in the number of network connections, an increase or decrease in average number of processes running in the system per minute, or a sudden sustained spike in CPU utilization when it does not normally occur could signify intrusion activity. Each anomaly or deviation may signal the symptoms of a possible intrusion. The challenge is mining the captured data and correlating one element of data to other captured data and determining what the two together might signify.

Characteristics of a Good Intrusion Detection System

There are several issues an IDS should address. Regardless of the mechanism on which it is based, it should include the following:

- Run continually with minimal human interaction. It should run in the background. The internal workings should be able to be examined from outside, so it is not a black box.
- Fault tolerance is necessary so that it can survive a system crash and not require that its knowledge base be rebuilt at restart.
- It must be difficult to sabotage. The system should be self-healing in the sense that it should be able to monitor itself for suspicious activities that might signify attempts to weaken the detection mechanism or shut it off.
- Performance is critical. If it creates performance problems, it will not get used.
- Deviations from normal behavior need to be observed.
- The IDS must be easy to configure to the system it is monitoring. Every system has a different usage pattern, and the defense mechanism should adapt easily to these patterns.
- It should be like a chameleon, adapting to its environment and staying current with the system as it changes — new applications added, upgrades, and any other modifications. The IDS must adapt to the changes of the system.
- To be effective, an IDS must have built-in defense mechanisms, and the environment around it should be hardened to make it difficult to fool.

Watch Out for Potential Network IDS Problems

ACIRI (AT&T Center for Internet Research at the International Computer Science Institute) does research on Internet architecture and related networking issues. Research has identified that a problem for a NIDS is its ability to detect a skilled attacker who desires to evade detection by exploiting the uncertainty or ambiguity in the traffic's data stream. The ability to address this problem introduces a network-forwarding element called a *traffic normalizer*. The normalizer needs to sit directly in the path of traffic coming into a site. Its purpose is to modify the packet stream to eliminate potential ambiguities before the monitor sees the traffic. Doing this removes evasion opportunities. There are a number of tradeoffs in designing a normalizer. Mark Handley and Vern Paxson discuss these in more detail in their paper titled "*Network Intrusion Detection: Evasion, Traffic Normalization, and End-to-End Protocol Semantics*." In the paper they emphasize the important question pertaining to the degree to which normalizations can undermine end-to-end protocol semantics. Also discussed

are the key practical issues of "cold start" and attacks on the normalizer. The paper shows how to develop a methodology for systematically examining the ambiguities present in a protocol based on walking the protocol's header. Refer to the notes at the end of this chapter to find more information on the paper.

Methodology for Choosing and Implementing an IDS

To choose the best IDS, evaluation is necessary of how well the tool can provide recognition of the two main classes of intrusion. Specific steps should be followed to make the best selection. Some of the steps are:

1. Form a team representing impacted areas, including network and server teams.
2. Identify a matrix of intrusion detection requirements and prioritize, including platform requirements, detection methodology (statistical or real-time), cost, resource commitments, etc.
3. Determine preferences for purchasing IDS software versus using a managed service.
4. Determine if the same product should provide both network- and host-based IDS.
5. Formulate questions that need to be answered about each product.
6. Diagram the network to understand what hosts, subnets, routers, gateways, and other network devices are a part of the infrastructure.
7. Establish priority for security actions such as patching known vulnerabilities.
8. Identify IDS sensor locations (critical systems and network segments).
9. Identify and establish monitoring and maintenance policies and procedures.
10. Create an intrusion response plan, including creation of an incident response team.

Suspicion of Compromise

Before doing anything, *define an incident*. Incident handling can be very tricky, politically charged, and sensitive. The IDS can flag an incident, but next is determining what first-level support will do when an alert is received or identifying what to do in case of a *real* incident. This is critical to the system reaching its full value.

An IDS can be configured to take an action based on the different characteristics of the types of alerts, their severity, and the targeted host. In some cases it may be necessary to handle an incident like a potential crime. The evidence must be preserved similar to a police crime scene. Like a police crime scene that is taped off to prevent evidence contamination, any logs that prove unauthorized activity and what was actually done must be preserved. Inappropriate actions by anyone involved can cause the loss of valuable forensic evidence, perhaps even tip off the intruder, and cause a bigger problem. An incident response program can be critical to proper actions and provide consistency when reacting to intrusion activity. Without documented procedures, the system and network administrators risk taking the wrong actions when trying to fix what might be broken and contaminating or even eliminating evidence of the incident.

The following outlines considerations for incident response:

- Scream loudly and get hysterical — your system has been compromised.
- Brew up a few pots of strong coffee.
- Actually, you need to remain calm — do not hurry.
- Create a documented incident handling procedure, including options if possible.
- Notify management and legal authorities as outlined in the incident response plan.
- Apply the need-to-know security principle — only inform those personnel with a need to know. The fewer the people who are informed about the incident, the better; but be sure to prevent rumors by supplying enough information to the right people.
- Use out-of-band communications and avoid e-mail and other network-based communication channels — they may be compromised.
- Determine the items you need to preserve as forensic evidence (i.e., IDS log files, attacked system's hard drive, snapshot of system memory, and protection and safety logs).
- Take good notes — the notes may be needed as evidence in a court of law. Relying on your memory is not a good idea. This will be a stressful time, and facts may become fuzzy after everything calms down.
- Back up the systems; collect forensic evidence and protect it from modification. Ensure a chain of custody for the information.

- Contain the problem and pull the network cable? Is shutting off the system appropriate at this point? Is rebooting the system appropriate? It might not be!
- Eradicate the problem and get back to business.
- Use what has been learned from the incident to apply modifications to the process and improve the incident response methodology for future situations.

Summary

Before doing anything, define an incident. Know what you are detecting so that you know what you are handling.

Every year thousands of computers are illegally accessed because of weak passwords. How many companies have users who are guilty of any of the following?

- Writing down a password on a sticky note placed on or near their computer
- Using a word found in a dictionary.
- Using a word from a dictionary followed by two or less numerics
- Using the names of people, places, pets, or other common items
- Sharing their password with someone else
- Using the same password for more than one account, and for an extended period of time
- Using the default password provided by the vendor

Chances are, like the majority of companies, the answer is yes to one or more of the above. This is a more basic flaw in overall security infrastructure and requires attention. The problem is, hackers are aware of these problems as well and target those who do not take the correct precautions. This makes systems very vulnerable, and more than simple technology is necessary to correct these problems.

If a company's current security posture (infrastructure) is unacceptable, it must be improved for additional security technology to provide much added benefit. Performing an assessment of the present security posture provides the information necessary to adequately determine a cost–benefit analysis or return on investment. Implementing all the best technology does not eliminate the basic exposure introduced by the basic problem described above. A team should be created to identify current protection mechanisms as well as other measures that could be taken to improve overall security infrastructure for the company. Immediate benefits could be realized by enhancement to procedures, security awareness, and better implementation of existing products (access control and password content) with minimum investment. The overall security improvement assessment could include a project to select and implement an intrusion detection system (IDS) and incident response (IR) programs. IDS without IR is essentially worthless. First steps are for management to identify a team to look into necessary security infrastructure improvements. From this team, recommendations will be made for security improvements and the requirements against which products can be judged to help reduce security vulnerabilities while being an enabler of company business objectives.

Now that you have the IDS deployed and working properly, it is possible to kick back and relax. Not yet — in fact, the cycle has just begun. IDS, although a critical component of the defense-in-depth for an organization's security infrastructure, is just that — only a component.

Systems Integrity Engineering

Don Evans

INTRODUCTION

The primary goal of any enterprise-wide security program is to support user communities by providing cost-effective protection to information system resources at appropriate levels of integrity, availability, and confidentiality without impacting productivity, innovation, and creativity in advancing technology within the corporation's overall objectives.

Ideally, information systems security enables management to have confidence that their computational systems will provide the information requested and expected, while denying accessibility to those who have no right to it. The analysis of incidents resulting in damage to information systems show that most losses were still due to errors or omissions by authorized users, actions of disgruntled employees, and an increase in external penetrations of systems by outsiders. Traditional controls are normally inadequate in these cases or are focused on the wrong threat, resulting in the exposure of a vulnerability.

There are so many factors influencing security in today's complex computing environments that a structured approach to managing information resources and associated risk(s) is essential. New requirements for using distributed processing capabilities introduces the need to change the way integrity, reliability, and security are applied across diverse, cooperative information systems environments. The demand for high-integrity systems that ensure a sustained level of confidence and consistency must be instituted at the inception of a system design, implementation, or change. The formal process for managing security must be linked intrinsically to the existing processes for designing, delivering, operating, and modifying systems to achieve this objective.

Unfortunately, the prevalent attitude toward security by management and even some security personnel is that the confidentiality of data is still the primary security issue. That is, physical isolation, access control,

audit, and sometimes encryption are the security tools most needed. While data confidentiality may be an issue in some cases, it is usually more important that data and/or process integrity and availability be assured. Integrity and availability must be addressed as well as ensuring that the total security capability keeps current with technology advancements that make it easier to share geographically distributed computing resources.

As the complexity of today's distributed computing environments continues to evolve independently, with respect to geographical and technological barriers, the demand for a dynamic, synergistically integrated, and comprehensive information systems security control methodology increases.

Business environments have introduced significant opportunity for process reengineering, interdisciplinary synergism, increased productivity, profitability, and continuous improvement. With each introduction of a new information technology, there exists the potential for an increased number of threats, vulnerabilities, and risk. This is the added cost of doing business. These costs focus on systems failure and loss of critical data. These costs may be too great to recover with respect to mission- and/or life-critical systems. Enterprise-wide security programs, therefore, must be integrated into a systems integrity engineering discipline carried out at each level of the organization and permeated throughout the organization.

The purpose of this document is to provide an understanding of risk accountability issues and management's responsibility for exercising due care and due diligence in developing and protecting enterprise-wide, interoperable information resources as a synergistic organizational function.

UNDERSTANDING DISTRIBUTED PROCESSING CONCEPTS AND CORRESPONDING SECURITY-RELEVANT ISSUES

Distributed systems are an organized collection of programs, data, and processes implemented in software, firmware, or hardware that are specifically designed to integrate separate operational systems into a single, logical information system infrastructure. This structure provides the flexibility of segmenting management control into domains or nodes of processing that are physically required or are operationally more effective and efficient, while satisfying the overall goals of the information processing community.

The operational environment for distributed systems is a combination of multiple separate environments that may individually or collectively store and process information. The controls over each operational environment must be based on a common integrated set of security controls that constitute the foundation for overall information security of the distributed systems.

The foundation of security-relevant requirements for distributed systems is derived from the requirements specified in the following areas:

- Operating systems and support software,
- Information access control,
- Application software development and maintenance,
- Application controls and security,
- Telecommunications,
- Satisfaction of the need for cost-effective business objectives.

Distributed systems must also address a common set of security practices, procedures, and processes because of the interaction of separate operational environments which include:

1. A multiplicity of components, including both physical and logical resources, that can be assigned freely to specific tasks on a dynamic basis. (Homogeneity of physical resources is not essential.) However, in general, there should be more than one resource capable of supporting any given task to maintain referential integrity of the information and the complexity of the connectivity interrelationships of heteromorphic processing environments.
2. A physical distribution of these physical and logical components intercommunicating through a network. Within the distributed system environment, a network is an information transmission mechanism that uses a cooperative protocol to control the transfer of information.
3. A high-level operating system that unifies and integrates the control of the distribution components. This high-level operating system may not exist as distinctly identifiable blocks of code. It may be merely a set of specifications or an overall, integrating philosophy incorporated into the design of the operating system for each component.
4. System transparency, permitting services to be requested by name only. The resource to provide the service may not need to be uniquely identified.
5. Cooperative autonomy, characterizing the operation as an interaction of both physical and logical resources.

These five criteria form an indivisible set that defines a fully distributed system. The degree of distribution of a system depends upon the distribution of data, programs, physical hardware location, and control. This is depicted in Exhibit 1.

To simplify this three-dimensional continuum, distributed systems may be classified into three nonoverlapping parts of the continuum, ranging from simple interactions to complex interactions of the environments. The three types of distributed systems, illustrated in Exhibit 1, are

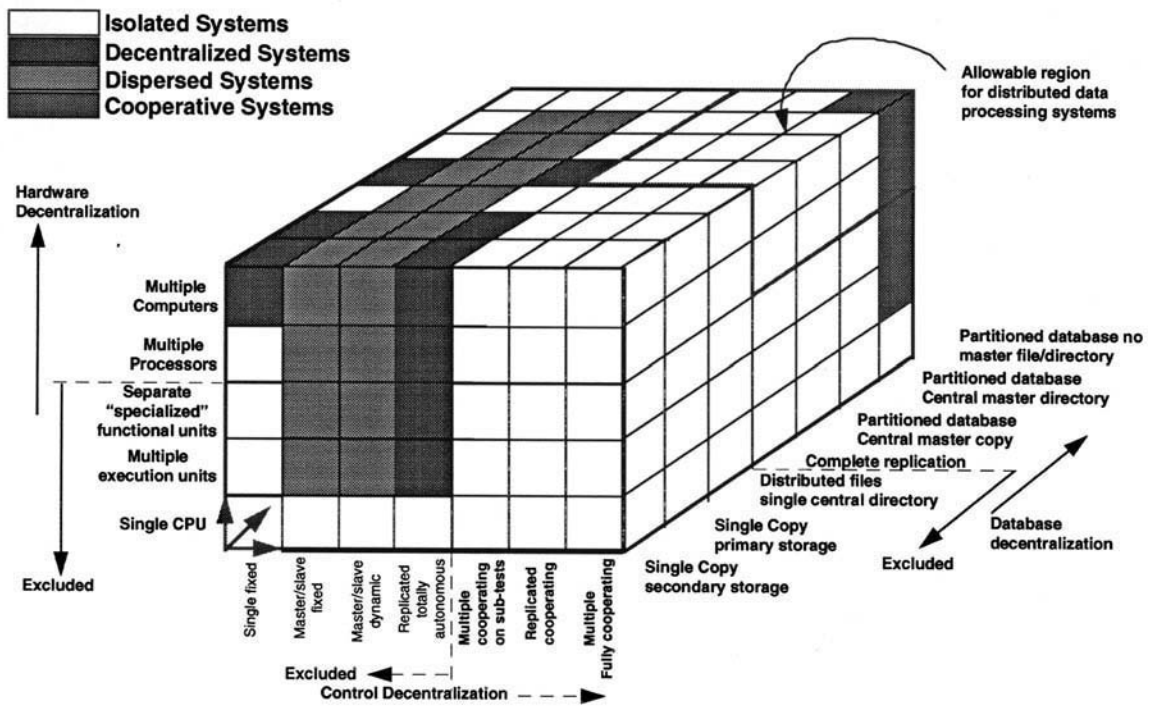

Exhibit 1. Distribution Continuum

- Decentralized systems
- Dispersed systems
- Interoperable or Cooperative systems

Decentralized systems are characterized by a group of related but not necessarily interconnected platforms running independent copies of the same (or equivalent) applications with independent copies of data. The current state of the group is not automatically maintained. Instead of a single (central) processor with multiple users, the decentralized system has multiple (distributed) processors with single or multiple users (Exhibit 2). The processors do not necessarily communicate electronically. This characteristic prevents the system from automatically maintaining the state of the distributed system and is the primary distinction between the decentralized model and the other two distributed system models.

Dispersed systems (Exhibit 3) are characterized by a group of related, interconnected platforms in which either the data or the software (but not both) is centralized. A dispersed system offers advantages over centralized systems in its capabilities to:

- Accommodate organizational change
- More effectively deploy resources through resource sharing
- Improve performance through intelligent matching of applications, media, access schemes, and grouping of related members
- Lower risk of overall system failure due to hardware failures

The dispersed system may have centralized data with dispersed processors (as in a system with a central file server) or centralized processing with dispersed data (as with remote transaction collection and central data processing). Dispersed systems may exist on multiple platforms in a single location or on platforms in multiple locations. The hardware may be homogeneous or heterogeneous.

The processors communicate electronically, usually to request or provide data. This characteristic allows the system to automatically maintain a single, collective, real-time state of the distributed system.

Interoperable or cooperative systems (Exhibit 4) are characterized by a group of related, interconnected platforms in which both the data and the software are distributed throughout the system. The interoperable system differs from the dispersed system by eliminating the dependency of centralized data or centralized applications. The interoperable system offers the same advantages over centralized systems as the dispersed system. The difference is in the degree to which the system can cooperatively exploit these advantages.

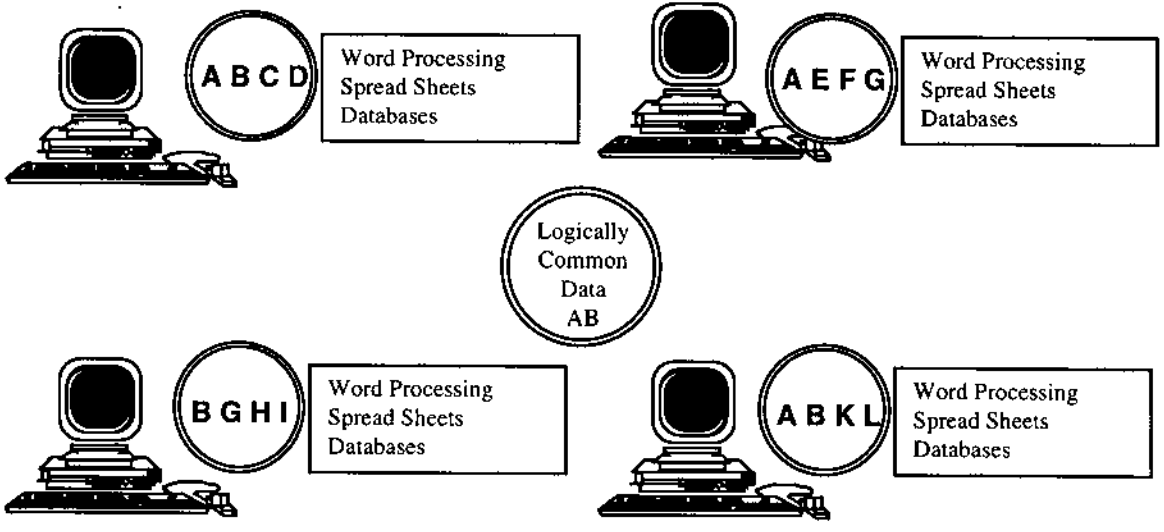

Exhibit 2. Decentralized Systems

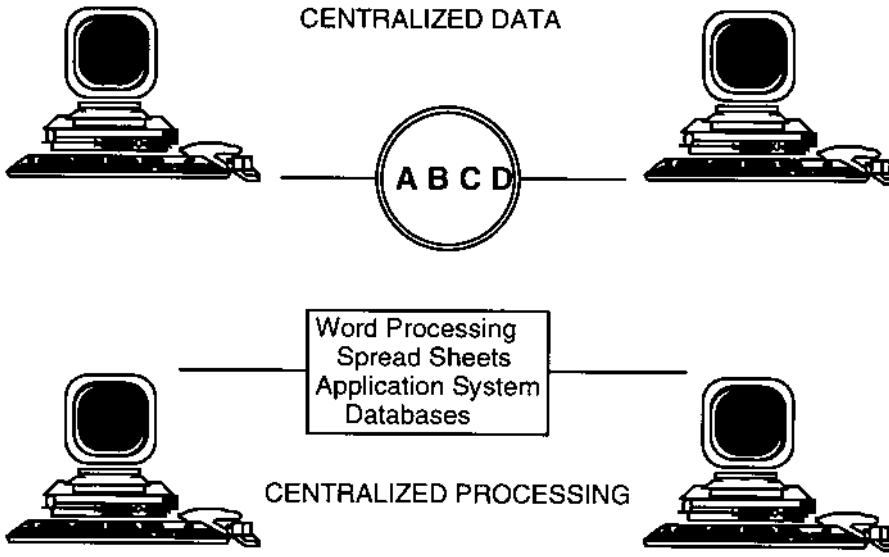

Exhibit 3. Dispersed Systems

Additionally, an interoperable system offers advantages over centralized systems in its capabilities to:

- Combine data from dissimilar hardware platforms
- Independently execute and test each component

Interoperable systems represent the highest level of the distributed processing continuum. In a fully interoperable system, each component is independent of all other components. Interfaces and data dependencies are implemented as messaging schemes or as data objects (consisting of data and operations). Interoperable systems may exist on multiple platforms in a single location, on platforms in multiple locations, or on multiple networks in multiple locations.

The hardware may be homogeneous or heterogeneous. The processors communicate electronically. Each component automatically maintains its own state and can provide its state on request. The existence of multiple states is the primary discriminant between the interoperable model and the other two distributed system models.

A distributed system may include characteristics of each of the three models described above. The application of security-relevant requirements from each model is necessary to build a complete security requirements set.

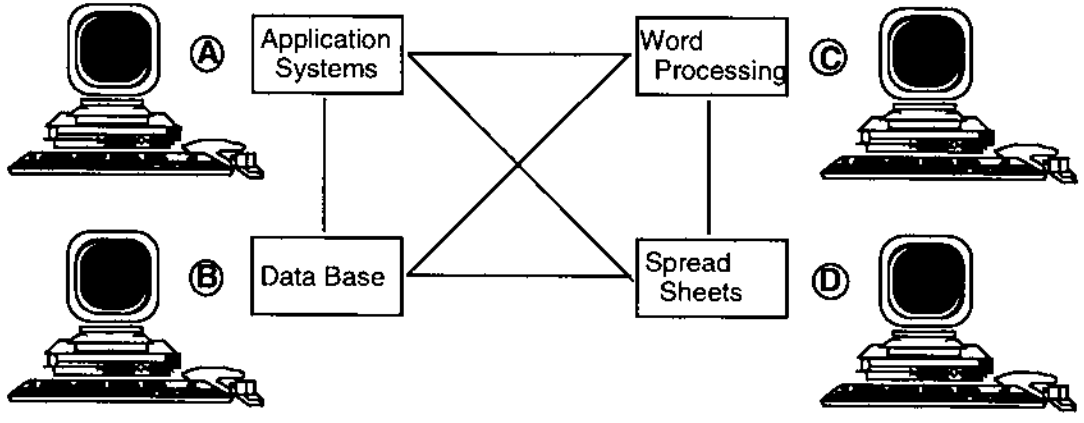

Exhibit 4. Interoperable Systems

Distributed Systems Integrity Control Issues

A system of controls for distributed (i.e., decentralized, dispersed, and cooperative) systems will need to be developed that addresses:

- Multisystem configuration management
- Establishing and maintaining connectivity
- Prevention of exploitation of connectivity
- Multilevel, multisite information transfers
- Contingency planning, backup, and recovery

Distributed systems are depicted in the three-dimensional continuum (Exhibit 5) represented by the simplest decentralized case in one bottom corner (centralized remote processing) and the most complicated cooperative case (fully interoperable system of systems) in the opposite top corner. Decentralized systems represent a stepwise departure from centralized processing and isolated system(s) controls.

For any two related systems, there generally exists some data common to the two systems. The larger the amount of common data and the more dynamic the data are, the more vulnerable the decentralized system is to integrity loss. Configuration management of the changes to common data, applications, and hardware can reduce the vulnerability to integrity loss. In addition, the processes for updating common data, applications, and hardware require controls to ensure that the approved changes and only the approved changes are received and installed.

Analysis from multiple systems may produce erroneous or tainted results caused by the inability to synchronize the data. If any correlation of time-based transactions from different platforms is required, these systems require either a synchronous time source or manual synchronization and periodic verification.

In implementations of a decentralized system where two identical (or equivalent) software applications and/or hardware platforms exist, users must periodically switch processing roles as part of planning, training, and disaster preparedness. The following suggestions are provided as guidelines for establishing a baseline set of controls that ensure high integrity and minimal risk accountability for managing distributed systems.

All common data, hardware, software, and each component system should be identified formally in a Distributed System Configuration Management (CM) Plan. Distributed System CM Plans must document system-level policies, standards and procedures, responsibilities, and requirements. For distributed systems where the nodes are not located at one site or where the components are not covered in a single CM Plan, management will need to appoint a Configuration Control Authority for all distributed

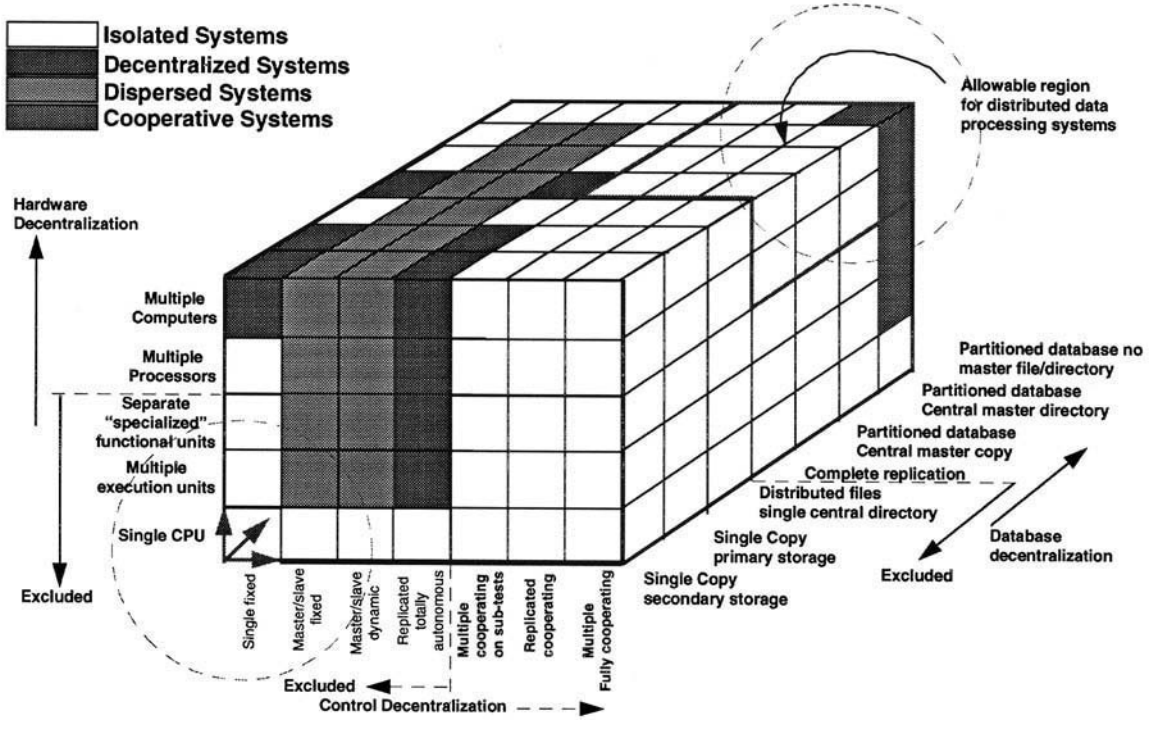

Exhibit 5. Decentralized Processing Complexities

system-level changes. Management must ensure that sufficient resources and personnel are provided for the Configuration Control Authority to manage distributed system-level changes. Additionally,

1. Site-level CM Plans should be hierarchically subordinate to distributed system-level CM Plans.
2. All changes at the site level need to be reviewed by a site Configuration Control Authority for potential impact at the distributed system level.
3. The Distributed System CM Plan should describe the distribution controls and audit checks that are used to ensure that the common data and applications are the same version across the decentralized system.

For distributed systems where the managers of components do not report to (are not managed by) the same organization, the Configuration Control Authority needs to enter into a more formal agreement with each of the managers. A memorandum of agreement should be generated that establishes policies, standards and procedures, roles, responsibilities, and requirements for the total system. At a minimum a memorandum of agreement must identify, document, and provide a detailed description of the information to be provided from each component and the recipient of that information. It must also provide a description of each level of sensitivity or criticality for each data item, delineating the levels of sensitivity or criticality at which the data will be used, and the process for moving each data item to each operation level.

All memoranda of agreement should include a description by component and interface, of all security countermeasures required of each component. This description should focus on:

1. Security countermeasures to ensure confidentiality, integrity, and availability during the transfer of data and applications software.
2. Access control countermeasures to ensure that the transfer process is not used to gain unauthorized access to each component.
3. Countermeasures to ensure that the transferred data and applications are received only by the intended receiver (for data and applications requiring a high level of confidentiality).
4. A description of the overall distributed system security policy.

It is essential to include a detailed description of the transfer process between each component, identifying:

1. A description of any physical and media controls to be used.
2. Electronic transfers (bulletin board systems, communications software not integrated with the decentralized component) must include a description of the software used.
3. The software communications protocol and standards used.
4. Encryption methods and devices used.

5. The security features and limitations of the communications application used.
6. All hardware requirements, hardware settings, and protocols used.
7. Assignment of all decentralized system-level responsibilities and authorities, including network management, performance monitoring and tuning, training, training plan development and management, resource configuration management, software and data configuration management, system access control and audit management.
8. A description of all required components or site-level security roles and responsibilities, including resource, software, and data configuration management; access control; site security management; security awareness training and training management; as well as verification and validation of security relevant issues and audit control management.
9. An identification and needs assessment of the user community, including the levels of sensitivity or functional criticality of the information expected to be created, maintained, accessed, shared, or disseminated in or by the decentralized system.
10. A description of the information required in each component's audit trail and how the audit trail tasks will be divided among the components.
11. Any results of risk assessments and how controls mitigate perceived risks.

For distributed systems managed under a single organization, the Distributed System CM Plan must identify, define, and substantiate distributed system-level policies, standards and procedures, roles, responsibilities, and requirements for the interchange of data, as well as for configuration management at the distributed system-level in accordance with corporate Configuration Management guidelines.

Systems should segregate data and applications according to their organizational and/or functional sensitivity or criticality levels. Transitions between levels should be explicitly controlled. The process for transitioning data or applications from one sensitivity level to another, as well as from office systems and or end-user systems to other systems, must be formally documented and well understood. The transition process must include measures to increase the integrity and reliability of data and/or applications moving from less stringent requirements. Data must not be transitioned from a higher sensitivity level to a lower level that provides insufficient sensitivity protection. Additional application software may need to be developed to remove sensitive data when those data are transitioned to a level that cannot provide adequate protection. Application software must increase and ensure the integrity and reliability required when transitioning data from a component of lower reliability and integrity. A

formal process of transformation, testing, and certification must be developed for each transition.

For systems requiring a high level of integrity, techniques such as digital signature or digital envelope may be used to ensure that the data are not changed in transit. The digital envelope technique will provide a means for implementing the principle of least privilege or need-to-know concept.

Dispersed Distributed Systems Integrity Control Issues and Concerns

The following suggestions are provided as additional guidance for establishing a baseline set of controls that ensure minimal risk accountability encountered in managing the more complex environments of dispersed and/or interoperable systems. Additional controls for dispersed and/or interoperable systems will need to be developed addressing:

- Multisystem configuration management.
- Establishing and maintaining connectivity.
- Multilevel, multisite information transfers.
- Contingency planning, backup, and recovery.
- Maintaining multisystem data and referential integrity.
- Attaining a graceful degradation capability.
- Hardware maintenance.

Change control should be applied to dispersed or interoperable system level data, applications, and hardware to reduce the vulnerability to integrity loss. Periodic verification should be performed to ensure that the common data and applications are the correct version. Techniques (such as digital signature) may be used to assure applications and common data are at their expected version levels.

The functional equivalence claimed between two different software applications executing on different platforms will need to be closely examined during the procurement process due to the possibility of nonhomogeneous hardware being used in the dispersed system.

Network management personnel must maintain connectivity by allowing only authorized, authenticated users to log on, responding to access violation alarms, and auditing access logs for evidence of unauthorized access attempts.

Systems requiring the highest levels of availability must use error correction software during transmissions and redundant transmission of data down multiple communications paths to ensure that at least one is received. Transmission along multiple paths may be simultaneous, as in a broadcast mode, or may be an automatic response to failure detection or performance degradation beyond a predetermined threshold. An automatic response can be implemented to protect specific transmission lines,

or it can be implemented as an overall network scheme for automatic reconfiguration to optimize data transfer. The multiple path approach makes denial of service more difficult and reduces the possibility of a single point of failure.

Dispersed/interoperable systems must be supported by an onsite backup and restore repository for archiving applications and data. Backup procedures should be posted and training given to ensure backup integrity of data. Additionally, backup procedures should be automated to the greatest extent possible. A system of periodic and requested backups should be developed and enforced based upon the functional criticality of the system with respect to availability, accessibility, operational continuity, and responsiveness of recoverability needs. The more dynamic the critical data, the more frequently backups should occur. Intelligent backup systems, which back up only changed data, must have their configuration periodically certified for use.

Contingency planning for dispersed and/or interoperable systems must exist for those failures which are inevitable and those which may be unlikely but may result in catastrophic consequences. Contingency Planning should concentrate on the ability to configure, control and audit, operate, and maintain the data processing equipment to achieve information integrity, availability, and confidentiality. Specifically:

1. Upon failure, critical components should be replaced, repaired, and restarted according to contingency planning procedures.
2. Referential integrity of the data will need to be preserved. In systems where several processes may manipulate a data object, state data must be maintained about the data object so that incorrect sequencing may be prevented.
3. Each component must be capable of executing a controlled shutdown without impacting unrelated functions in other components in the event of a security breach or failure.
4. The dispersed system topology should be designed so that when hardware is taken out of service for maintenance, impact on the rest of the system is minimized.

Cooperative Distributed Systems Integrity Control Issues and Concerns

Additional controls for fully cooperative systems will need to be developed focusing on:

- Establishing and maintaining connectivity.
- Multilevel, multisite information transfers.
- Software development and maintenance.
- Hardware maintenance.

System management will need to conduct an impact analysis to determine the affect of monitoring all transactions involving data, process, and control information without causing degradation of the work in progress.

When transferring data between platforms, the classification access and the identity and authorization of the requester, the accredited classification range of the destination system, and destination level within that system should be authenticated. It is important to document any risks that have been accepted when classifying the level upon which a platform may process. This allows platforms under different management control to be evaluated for risks and have them taken into consideration when making reconfiguration plans. The transfer process must ensure that if the information fails to reach its destination the information is protected at the level required and appropriate warnings are raised.

A process will need to be implemented for introducing new platforms to an existing network. Cooperative processes will need to describe how the access control, security features, and auditability must be ensured prior to operational use of the new platform and how access will be granted. In a cooperative system with diverse platforms, a risk analysis will need to be performed to ensure that the combination of network operating system(s), platform operating system(s), and security software features available on each platform meet the access control and security requirements for that platform's assigned role in the network/system. In cooperative systems, the differences in security software present on or available for each platform must be reconciled to ensure the consistent deployment of the system of controls. The results of this risk analysis must be used when developing reconfiguration and/or recovery options.

A risk assessment of security requirements must be a product of each formal review (i.e., system specification review, preliminary design review, critical design review, etc.) during the software development life cycle. In systems where several processes may manipulate a data object, state data must be maintained about the data object so that incorrect sequencing may be prevented and processing completion can be determined.

Software targeted for use in cooperative systems must be designed using the principle of loose coupling and high cohesion. Loose coupling indicates weak software module-to-module dependency. High cohesion indicates that a module performs a discrete function. In concert, the properties of loose coupling and high cohesion indicate a software module designed for independent performance. Using this principle produces software modules that can execute alone and enable the production of software which may degrade gracefully. Software targeted for use in cooperative systems must be designed so that each component is network topology independent. This will enable components to more readily be installed or reconfigured onto any platform within the network.

Components of cooperative systems must be designed to allow the removal of components to perform maintenance, testing, etc. with minimal impact to operations. Before an element can be removed from the cooperative network, the component must conclude all pending transactions. The work being performed by that component will need to either be done on another platform or the system must continue in a degraded state. Cooperative systems need to be designed with an operational capability for placing the components in a quiescent state. This operation must:

- Cause a component to notify all other components in the system that it is about to terminate.
- Cause all other components in the system to respond by ceasing any transmissions to that component.
- Cause the component to conclude all pending transactions.
- Cause the component to post notification that it is now quiescent.

An operational capability must also exist that allows the component to reenter the network in diagnostic mode for checkout and to notify other components that the component/platform is back in the network but not ready for operational use. Additionally an operational capability will need to exist to allow the component to reenter the system as active from the diagnostic mode and to notify other components that the component is active and fully functional.

INTEROPERABLE RISK ACCOUNTABILITY CONCEPTS

In designing and developing high-integrity interoperable systems, management is faced with the issue that connectivity is still a point-to-point transmission irregardless of the transmission mechanism itself. Unfortunately in today's infrastructure, the majority of attention is focused on adding layers of protection, rather than building controls into the application systems at either end of the transmission. Even with advances in firewall technology, authentication processes, and encryption, management must address the issues of intrusion and infiltration into, as well as exploitation of their information resources by an increasing number of external threat manifestations.

Management must address the following key issues about risk, mitigation of risk, residual risk acceptance, and exercising a standard of due care in protecting its information resources. Additionally, management must recognize that an integrated intrusion detection process and penetration testing are integral components of today's system life cycle. Penetration testing offers the only suite of tests that reflect "real-world" scenarios; and must be integrated into the verification and validation of a system's productional acceptance criteria throughout all life-cycle phases. Intrusion detection, on the other hand, must be instantiated into the overall operational control, similar to, or as a part of the access control and audit.

Risk Accountability Associated with Developing, Maintaining, and Protecting Information Resources

Information security is still largely an unknown entity to most people. Managers can and often do ignore advice offered by security professionals. In the past, when the integrity, availability, or confidentiality of information systems was breached and damages occurred, the majority of damages were internal and simply absorbed by the organization. Limited incident investigation was performed. With the advent of virus infections and the susceptibility of interoperable, intra/Internetworked systems, management must take a proactive approach to managing and protecting its information resources.

Any organization and/or individual is liable when they act in a way that they should not have, or fail to act the way they should, and this act or failure results in harm that could have been prevented. Therefore, it is exceedingly important for management to fully understand the limits of liability associated with managing and protecting corporate information resources and which method of security management to implement.

Compliance-Based Security Management

The compliance-based approach has been an accepted method of protecting information resources. It yields clear requirements that are easy to audit. However, a compliance-based approach to information security does have notable disadvantages when applied to both classified or unclassified information systems.

A compliance-based approach treats every system the same, protecting all systems against the same threats, whether they exist or not. It also eliminates flexibility on the part of a manager who controls and processes the information and who makes reasonable decisions about accepting risks. Utilization of a compliance-based approach may often leave the owners of the information systems with a false impression that a one-time answer to security makes the system secure forever. Usually, the inflexibility of a compliance-based approach significantly increases the cost of the security program, while failing to provide a higher level or more secure information systems.

Risk-Based Security Management

Management often confuses Risk Management with Risk-Based Management. Risk Management is an analytical decision-making process used to address the identification, implementation, and administration of actions and responses, based upon the propensity for an event to occur that would have a negative effect upon an organization or its functional programs or components. Risk Management address probabilistic threats (e.g., natural disasters, human errors, accidents, technology failures, etc.), but fails to

take into account speculative risks (e.g., legal or regulatory changes, economic change, social change, political change, technological change, or management and organizational strategies). In contrast, Risk-Based Management is a methodology that involves the frequent assessment of events (both probabilistic and speculative) affecting an environment.

In managing the security of information systems, a risk-based approach is essentially an integrity failure impact assessment of the environment, program, system, and subsystem components. As such, it must be integrated as a part of the system life cycle. A risk-based approach to security directly places the responsibility for determining the actual threats to a processing environment and for determining how much risk to accept, in the hands of the managers who are most familiar with the environment in which they have to operate.

Both compliance-based security management and risk-based security management take advantage of risk management processes and assessment practices. In contrast to the compliance-based security management discussed above, using a risk-based security management approach allows managers to make decisions based on identified risks rather than on a comprehensive list of risks, many of which may not even exist for the facility in question. Security control requirements for each information system may then be determined throughout the system's life cycle by iterative risk management processes and summarized as a control architecture under configuration management. Implementation of a security control architecture as a primary point of control ensures that each information system is protected in accordance with organizational policy, and at the levels of integrity, availability, and confidentiality appropriate for the functions of the corporation's systems.

Exercising Due Care

A standard of due care is the minimum and customary practice of responsible protection of assets that reflects a community or societal norm. In the private sector this norm is usually based on type or line of business (e.g., banking, insurance, oil and gas, medical, etc.), and within the public sector this norm is determined by legislative, federal, and agency requirements. Efforts to develop a universal norm for both the public and private sectors as well as for the international community have been initiated in response to the National Information Infrastructure and the development of the international Common Criteria.

In either sector, failure to achieve minimum standards would be considered negligent and could lead to litigation, higher insurance rates, and loss of assets. Sufficient care of assets should be maintained such that recognized experts in the field would agree that negligence of care is not apparent.

Due care must be exercised to ensure that the type of control, the cost of control, and the deployment of control are appropriate for the system being managed. Due care implies reasonable care and competence, not infallibility or extraordinary performance, providing assurance that management does not overcontrol nor take an unnecessary reactionary, politically motivated, or emotional position.

Due diligence, on the other hand, is simply the prudent management and execution of due care. Failure to achieve the minimum standards would be considered negligent and could lead to loss of assets, life, and/or litigation.

Understanding the Accountability Associated with Exercising a Standard of Due Care

Although significant strides have been made in criminal prosecution of computer and "high tech" crime in the last few years, the civil concepts (contractual and common law) of negligence and exercising a standard of due care for the protection of information of inter/intranetworked systems and the National Information Infrastructure are still in their embryonic state.

Under the standard of Due Care, managers and their organizations have a duty to provide for information security even though they may not be aware they have such obligations. These obligations arise from the portion of U.S. Common Law that deals with issues of negligence.

Since information systems are relied on by a rapidly increasing number of people outside the organizations providing the services, the lives, livelihood, property, and privacy of more and more individuals may be affected. As a result, an increasing number of users and third-party nonusers are being exposed to and are now actually experiencing damages as a result of failures of information security in information systems. If managers take actions that leave their information resources unreasonably insecure, or if they fail to take actions to make their information resources reasonably secure, and as a result someone suffers damages when those systems are penetrated, usurped, or otherwise corrupted, both the managers and their organizations may be sued for negligence.

Integrity Issues and Associated Policy Concerns

1. Duties and responsibilities must be defined so that security controls are established to ensure separation of logical and physical environments (i.e., maintenance, test, production, quality assurance, and configuration management) for each distributed system node and the interaction between nodes. Policies must also address the various resources, skills, and information requirements that exist for consistent deployment of controls supporting the management and

maintenance of the distributed systems facilities. Additional policies may need to be developed based on the characteristics of a specific distributed system node after the software and hardware for that node have been selected for implementation.

2. Organizational functions and individual duties must be separated. Separation of functions and duties along organizational lines will complicate circumvention of security controls in the acquisition, implementation, and operation of the software at each distributed node or in defining the permissibility of actions between nodes.
3. Configuration Management (CM) plans will need to be developed at the system level, or at a minimum redesigned to include the following:
   - Distributed system CM plans must document system-level and site-level policies, standards, procedures, responsibilities, and requirements for the overall system control of the exchange of data.
   - Distributed system CM plans must document the identification of each individual site's configuration.
   - Distributed system CM plans must include documentation for common data, hardware, and software.
   - Maintenance of each component's configuration must be identified in the CM plan.

   A system-level CM plan is needed that will describe distribution controls and audit checks to ensure common data and application versions are the same across the distributed system in which site-level CM plans are subordinate to distributed-level CM plans. For distributed-level changes, if the components are not documented in a single CM plan, a change control authority will need to be established as a point of control. In distributed systems where nodes are geographically separated or when the components are not documented in a single CM plan, site-level changes must be reviewed by a site's change control authority for potential impacts at the distributed level. Additionally, the change control authority(s) will need to establish agreements with all distributed systems on policies, standards, procedures, roles, responsibilities, and requirements for distributed systems that are not managed by a single organizational department, agency, or entity.

4. If digital signatures are used for configuration management of critical software components; then the digital signature technology must validate the configuration of each node during system validation tests. It is imperative that the signature construct be formulated during node certification.
5. Security control requirements and responsibilities will need to be identified that focus on establishing procedures for owners, users, and custodians of distributed systems hardware and software; as well as procedures for the overall system and for each node to

ensure consistent implementation of security controls for handling data between components of distributed systems.

6. Organizational and functional access controls must be implemented for each node identifying and establishing the relationship between node software and hardware resources, and that periodic assessment of the relationship between node software and hardware resources be performed to ensure that access is limited to a definite minimum.
7. Security controls need to be assessed, by node, at each phase review of the system development life cycle to ensure that as requirements and vulnerabilities are discovered, they are addressed using the design/implementation approach. Additionally, independent testing and verification responsibilities should be assigned, by node, for maintenance and production processes to ensure that safeguards and protection mechanisms are not compromised by special interests.
8. Since distributed systems require network connection for communication with other nodes, network security controls must be considered which address:
   - User authentication
   - Data flow disguise
   - Traffic authentication
   - System attack detection
   - Repudiation protection
9. The level of physical access control depends on the functional criticality or sensitivity level of the information being processed, proprietary process(es) invoked, and/or software/hardware employed. Distributed system components that normally need to be guarded include:
   - Terminals
   - Equipment
   - Nodes
   - Communication lines
   - Connections
10. Intrusion detection processes and mechanisms will need to be deployed to detect, monitor, and control both internal and external intrusion and/or infiltration attempts. Additionally, corresponding controls will need to be established to address all security incidents. A security incident is considered to be an event that is judged unusual enough to warrant investigation to determine if a threat manifestation or vulnerability exploitation has occurred. For distributed systems, security incident detection requires the reporting of and warning to other nodes of the system that such an event has occurred within the control domain.

11. A capability will need to be provided to evaluate the effectiveness of security controls. In order to evaluate the effectiveness, security controls must be modular and measurable.
12. Software with privileged instruction sets that can override security controls within the system must be identified, certified, and controlled.
13. Designers will need to reconcile the differences in security software installed or available on each platform.
14. Designers must be able to ensure a consistent implementation of security controls.
15. Communications subsystem packages for each node must be capable of logging the status of information transfer attempts. Additionally, security management personnel must periodically review these data for evidence of attempts to gain unauthorized access or corrupt data integrity during the transfer process.
16. Distributed system managers will need to maintain connectivity capabilities by allowing only authorized, authenticated users to log on, responding to access violation alarms, and auditing access logs for attempts at unauthorized access.
17. Functions will need to be identified and separated into isolated security domains. These isolated security domains will ensure the confidentiality, integrity, and availability of information for the overall system and for each node. Management may decide that a security control architecture (the composite of all controls within the design of the system addressing security-related requirements) will need to be established that defines isolatable security domains within the environment to ensure integrity within each domain, as well as between levels of sensitivity and domain boundaries.
18. System reconfiguration plans will need to be developed. Additionally, procedures must be established for introducing new platforms to existing distributed systems. These procedures must describe how access controls, security features, and audit capabilities will be implemented before operational use, and how access will be granted gradually as controls are assured. In distributed systems with diverse platforms, a risk analysis will need to be performed to ensure that the combination of network operating system, platform operating system, and security software features on each platform meet security requirements for their roles in the system. The analysis is necessary to identify and develop reconfiguration and recovery options.
19. Distributed system components must be capable of executing a controlled shutdown without impacting unrelated functions in other components. The mode (automated or manual) to perform a controlled shutdown should be based on predefined, documented criteria to ensure consistency and continuity of operations.

20. System management will need to conduct impact assessment to discover, for each node and for the network as a whole, factors that may affect the system connectivity, including:
    - The type of information traveling from node to node.
    - The levels of sensitivity or classification of each node and of the network.
    - The node and network security countermeasures in place.
    - The overall distributed system security policy.
    - The method of information transfer between nodes and the controls implemented.
    - The audit trails being created by each node and the network.

THE SYSTEMS INTEGRITY ENGINEERING METHODOLOGY

From the previous discussions on understanding the control issues and concerns associated with fully distributed and/or dispersed interoperable systems, it is clearly evident that management must take a proactive approach to designing, developing, and securing its information resources. In order to address this dynamic environment in which the system development life cycle has been shortened from weeks and months to hours and days (e.g., LINUX development), management is faced with making real-time decisions with limited information and assurances.

The model used in the development of this methodology is a highly complex global, multicorporate, multiplatform, intra- and Internetworked environment that substantiates the need for a synergistic business approach for bridging the gaps between the four key area product development support functions: system design and development, configuration management, information security, and quality assurance. These systems encompass:

- Some 3,600 personnel,
- About 1,682 large mainframes, minis, and dispersed cooperative systems,
- Five types of operating systems,
- A variety of network and communication protocols, and
- Varying geographical locations.

This approach forms an enterprise-wide discipline needed for assuring the integrity, reliability, and continuity of secure information products and services. Although the development and maintenance concepts for high-integrity systems are specifically addressed, the processes described are equally applicable to all systems, regardless of size or complexity.

Information Systems Integrity Program

Change is not easy whenever an enterprise considers reengineering its business processes. This kind of competitive business initiative typically

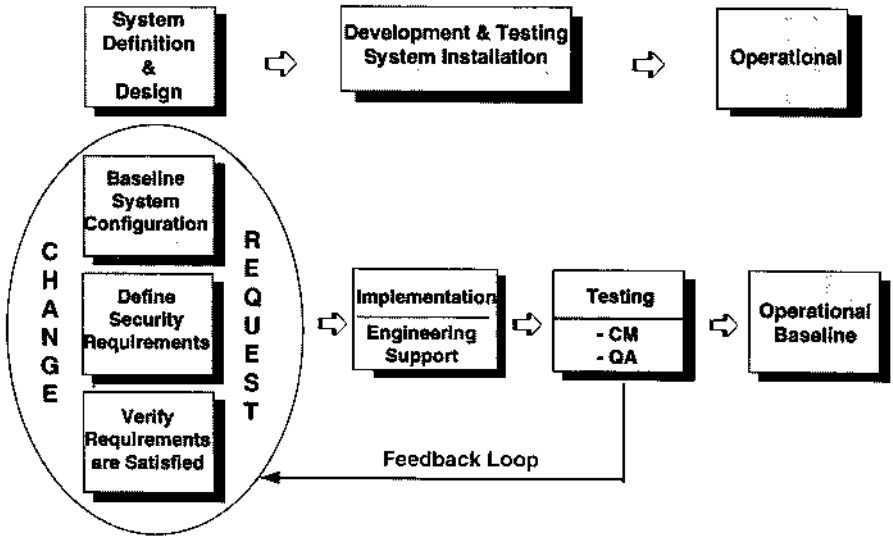

Exhibit 6. Change Process

involves redesigning and retooling value-added systems for new economies. Many of these are legacy systems which are being pulled along by new technology, making change very difficult to manage. The speed at which new emerging information technology is introduced to market has also made it difficult to maintain an information systems control architecture baseline. Continued budget constraints have become a recognized element in managing this change.

Systems Integrity Engineering Process

In today's computing world, distributed processing technologies and resources change faster than most operational platforms can be baselined. As they evolve with an ever-increasing speed, organizations are challenged with an opportunity to maintain stability for growth and strategic competitiveness. Management must consider that sensitive business systems increasingly demand higher levels of integrity in system and data availability. Within this framework, reliability, through product assurance and security assurance constructs, provides a common enterprise objective. Accordingly, the scope of an enterprise-wide product assurance partnership and management-friendly metrics must be expanded to all four functional areas as a single, logical, integrated entity with fully matrixed management (i.e., both horizontal and vertical management control). The process in which requirements for new information technology are infused into the enterprise and managed becomes the pivotal business success

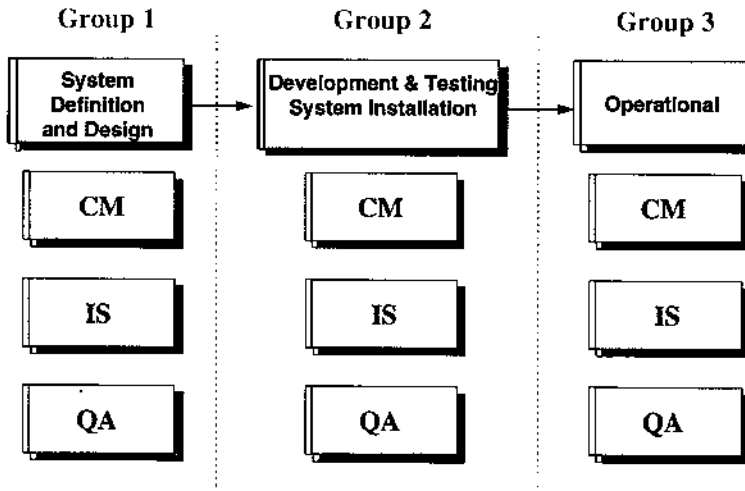

Exhibit 7. Interdependencies of Change

factor that must be defined, disseminated, and understood by the key functional support organizations.

New Alliance Partnership Model (NAPM)

In their presentation to the 18th National Information Systems Security Conference (October, 1995) on "The New Alliance: Gaining on Security Integrity Assurance", Sanchez and Evans described a new alliance partnership model developed from a four-year case study in which security, configuration management, and quality assurance functions were combined with an overall automated information systems (AIS) security engineering process. In this paper, Sanchez and Evans delineated the following.

It has become critically essential for enterprise management to understand the interdependencies and complementary pursuits that exist between the Information Systems Design and Development, the Quality Assurance (QA), Configuration Management (CM), and the Information Systems Security (IS) organizational support functions. With this knowledge, it is equally important to identify and examine a synergistic approach for realizing additional economies (cost savings/avoidances) throughout the system development life cycle with continuous improvement techniques.

Implementation of product assurance and secure information technology development is a management decision that must be judiciously exercised and integrated as part of a system control architecture. In this model, automated information systems security management is recognized as the functional point of control and authority for coordinating and guiding the

development, implementation, maintenance, and proceduralization of information security into a unique, integrated management team. The use of a security control architecture is the approved strategic methodology used to produce a composite system of security controls, requirements, and safeguards planned or implemented within an IS environment to ensure the integrity, availability, and confidentiality. This is the only approach that will allow for integration and cooperative input from the CM, AIS security engineering, and QA management groups. Each of these product assurance functional support groups must understand and embrace common corporate product assurance objectives, synergize resources, and emerge as a partnership free of corporate political strife dedicated to providing a harmonization of systems integrity, availability, and confidentiality.

The harmonization effort evolves as an enterprise-wide New Alliance Partnership Model (NAPM) in which:

- QA provides an enhanced product assurance visibility by ensuring that the intended features and requirements, including but not limited to security, are present in the delivered software. QA allows program management and the customer to follow the evolution of a capability from request through requirement and design, to a fielded product. This provides management with an enhanced capability as well as a forum for identifying and minimizing misinterpretations and omissions which may lead to vulnerabilities in a delivered system. The formal specifications required by QA increase the chance that the desired capabilities will be developed. The formal documentation of corrective actions from reviews (of specifications, designs, etc.) lessens the chance that critical issues may go undetected.
- CM provides management with the assurance that changes to an existing AIS are performed in an identifiable and controlled environment and that these changes do not adversely affect the integrity or availability properties of secure products, systems, and services. CM provides additional security assurance levels in that all additions, deletions, or changes made to a system do not compromise its integrity, availability, or confidentiality. CM is achieved through proceduralization and unbiased verification ensuring that changes to an AIS and/or all supporting documentation are updated properly, concentrating on four components: identification, change control, status accounting, and auditing.
- IS provides additional controls and protection mechanisms based upon system specifications, confidentiality objectives, legislative requirements and mandates, or perceived levels of protection. AIS security primarily addresses the concerns associated with unauthorized access to, disclosure, modification, or destruction of sensitive or

proprietary information, and denial of IT service. AIS security may be built into, or added onto, existing IT or developed IT products, systems, and services.

- Organizational management provides the empowerment and guidance for the economies of scale.

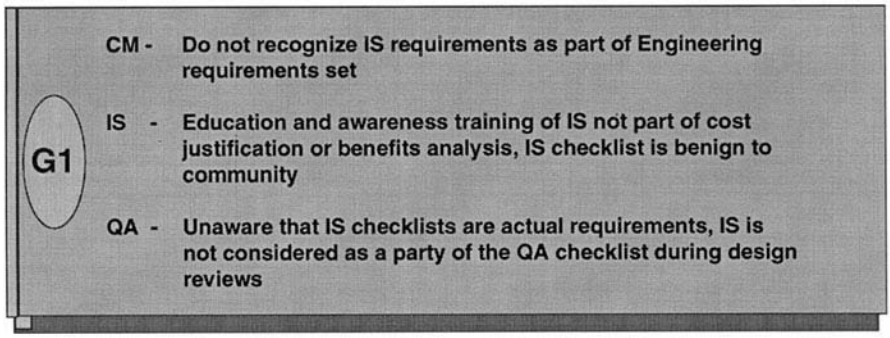

Exhibit 8. System Definition and Design Constraints

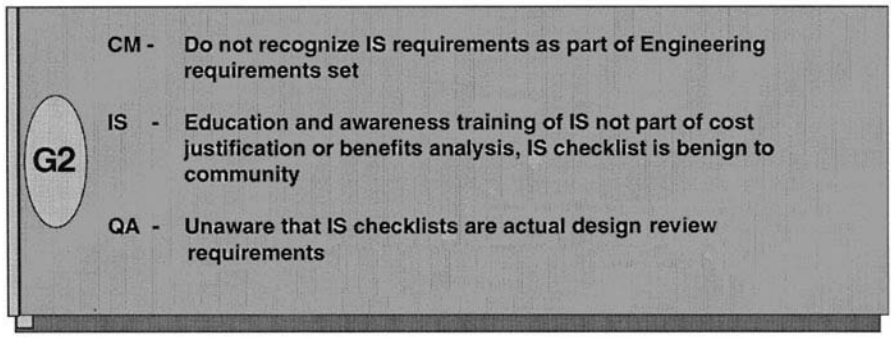

Exhibit 9. Development, Testing, and Installation Constraints

A seminal case study was presented as proof of the concept for gaining security integrity assurance. It identified the interdependencies and synergy that exist between the CM, IS security engineering, and QA functional management activities. It describes how information technology, as a principle change driver, is forcing the need for a QA, CM, and AIS security forum to evolve if the enterprise is to be successful in providing high-integrity systems.

Sanchez and Evans were able to provide the following:

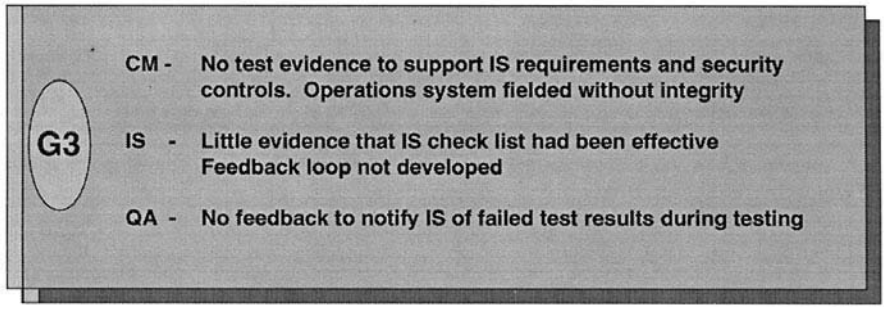

Exhibit 10. Operational Constraints

1. Change is not easy. Change has not been easy. Change will not be easy. In this case study, the members of each respective management support team have championed the process improvement initiatives and the corrective actions taken thus far. It is important to emphasize that employee empowerment of this type must be supported by top management because security integrity engineering and the implementation of an integrated product assurance and secure information technology development process such as a control architecture is a proactive management decision.
2. Information technology has been and will continue to be a major change driver that establishes a need for a functional organizational support forum dedicated to delivering high-integrity products and services. Each of the product assurance functional support organizations must understand and embrace common corporate product assurance objectives, synergize resources, and emerge as a partnership independent of corporate political strife and dedicated to harmonizing systems integrity, availability, and confidentiality.
3. The New Alliance Partnership Model (NAPM) is a viable solution that has been put to the test and proven in a highly dynamic operational environment of ever-changing distributed processing technologies. The NAPM supports the integration process and requires that direct lines of communication be bridged between key functional support organizations so as to input and feedback closure information.

Incorporating NAPM into the System Development Life Cycle

In order to fully integrate the partnership model into a System Integrity Engineering discipline it is imperative that the designers and system architects understand and embrace the requirements imposed by technology infusion and the insatiable demand for more interoperable processing capabilities and applications.

Management can no longer afford to "bury its head in the sand" and ignore threats simply because there is (1) no commercially available hardware and/or software solution(s) available; or (2) prohibitive budgetary restraints make addressing the issues improbable. The threats will not magically disappear. They must be openly and intelligently addressed. Application design or enhancements may no longer be the sole major driving force in today's interoperable development environment. Management is beginning to be more interested in systems that provide them with a high degree of confidence in protecting their information, consistency, and continuity of operation, as well as efficiency and computational effectivity.

The basic System Development Life Cycle has changed dramatically. Design and development efforts that once took months, even years, has been replaced by rapid application and joint analysis development (RAD/JAD) processes, prototyping, reuse engineering, and fourth-generation languages. These have modified the timing cycle by drastically shortening it to days and weeks, or in some cases hours and minutes.

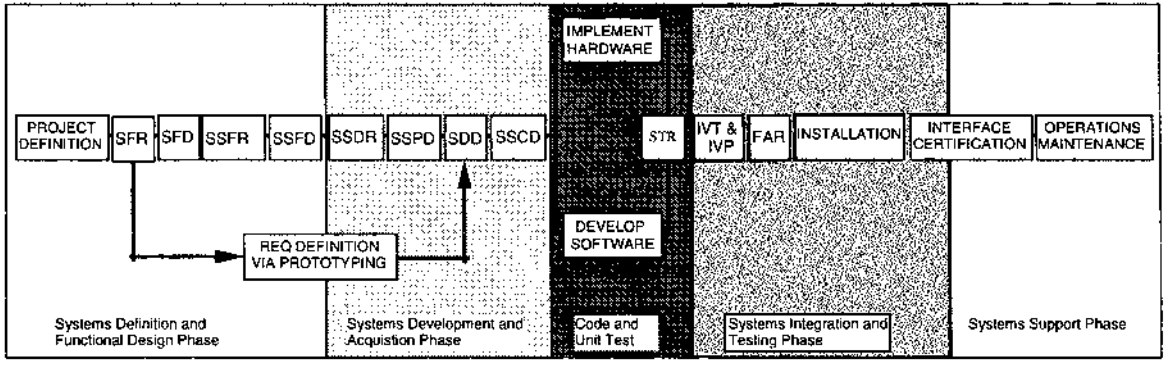
To effectively integrate a system of controls into the life cycle, designers and developers will need to consider a modified model that recognizes that in an iterative system development life cycle, security controls and protection mechanisms need to be addressed in an iterative manner as well.

Software Life Cycle as a Control Process. The basic life cycle is still comprised of a series of phases to be executed sequentially or recursively as a continual process. A set of software products to be produced during each phase is identified, including security-related analyses, documentation, and reports. The controls deployed as well as those planned during each of the life cycle phases comprises a unique control architecture for the developing software products.

It is imperative that all relevant products are developed, all reviews are held, and all follow-up actions performed within each of the life cycle phases in sequence. To provide adequate management control, it is normally necessary that the developer not be allowed to proceed unless the defined phases of development are approved, performed in their predefined order, and the developer receives authority to proceed. The controls governing the applicability of a life cycle model to development and maintenance projects must be identified, evaluated, and specified with the consideration of integrity and security-relevant controls deployment criteria.

Each of the following development life cycle approaches provides inherent integrity controls:

- The classical software development method recognizes discrete phases of development and requires that each phase of development



FAR	Final Acceptance Review	SSDR	Subsystem Detailed Requirements (Level C)
IVP	Integrity Verification Process	SSFD	Subsystem Functional Design
IVT	Independent Verification & Test	SSFR	Subsystem Fucntional Requirements (Level B)
SDD	System Detailed Design	SSPD	Subsystem Preliminary Design
SFD	System Functional Requirements (Level A)	STR	Start of Testing Review
SSCD	Subsystem Critical Design		

Exhibit 11. Example of a System Life Cycle

be complete, with the presentation of formal reviews and release of formal documentation prior to transitioning to the next phase.
- Spiral development is an iterative approach toward the classical method where the development life cycle is restarted to enable the rolling in of lessons learned into the earlier development phases.
- Rapid application development (RAD) is a method of rapidly fielding experimental and noncritical systems in order to determine user requirements or satisfy immediate needs.
- Joint analysis development (JAD) is a workshop-oriented, case-assisted method for application development within a short time frame using a small team of expert users, expert systems, expert developers, and outside technical experts, a project manager, executive sponsor, a JAD/CASE specialist, and observers.
- Cleanroom is a method for developing high-quality software with certifiable reliability. Cleanroom software development attempts to prevent errors from entering the development process at all phases. The process provides for specifiers, programmers, and testers in which a specification is prepared either formally or semiformally as notations. Programmers prepare software from the specifications. A separate team prepares tests that duplicate the statistical distribution of operational use. Programmers are not permitted to conduct tests; all testing is done by an independent test team.

Regardless of method, formal reviews and audits need to be performed to provide management and user insight into the developing system. Through the use of the review process, potential problems may be readily identified and addressed. Technical interchange meetings and peer reviews, involving technical personnel only, should be used to promote communication within the development organization and with the user community, enable the rapid identification and clarification of requirements, reduce risk, and promote the development of quality products.

Modified Interoperable Software Development Life Cycle Process. The software development life cycle (see Exhibits 12 and 13) for dispersed and distributed interoperable systems requires that prototyping be done which redefines the requirements definition, provides early identification of interfaces, and shortens the hardware and software development and acceptance phases of the life cycle when combined with real-time testing and anomaly resolution. In order to assure that appropriate controls deployments are considered and incorporated, system designers and developers will need to consider a slightly modified approach in which security-relevant safeguards and protection mechanisms are managed.

Management must be able to identify a protection strategy that addresses threat manifestations before, after, and during their occurrence(s) as a qualitative "relative timing factor" rather than as a calculated

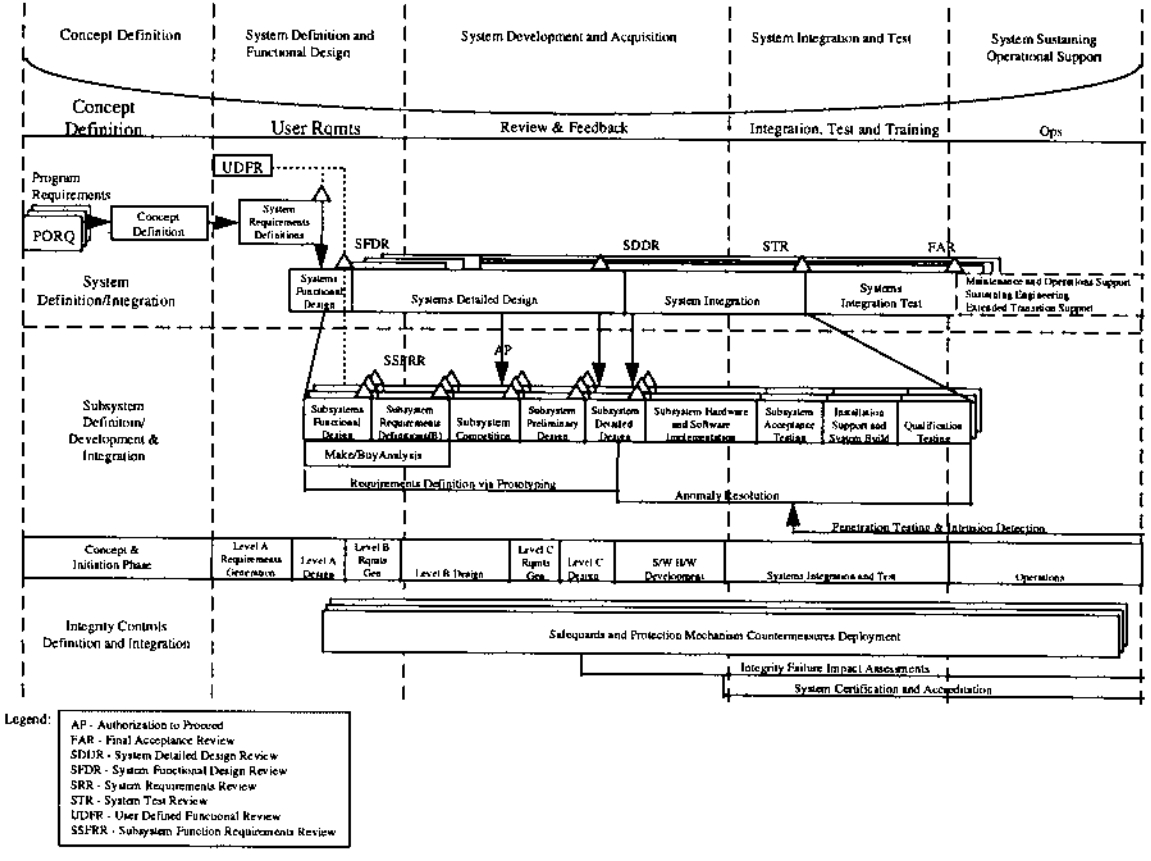


Exhibit 12. Modified System Development Life Cycle

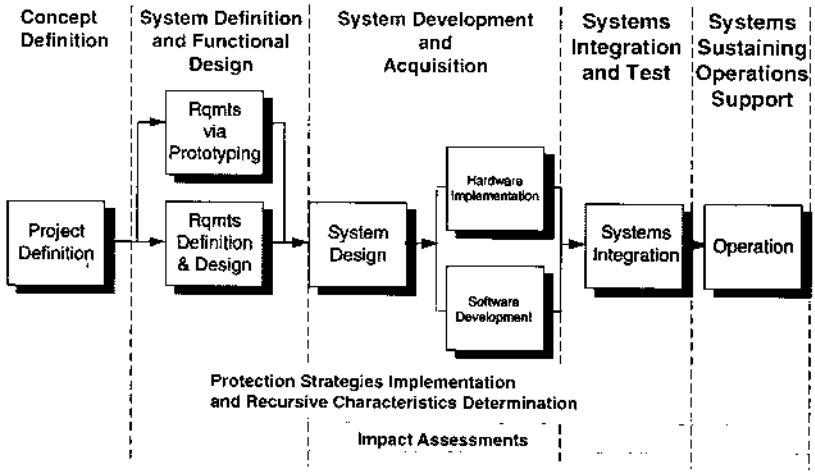

Exhibit 13. System Development Life Cycle Protection Strategies Deployments

probability of occurrence or frequency, since interoperable systems have a high probability of being exploited. For most systems an attack(s) is a foregone conclusion and simply a matter of "when" rather than " what if" or "will" a threatening event occur.

In Exhibits 13 and 14, consideration is given to the types of controls and associated safeguards and protection mechanisms deployed as countermeasures to threats. Types of controls and safeguards are generally classified as detective, preventative, and recovery controls. Since these control types may have an associated protection strategy and occur in a recursive process throughout each phase of the life cycle, then each safeguard has a unique signature depending upon each of the three types of controls and protection strategy(s) employed, as well as individualized recursive characteristics.

In Exhibit 14, the recursive characteristics and uniqueness of signature are clearly evident. Regardless of the point of origin within the PDR iteration, there is an identification (real or perceived) and a detection (D) of an exposure or risk, an associated recovery (R) strategy, followed by a preventative mechanism (P) or strategy that is for all practical purposes independent of when the threat manifestation actually occurs.

If taken in a controlled environment, prevention is normally the first of the recursive steps since there are normally control deployments based upon perceived threats rather than actual manifestations. The uniqueness of the PDR signature (i.e., 1 + 2 + 3 + … n + n+1) is attributed to the combinations of subsequent activities and protection strategies introduced into

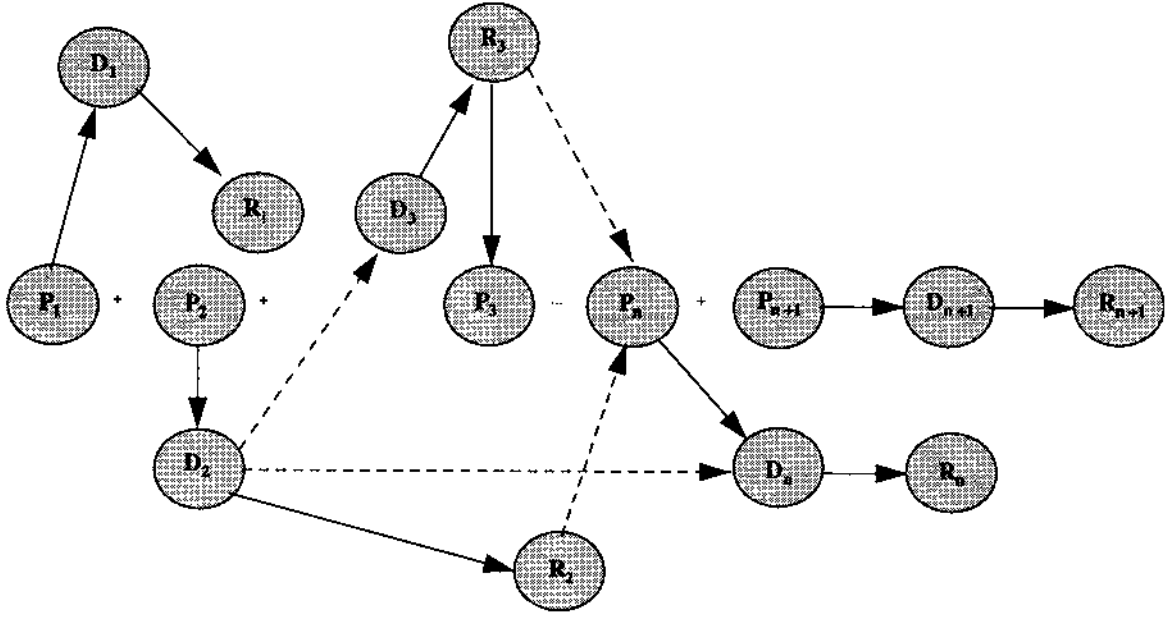

Exhibit 14. Recursive Characteristics of Protection Controls

each iteration of the process. The combination of all safeguards with respect to detection, prevention, or recovery, therefore, provides management with a process and a metric that is relatively independent of time for determining risk accountability and propensity of threat manifestation(s).

Stacey, Helsley, and Baston in their paper, "Risk-Based Management, How To: Identify Your Information Security Threats" arrived at a similar conclusion in determining threat events and their relationship to protection strategies.

They outline a structured approach for the identification of a threat population, correlating threat events and protection control strategies to security concerns. In determining when to protect a system from a threat event (before, during, or after the occurrence of a threat event), they arrived at the conclusion that once a threat event had been identified, one could assign a set of safeguards for each protection strategy (i.e., prevention, detection, and recovery) as an independent point of control.

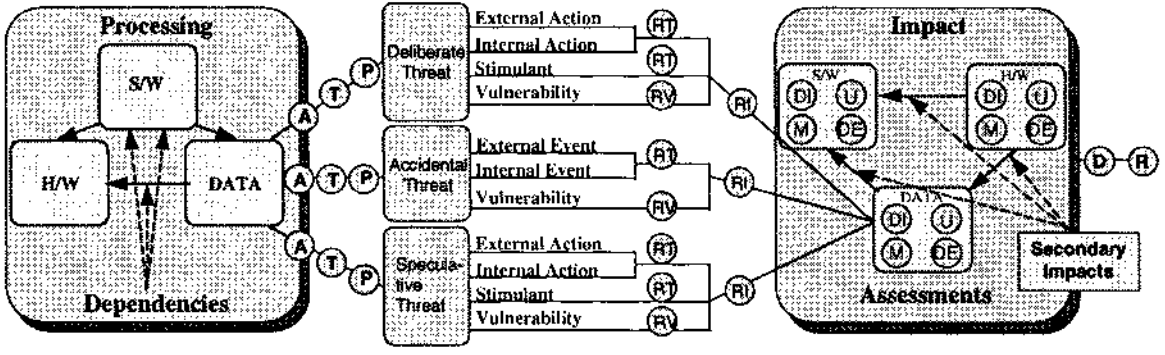
Integrity Failure Impact Assessments (IFIA)

System availability and robustness often erroneously preempt reliability and integrity concepts. In an interoperable environment comprised of a system(s), management's confidence in the integrity of the system (level of trustworthiness) is primarily based on whether the "system" is readily accessible for use and possesses the capability of being able to process information, rather than the integrity of what is produced, when it was produced, who used it (or was authorized to used it), or how was the information produced, protected, stored, transmitted, and/or disseminated.

In assessing the level of trustworthiness of a system, processing dependencies and types of controls, threat events, and impacts to its integrity, as well as the associated relationship to an enterprise's protection strategy (PDR) must be identified.

This relationship is best described as an Integrity Failure Impact Assessment (IFIA), in which deliberate and accidental threat events (including associated actions/reactions and vulnerabilities), primary and secondary impacts, processing dependencies, and protection strategies are evaluated, documented, and preserved as an enterprise-wide baseline supporting the corporate decision-making process. IFIA, which are similar in nature to reliability engineering determinations of mean-time between failure and mean-time to repair, will need to be developed based upon the enterprise's overall protection strategies.

Once IFIA have documented the frequency of occurrence and the mean-time to restore a system(s) to a known integrity state(s), management can qualitatively ascertain and maintain an acceptable level of confidence in its



Type of Control			Type of Impact
Preventative	Detective	Recovery	
(A) Avoid the Threat	(D) Detect	(R) Recover	(D) Disclosure
(T) Transfer the Threat			(M) Modification
(TR) Reduce the Threat			(U) Loss of Availability
(VR) Reduce the Vulnerability			(DE) Destruction
(RI) Reduce the Impact			
(P) Prevent			

Exhibit 15. Protection Strategies

high-integrity systems and processes based upon sound engineering concepts and practices.

MOTIVATIONAL BUSINESS VALUES AND ISSUES

The business values, issues, and management challenges that drive integrity initiatives and commitments are primarily comprised of, but are not limited to the following:

- The value of a surprise-free future.
- The value of system survivability and processing integrity.
- The value of information availability.
- The issue of the sensitivity and/or the programmatic criticality of information.
- The issue of trust.
- The issue of uncertainty.
- The issue of measurability of risk.
- The challenges in managing critical resources.
- The administrative challenge of controlling and safeguarding access to and usage of proprietary information.
- The challenge of technology infusion.

Value of a surprise-free future — If management is continually addressing unwelcome surprises, denials of services, and impacts to its processing objectives, the enterprise will experience (1) loss of credibility, (2) investment in less than optimum resource commitments and unnecessary expenditures, (3) and unproductive reactive management decisions. The optimum value is a surprise-free future which can be proactively managed. The ideal can and should be approached through substantiation of both strategic and tactical countermeasures and protection mechanisms that safeguard against those factors that contribute to the uncertainty of resources and assets These countermeasures cover a wide spectrum ranging from administrative manual procedures and processes to sophisticated engineering processes and tools that focus on disparate heteromorphic processing environments and the complexity of the domains, components, and subcomponents that comprise a corporation's overall processing program.

Value of system survivability and processing integrity — This is attained through the management of uncertainty surrounding the robustness of critical information processes and resources, their identification, quantification, assessment, and use. A system's robustness is a relational correlation of the system's components, to each component's "built in" resistance capability (including processing redundancy, logical self propagation, and accessibility to, and deployment of, additional sustaining countermeasures and protection mechanisms), to internal and external threats of misuse, abuse, espionage, or attack(s). In complex intra/Internetworked systems or systems of systems, the capability to maintain the referential

integrity of the information created, used, stored, and/or transmitted is imperative.

Value of information availability — This focuses on the demand, responsiveness, and accessibility of information resources, as needed, including preservation and recoverability following the manifestation of a disruption or denial of service.

Issue of sensitivity and/or programmatic functional criticality of information — This is determined by an enterprise-wide programmatic assessment of the values of information resources and operational performance(s). The valuation items and/or issues identified are used by management to determine the relevant consequences of both real and perceived loss of information integrity, availability, and confidentiality; and are assigned a weighting factor(s) as to their significance or perceived significance. These valuation items are imperative in determining appropriate strategic and tactical control deployments and justification of associated expenditures to meet business objectives.

Issue of trust — This is a determination resulting from the identification and assessment of where and/or how information resources are assembled, stored, and processed by human or electronic entities/agents/systems. Each process and/or associated agent normally has differing levels of privileges that may impact the integrity of the information resources. The use of trusted agents and systems to establish "webs of trust" for intra/Internetworked systems demands proactive management of uncertainty in using information resources, and is based upon the assumption that:

1. The trust level or the "need to know" and privileges of agents accessing and using information resources are assignable, verifiable, and controlled at all times.
2. Agents have certifiable skills for correctly operating interfaces to information resources.
3. The state and attributes of information environments, processing capabilities, and carriers are identifiable, accountable, and assignable at all times.
4. Systems in which uncertainties in these attributes exist have been (or are in the process of being) reduced to acceptable levels which may be independently verified.
5. Penetration testing procedures and processes will be implemented as a normal suite of tests to simulate real-world tests of the web of trust and to determine true protection limitations.

Issue of uncertainty — This is the motivational factor in which full certainty of information processing agents, systems, and information resources may not be practically achievable. Proactive minimization of

uncertainty demands accountability for risk acceptance. Acceptable levels of risk are measured in terms of those exposures that do not have corresponding safeguards to reduce or eliminate risk(s) due to weaknesses in existing or recently deployed safeguards or protection mechanism design faults, inappropriate application, or issues identified as anomolies resulting from new technology implementations.

Issue of measurability of risk — This focuses on the management of uncertainty surrounding the state of information resources. Uncertainty is identified, quantified, assessed, and is used to ascertain residual risk resulting from unavailable or improperly deployed safeguards and protection mechanisms, implementation of new technology, or speculative change (e.g., legislative or regulatory mandates, politics, etc.).

Challenges in managing critical resources — In which the management of uncertainty of impacts includes the design and implementation of:

1. Indicators that provide continuous visibility of the states of confidence.
2. Sensors and procedures that can positively verify the identity and privilege status of access to information, including verification of connectivity and interfaces.
3. Administrative and electronic controls to ensure separation of duty and assignment of privilege, and to limit unintentional or unauthorized granting and propagation of privileges.
4. Administrative and electronic mechanisms for assuring continuity of access to information, including the capability to restore systems to a known state that have been or, are perceived to be in the process of being interrupted by natural or induced disasters.

Administrative challenge of controlling and safeguarding access to and usage of proprietary information — In which an independent verification and validation process is institutionalized that attests to an acceptable status of trust in the integrity of information resources, systems, and agents.

Challenge of technology infusion — In which the management of enhancements to technology is addressed. Currently, technological enhancements of products and services is expanding at a phenomenal rate, while management methodologies, prototyping strategies, and tactical planning for their incorporation into enterprise domains are expanding at a much slower rate. Due to the dynamics and the proliferation of products and services, management is faced with a significant degree of uncertainty in deciding whether or not to use freeware, shareware, COTS products, or end-user-developed systems. Furthermore, if these are used, how will management control proprietary and/or critical information,

when should they be used, and what will be the associated long-range sustaining costs?

"EYE OF NEWT, HAIR OF DOG, BLOOD OF BAT, . . ."

In conclusion, information security is bounded only by our own prejudices and short sightedness.

In the last five years, security has changed from a discipline that was fairly isolated and unique, and easily controlled and administered, into a management dream turned into a nightmare. The Security "druids" of the 1980s, crouched over boiling cauldrons muttering strange incantations and peering into the future, have been replaced with the 1990s "techno-wennies" and "security geeks" who were let out of their closets gloomily forecasting that:

- Security can no longer be effectively added as an independent layer of protection.
- Every PC is equivalent to an international data center and should be similarly protected.
- Security in a distributed environment is a logical configuration, and cannot be physically controlled.
- Security cannot be legislated.
- Security is an operational decision, it is not part of the development life cycle and therefore, should not be addressed as a technical requirement until after a system is built and delivered.
- Once systems are opened, they can probably never be closed.
- Effective security is cost prohibitive and we can't do anything about it until a COTS product is available.

We have looked "SATAN" in the eye (1994) and "danced with the devil in the pale moonlight (1995,1996)". We are still here, the values, issues, and concerns are still here. Although we have made progress in determining what is needed, we are still ignoring the simple fact that adequate security safeguards and protection mechanisms have to be designed for, and built into our systems. We must take the initiative by accepting a synergistic approach that combines the current development and maintenance disciplines into a single Integrity Engineering discipline as the future answer to our concerns.

Introduction to UNIX Security for Security Practitioners

Jeffery J. Lowder

IN AN AGE OF INCREASINGLY SOPHISTICATED SECURITY TOOLS (e.g., firewalls, virtual private networks, intrusion detection systems, etc.), MANY PEOPLE DO NOT CONSIDER OPERATING SYSTEM SECURITY A VERY SEXY TOPIC. Indeed, given that the UNIX operating system was originally developed in 1969 and that multiple full-length books have been written on protecting UNIX machines, one might be tempted to dismiss the entire topic as "old hat." Nevertheless, operating system security is a crucial component of an overall security program. In the words of Anup Ghosh, the operating system is "the foundation for any software that runs on a machine," and this is just as true in the era of E-commerce as it was in the past. Thus, security practitioners who are even indirectly responsible for the protection of UNIX machines need to have at least a basic understanding of UNIX security. This chapter attempts to address that need by providing an overview of security services common to all flavors of UNIX; security mechanisms available in trusted UNIX are beyond the scope of this chapter (but see Exhibit 21-1).

OPERATING SYSTEM SECURITY SERVICES

Summers[7] lists the following security services that operating systems in general can provide:

1. *Identification and authentication.* A secure operating system must be able to distinguish between different users (identification); it also needs some assurance that users are who they say they are (authentication). Identification and authentication are crucial to the other operating system security services. There are typically three ways to authenticate users: something the user *knows* (e.g., a password), something the user *has* (e.g., a smart card), or something the user *is*

Exhibit 21-1. Versions of trusted or secure UNIX.

A1 (Verified Design)	No operating systems have been evaluated in class A1
B3 (Security Domains)	Wang Government Services, Inc. XTS-300 STOP 4.4.2
B2 (Structured Protection)	Trusted Information Systems, Inc. Trusted XENIX 4.0
B1 (Labeled Security Protection)	Digital Equipment Corporation ULTRIX MLS+ Version 2.1 on VAX Station 3100 Hewlett Packard Corporation HP-UX BLS Release 9.09+ Silicon Graphics Inc. Trusted IRIX/B Release 4.0.5EPL
C2 (Controlled Access Protection)	No UNIX operating systems have been evaluated in class C2
C1 (Discretionary Access Protection)	Products are no longer evaluated at this class
D1 (Minimal Protection)	No operating systems have been evaluated in class D1

Note: Various versions of UNIX have been evaluated by the U.S. Government's National Security Agency (NSA) according to the Trusted Computer System Evaluation Criteria. (By way of comparison, Microsoft Corporation's Windows NT Workstation and Windows NT Server, Version 4.0, have both been evaluated at class C2.) The above chart is taken from the NSA's Evaluated Product List.

(e.g., a retinal pattern). Passwords are by far the most common authentication method; this method is also extremely vulnerable to compromise. Passwords can be null, easily guessed, cracked, written down and then discovered, or "sniffed."

2. *Access control.* An operating system is responsible for providing logical access control through the use of subjects, objects, access rights, and access validation. A subject includes a userID, password, group memberships, privileges, etc. for each user. Object security information includes the owner, group, access restrictions, etc. Basic access rights include read, write, and execute. Finally, an operating system evaluates an access request (consisting of a subject, an object, and the requested access) according to access validation rules.
3. *Availability and integrity.* Does the system start up in a secure fashion? Does the system behave according to expectations during an attack? Is the data on the system internally consistent? Does the data correspond with the real-world entities that it represents?
4. *Audit.* An audit trail contains a chronological record of events. Audit trails can be useful as a deterrent; they are even more useful in investigating incidents (e.g., Who did it? How?). Audit trails have even been used as legal evidence in criminal trials. However, for an audit trail to be useful in any of these contexts, the operating system must record all security-relevant events, protect the confidentiality and integrity of the audit trail, and ensure that the data is available in a timely manner.

5. *Security facilities for users.* Non-privileged users need some method for granting rights to their files and changing their passwords. Privileged users need additional facilities, including the ability to lock accounts, gain access to other users' files, configure auditing options, change ownership of files, change users' memberships in groups, etc.

The following pages explore how these services are implemented in the UNIX family of operating systems.

IDENTIFICATION AND AUTHENTICATION

UNIX identifies users according to usernames and authenticates them with passwords. In many implementations of UNIX, both usernames and passwords are limited to eight characters. As a security measure, UNIX does not store passwords in plaintext. Instead, it stores the password as ciphertext, using a modified Digital Encryption Standard (DES) algorithm (crypt) for encryption. The encrypted password, along with other pertinent account information (see Exhibit 21-2), is stored in the */etc/passwd* file according to the following format:

```
username:encrypted password:UserID:GroupID:user's
          full name:home directory:login shell
```

Exhibit 21-2. Sample */etc/passwd* entries.

```
keith::1001:15:Keith Smith:/usr/keith:/bin/csh
greg:Qf@14pL1aqzqB:Greg Jones:/usr/greg/:/bin/csh
cathy:*:1003:15:Cathy Jones:/usr/cathy:/bin/csh
```

(In this example, user keith has no password, user greg has an encrypted password, and user cathy has a shadowed password.)

Unfortunately, the */etc/passwd* file is world-readable, which can place standard, "out-of-the-box" configurations of UNIX at risk for a brute-force password-guessing attack by anyone with system access. Given enough computing resources and readily available tools like Alec Muffet's **crack** utility, an attacker can eventually guess every password on the system. In light of this vulnerability, all current implementations of UNIX now provide support for so-called "shadow" passwords. The basic idea is to store the encrypted passwords in a separate file (*/etc/shadow* to be exact) that is only readable by the privileged "root" account. Also, although vanilla UNIX does not provide support for proactive password checking, add-on tools are available. Finally, password aging is not part of standard UNIX but is supported by many proprietary implementations.

UserIDs (UIDs) are typically 16-bit integers, meaning that they can have any value between 0 and 65,535. *The operating system uses UIDs, not usernames, to track users.* Thus, it is entirely possible in UNIX for two or more usernames to share the same UID. In general, it is a bad idea to give two usernames the same UID. Also, certain UIDs are reserved. (For example, any username with an UID of zero is considered root by the operating system.) Finally, UNIX requires that certain programs like **/bin/passwd** (used by users to change their passwords) and */bin/login* (executed when a user initiates a login sequence) run as root; however, users should not be able to arbitrarily gain root permissions on the system. UNIX solves this problem by allowing certain programs to run under the permissions of another UID. Such programs are called Set UserID (SUID) programs. Of course, such programs can also be risky: if attackers are able to interrupt an SUID program, they may be able to gain root access and ensure that they are able to regain such access in the future.

GroupIDs (GIDs) are also typically 16-bit integers. The GID listed in a user's entry in */etc/passwd* is that user's primary GID; however, in some versions of UNIX, a user can belong to more than one group. A complete listing of all groups, including name, GID, and members (users), can be found in the file */etc/group*.

Once a user successfully logs in, UNIX executes the global file */etc/profile* along with the *.profile* file in the user's home directory using the user's shell specified in */etc/passwd*. If the permissions on these files are not restricted properly, an attacker could modify these files and cause unauthorized commands to be executed each time the user logs in. UNIX also updates the file */usr/adm/lastlog,* which stores the date and time of the latest login for each account. This information can be obtained via the **finger** command and creates another vulnerability: systems with the **finger** command enabled may unwittingly provide attackers with useful information in planning an attack.

ACCESS CONTROL

Standard UNIX systems prevent the unauthorized use of system resources (e.g., files, memory, devices, etc.) by promoting discretionary access control. Permissions are divided into three categories: owner, group, and other. However, privileged accounts can bypass this access control. UNIX treats all system resources consistently by making no distinction between files, memory, and devices; all resources are treated as files for access control purposes.

The UNIX filesystem has a tree structure, with the top-level directory designated as **/**. Some of the second-level directories are standards. For example, */bin* contains system executables, */dev* contains devices, */usr*

contains user files, etc. Each directory contains a pointer to itself (the '.' file) and a pointer to its parent directory (the '..' file). (In the top-level directory, the '..' file points to the top-level directory.) Every file (and directory) has an owner, a group, and a set of permissions. This information can be o btained using the **ls -l** command:

```
drwxr-xr-x   1  jlowder  staff    1024   Feb 21 18:30   ./
drwxr-xr-x   2  jlowder  staff    1024   Oct 28 1996    ../
-rw-------   3  jlowder  staff    2048   Feb 21 18:31   file1
-rw-rw----   4  jlowder  staff    2048   Feb 21 18:31   file2
-rw-rw-rw-   5  jlowder  staff    2048   Feb 21 18:31   file3
-rws------   6  jlowder  staff   18495   Feb 21 18:31   file4
```

In the above example, file1 is readable and writable only by the owner; file2 is readable and writable by both the owner and members of the 'staff' group; file3 is readable and writable by everyone; and file4 is readable and writable by the owner and is a SetUID program.

Devices are displayed a bit differently. The following is the output of the command **ls -l /dev/cdrom /dev/tty02**:

```
br--------   1   root   root   1024  Oct 28 1996   /dev/cdrom
crw-------   2   root   root   1024  Oct 28 1996   /dev/tty02
```

UNIX identifies block devices (e.g., disks) with the letter 'b' and character devices (e.g., modems, printers) with the letter 'c.'

When a user or process creates a new file, the file is given default permissions. For a process-created file (e.g., a file created by a text editor), the process specifies the default permissions. For user-created files, the default permissions are specified in the startup file for the user's shell program. File owners can change the permissions (or mode) of a file by using the **chmod** (change mode) command.

UNIX operating systems treat directories as files, but as a special type of file. Directory "files" have a specified structure, consisting of filename-inode number pairs. Inode numbers refer to a given inode, a sort of record containing information about where parts of the file are stored, file permissions, ownership, group, etc. The important thing to note about the filename-inode number pairs is that *inode numbers need not be unique*. Multiple filenames can (and often do) refer to the same inode number. This is significant from a security perspective, because the **rm** command only removes the directory entry for a file, not the file itself. Thus, to remove a file, one must remove all of the links to that file.

AVAILABILITY AND INTEGRITY

One aspect of availability is whether a system restarts securely after failure. Traditional UNIX systems boot in single-user mode, usually as root. And, unfortunately, single-user mode allows literally anyone sitting at the system console to execute privileged commands. Thus, single-user mode represents a security vulnerability in traditional UNIX. Depending on the flavor of UNIX, the security administrator has one or two options for closing this hole. First, if the operating system supports it, the security practitioner should configure the system to require a password before booting in single-user mode. Second, tight physical controls should be implemented to prevent physical access to the system console.

System restarts are also relevant to system integrity. After an improper shutdown or system crash, the UNIX **fsck** command will check filesystems for inconsistencies and repair them (either automatically or with administrator interaction). Using the **fsck** command, an administrator can detect unreferenced inodes, used disk blocks listed as free blocks, etc.

Although there are many ways to supplement UNIX filesystem integrity, one method has become so popular that it deserves to be mentioned here. Developed by Gene Kim and Gene Spafford of Purdue University, Tripwire is an add-on utility that provides additional filesystem integrity by creating a signature or message digest for each file to be monitored. Tripwire allows administrators to specify what files or directories to monitor, which attributes of an object to monitor, and which message digest algorithm (e.g., MD5, SHA, etc.) to use in generating signatures. When executed, Tripwire reports on changed, added, or deleted files. Thus, not only can Tripwire detect Trojan horses, but it can also detect changes that violate organizational policy.

AUDIT

Different flavors of UNIX use different directories to hold their log files (e.g., */usr/adm, /var/adm,* or */var/log*). But wherever the directory is located, traditional UNIX records security-relevant events in the following log files:

- *lastlog:* records the last time a user logged in
- *utmp:* records accounting information used by the **who** command
- *wtmp:* records every time a user logs in or out; this information can be retrieved using the **last** command.
- *acct:* records all executed commands; this information can be obtained using the **lastcomm** command (unfortunately, there is no way to select events or users to record; thus, this log can consume an enormous amount of disk space if implemented)

Furthermore, most versions of UNIX support the following logfiles:

- *sulog:* logs all su attempts, and indicates whether they were successful
- *messages:* records a copy of all the messages sent to the console and other *syslog* messages

Additionally, most versions of UNIX provide a generic logging utility called *syslog*. Originally designed for the *sendmail* program, *syslog* accepts messages from literally any program. (This also creates an interesting audit vulnerability: any user can create false log entries.) Messages consist of the program name, facility, priority, and the log message itself; the system prepends each message with the system date, time, and name. For example:

```
Nov 7 04:02:00 alvin syslogd: restart
Nov 7 04:10:15 alvin login: ROOT LOGIN REFUSED on ttya
Nov 7 04:10:21 alvin login: ROOT LOGIN on console
```

The *syslog* facility is highly configurable; administrators specify in */etc/syslog.conf* what to log and how to log it. *syslog* recognizes multiple security states or priorities, including emerg (emergency), alert (immediate action required), crit (critical condition), err (ordinary error), warning, notice, info, and debug. Furthermore, *syslog* allows messages to be stored in (or sent to) multiple locations, including files, devices (e.g., console, printer, etc.), and even other machines. These last two options make it much more difficult for intruders to hide their tracks. (Of course, if intruders have superuser privileges, they can change the logging configuration or even stop logging altogether.)

SECURITY FACILITIES FOR USERS

Traditional UNIX supports one privileged administrative role (the "root" account). The root account can create, modify, suspend, and delete user accounts; configure auditing options; administer group memberships; add or remove filesystems; execute any program on the system; shut the system down; etc. In short, root accounts have all possible privileges. This violates both the principle of separation of duties (by not having a separate role for operators, security administrators, etc.) and the principle of complete mediation (by exempting root from access control).

Non-privileged users can change their passwords using the **passwd** command, and they can modify the permissions of their files and directories using the **chmod** program.

MISCELLANEOUS TOPICS

Finally, there are a few miscellaneous topics that pertain to UNIX security but do not neatly fall into one of the categories of operating system

security listed at the beginning of this chapter. These miscellaneous topics include *tcpwrapper* and fundamental operating system holes.

Vulnerabilities in Traditional UNIX

Many (but by no means all) UNIX security vulnerabilities result from flaws in its original design. Consider the following examples:

1. *Insecure defaults.* Traditional UNIX was designed for developers; it is shipped with insecure defaults. Out-of-the-box UNIX configurations include enabled default accounts with known default passwords. Traditional UNIX also ships with several services open by default, password shadowing not enabled, etc. Administrators should immediately disable unnecessary accounts and ports. If a default account is necessary, the administrator should change the password.
2. *Superuser and SUID attacks.* Given that UNIX does not have different privileged roles, anyone who compromises the root account has compromised the entire system. When combined with SUID programs, the combination can be disastrous. An attacker need simply "trick" the SUID program into executing an attack, either by modifying the SUID program or by supplying bogus inputs. If the SUID program runs as root, then the attack is likewise executed as root. Given this vulnerability, SUID programs should be prohibited if at all feasible; if not, the system administrator must continually monitor SUID programs to ensure they have not been tampered with.
3. *PATH and Trojan horse attacks.* When a user requests a file, the PATH environment variable specifies the directories that will be searched and the order in which they will be searched. By positioning a Trojan horse version of a command in a directory listed in the search path, such that the Trojan horse directory appears prior to the real program's directory, an attacker could get a user to execute the Trojan horse. Therefore, to avoid this vulnerability in the PATH variable, administrators can specify absolute filepaths and place the user's home directory last.
4. *Trust relationships.* UNIX allows both administrators and users to specify trusted hosts. Administrators can specify trusted hosts in the */etc/hosts.equiv* file and users in a file named *.rhosts* in their home directory. When a trust relationship exists, a user on a trusted (remote) machine can log into the local machine without entering a password. Furthermore, when the trust relationship is defined by an administrator in the */etc/hosts.equiv* file, the remote user can log into the local machine *as any user on the local system*, again without entering a password. Clearly, this is extremely risky. Even if one

trusts the users on the remote machine, there are still two significant risks. First, the trust relationships are transitive. If one trusts person A, then one implicitly trusts everyone who person A trusts. Second, if the remote machine is compromised, the local machine is at risk. For these reasons, trust relationships are extremely risky and should almost always be avoided.

TCP Wrapper

Written by Wietse Venema, *tcpwrapper* allows one to filter, monitor, and log incoming requests for various Internet services (systat, finger, ftp, telnet, rlogin, rsh, exec, tftp, talk, etc.). The utility is highly transparent; it does not require any changes to existing software. The chief advantage of *tcpwrapper* is that it provides a decent access control mechanism for network services. For example, an administrator might want to allow incoming FTP connections, but only from a specific network. *tcpwrapper* provides a convenient, consistent method for implementing this type of access control. Depending on the implementation of UNIX, *tcpwrapper* might also provide superior audit trails for the services it supports.

Login or Warning Banner

UNIX can be configured to display a "message of the day," specified in the file */etc/motd*, to all users upon login. At least part of this message should be a so-called login or warning banner, advising would-be attackers that access to system resources constitutes consent to monitoring and that unauthorized use could lead to criminal prosecution (see Exhibit 21-3).

Exhibit 21-3. Sample warning banner.

```
WARNING: THIS SYSTEM FOR AUTHORIZED USE ONLY. USE OF THIS
SYSTEM CONSTITUTES CONSENT TO MONITORING; UNAUTHORIZED USE
COULD RESULT IN CRIMINAL PROSECUTION. IF YOU DO NOT AGREE
TO THESE CONDITIONS, DO NOT LOG IN!
```

CONCLUSION

Traditional UNIX implements some of the components of operating systems security to varying extents. It has many well-known vulnerabilities; out-of-the-box configurations should not be trusted. Furthermore, add-on security tools can supplement core UNIX services. With proper configuration, a UNIX system can be reasonably protected from would-be intruders or attackers.

Microcomputer and LAN Security

Stephen Cobb

INTRODUCTION

This chapter focuses on preserving the confidentiality, integrity, and availability of information in the microcomputer and local area network (LAN) environment. We often refer to this as the desktop environment, desktop computing, or PC-based computing.

Why Desktop Computing Matters

Although mainframe computers continue to be used extensively for such tasks as large-scale batch processing and online transaction processing, for many organizations today, computer security is, in effect, desktop computer security. Networked desktop computers are the dominant computing platform of the late 1990s, from the Microsoft Windows-based computers that some airlines use to check in passengers at airports, to the stock transaction and account inquiry systems used in banking and financial institutions, from personal computer-controlled assembly lines to PC-based medical information systems.

In many of these applications the personal computer may appear to be working as a terminal access device for a larger system. But from a security perspective it is important to understand that every personal computer system is a complete computer system, capable of input, output, storage, and processing. As such, a PC poses a much more significant threat than a dumb terminal, should the PC be subverted or illegally accessed. Furthermore, with very few exceptions, none of the desktop computing devices deployed today were designed with security in mind. Add to this the enormous increase in both the depth and the breadth of computer literacy within society over the last 10 years and you have a recipe for serious security headaches.[1]

The Approach Taken

All major aspects of desktop security will be addressed in this chapter, beginning with the need to address desktop issues within the organization's information security policies. Security awareness on the part of both users and managers is stressed. The need for, and implementation of, data backup systems and regimes is outlined. Passwords and other forms of authentication for desktop users are discussed, along with the use of encryption of information on desktop machines and LANs. There is a section on malicious code. The network dimensions of desktop computing security are explored, together with the problems of remote access.

Centralized, Layered, and Design-Based Approaches

A good case can be made for saying that desktop computer security is best handled through automated background processes, preferably centrally managed on a network.[2] Desktop computer users, so the argument goes, should not be expected to worry about backups and virus scanning and access controls. These security mechanisms should be handled for them as part of the operating system.

This sounds appealing, but there are several practical reasons why an understanding of the security weaknesses of stand-alone PCs and undermanaged LANs remains critical, and why, in at least some cases, it is necessary to implement piecemeal solutions that lack the elegance and obvious efficiency of the automated, centrally managed approach:

- A lot of desktop computers are currently connected to networks that have little hope of ever being centrally managed, yet the information they handle is still important and so warrants protection.
- Many of the methods for automating and managing security will only be applicable to, or compatible with, newer hardware and software. Older systems will remain in use and will still need to be protected.[3]
- Mature tools with which to automate and centrally manage security on local area networks are only just coming to market, and many organizations are only just realizing that they need them and will have to pay for them.
- A fairly high level of security can be achieved on both current and older personal computers with the layered approach, described next.

The layered approach to desktop security maximizes existing, but underutilized, security mechanisms, plus low-cost add-ons, through policy, awareness, and training. For example, the floppy disk drive of a PC is a major security problem. Confidential and proprietary data can be copied to a floppy diskette and smuggled out.[4] Incoming diskettes may introduce pirated software, Trojan code, and viruses to the company network. Yet the BIOS in most of today's PCs allows you to tightly control use of the floppy drive, for example, disabling boot from, read from, or write to. PC security

is considerably enhanced by implementing this type of control, which is essentially free. The layered approach would extend this protection by also requiring antivirus software on the PC and putting in place a company policy governing the use of floppy disks in the office. When employees understand the threat that a serious virus outbreak or data theft poses to their jobs, most are apt to support the policy.

DESKTOP SECURITY: PROBLEMS, THREATS, ISSUES

The problems, threats, and issues of desktop security need to be placed in perspective. A common, but dangerous, mistake is to underestimate the seriousness of this aspect of information system security. A clear understanding of desktop system architecture and its security implications is required.

The Ubiquitous Micro

Historically, desktop computers have been on the fringe of information security, which has its roots in the protection of very expensive, highly centralized, multi-user information processing systems. Today, desktop computers performing distributed computing are no longer on the fringe. Failure to realize this will undermine your ability to protect any information system, big or small, for four reasons:

1. A significant percentage of mission-critical computing is now performed on personal computers deployed as LAN work stations and network file servers.[5]
2. Most large-scale computer systems are at some point connected to one or more desktop systems. Even when PC connectivity is not specifically provided to a large system, PC access may be possible, for example, via a remote maintenance line.
3. Inexpensive and widely available desktop systems now have the power to mount attacks that endanger the security of large-scale systems, such as brute force cryptanalysis, password-cracking, and denial-of-service attacks.[6]
4. Knowledge about how to use, and abuse, desktop computers is widely dispersed throughout most areas of society and most countries of the world. This is a far less homogeneous, and thus less predictable, population than previous generations of computer users.[7]
5. Such knowledge, particularly new developments in software techniques that can be abused to compromise security, is instantly accessible via the Internet.[8]

Clearly, an understanding of desktop security is more important than ever. Desktop machines are an integral part of the client–server distributed computing paradigm that dominates the late 1990s. In the vast majority of systems, the clients to which servers serve up data are microcomputers;

the primary topology by which they do this is the local area network. Furthermore, in an increasing number of systems, the servers themselves are essentially beefed-up microcomputers. This is particularly true of the Internet, which is beginning to rival leased lines and private value-added networks as the data communication channel of choice.

Desktop System Architecture

Although you may be familiar with the following definitions they are stated here because they have important security implications which are not always understood.[9] A microcomputer is a computer system in miniature, a collection of hardware and software that is small enough to fit on a desk (or into a briefcase or even a shirt pocket) but able to perform the four major functions that define a computer system: input, processing, storage, and output. Note that processing requires both a processor and random access memory (RAM). Also note that RAM is different from storage (data that are stored remains accessible after system reset or reboot, data held in RAM are typically not accessible after system reset or reboot).

Soon after microcomputers were developed, the term "personal computer" was coined to describe these self-contained computer systems. This was later shortened to "PC" although this term is often used to refer to a specific type of personal computer, that is, one based on the nonproprietary architecture developed by IBM around the Intel 8086 family of processors (including the 80286, 80386, 80486, and Pentium chips).

Today, the majority of personal computers conform to the IBM/Intel architecture, and most of these run the DOS/Microsoft Windows operating systems (a small but significant percentage still adhere to the proprietary Apple Macintosh architecture). A separate class of desktop machines are those using the UNIX operating system. Often referred to as "work stations," these UNIX machines are typically more expensive, more powerful, and confined to specialized areas such as engineering and scientific research. While the DOS and Windows 95 operating systems use an open file system, with no provision for separate user accounts on a single machine, UNIX offers tight control of file permissions and multiple accounts. UNIX machines are often used as high-performance back-room database hosts and World Wide Web servers.

Recently, a new category of machine, the network computer or NC, has been making headlines. In many ways this is simply the re-birth of the diskless PC, several models of which were unsuccessfully marketed in the late 1980s. Both the NC and the diskless PC are machines that have their own processor and random access memory and so perform local processing, but possess no local storage devices. Their operating system is a combination of a ROM-based boot process and server-based network operating system. However, whereas the diskless PC was aimed at solving

security, management, and support problems on local area networks, the NC concept has been developed in a wide area context, specifically the Internet, and in particular, the World Wide Web.

Strict categorization of desktop systems is seldom helpful. For example, IBM/Intel-based machines can run powerful versions of UNIX, such as SCO UNIX. Both BSDI UNIX and Linux run on Intel chips and are very popular as Web servers. Furthermore, Microsoft Windows NT and IBM OS/2 both offer a multi-user, multitasking alternative to UNIX, with a familiar graphical user interface (GUI). They also allow you to use a closed file system. What may be helpful is further clarification of the terms PC, work station, terminal, server, and client.

- PC: a self-contained computer system with its own processor, storage, and output devices (the screen is perhaps the most basic of output devices). Typically, it is small enough to fit on or under a desk.
- Work station: a self-contained computer system with its own processor that is also connected to a server. A work station does at least some of its own processing and may have its own storage, but may also use or rely on the server for storage.
- Terminal: a computer access device with screen and keyboard that does not have its own processing or storage capabilities.
- Server: any computer system that is providing access to its resources to another computer system, for example, a Web server provides a browser/client with access to Web pages stored on the server.
- Client: any computer system that is accessing resources made available to it by another computer system, for example, a Web browser/client accesses to Web pages stored on a Web server.

DESKTOP SECURITY POLICY AND AWARENESS

Every organization should have an information security policy. However, field experience suggests that these policies often fail to address desktop computing issues appropriately or adequately. For example, it is common for companies to have comprehensive policies for mainframe systems that address all contingencies, but only a few specific desktop policies such as antivirus procedures written in response to specific incidents such as a virus infection.

From the Top Down

Effective information security policies are created from the top down, beginning with the organization's basic commitment to information security formulated as a general policy statement. Here is a good example of a general policy statement:

1. Timely access to reliable information is vital to the continued success of Megabank.
2. Protection of Megabank's information assets and facilities is the responsibility of each and every employee and officer of Megabank.
3. The information assets and processing facilities of Megabank are the property of Megabank and may only be used for Megabank business as authorized by Megabank management.

When a general policy like this has been agreed to by top management, each employee should be required to sign, upon hiring and each year thereafter, a document consisting of the policy statement and words to this effect:

> I have read and understood the company's information security policy and agree to abide by it. I realize that serious violations of this policy are legitimate grounds for dismissal.

Once you have a general policy like this in place, you can elaborate upon particulars. In the case of desktop systems these include:

- Password policies (e.g., minimum length, storage of passwords)
- Backup duties (for individual PCs as well as the network server)
- Data classification (rating each document for sensitivity)
- Removable media handling (e.g., who can take diskettes in or out)
- Encryption (what data will be encrypted, which algorithms to use)
- Physical security (how is equipment protected against theft/tampering)
- Access policies (who is allowed to access which machines/files)

There will also need to be policies for specific systems, for example, the accounting department LAN. These can be promulgated by the staff who have responsibility for those systems provided there is oversight and sign-off by the managers of those departments and the security staff.

The Fine Print

The task of developing detailed policy is often avoided because it is seen as too daunting. It is sometimes postponed because "there is no way to predict where information technology will go next." While this is true, you need specific policies as soon as they become feasible, plus a general policy to deal with emerging areas of concern. For example, consider the fairly recent ability to browse the World Wide Web with a desktop computer attached to the company's Internet connection. It is now possible to formulate specific policy such as "employees must not use company systems to visit Web sites that contain sexually explicit material."

However, in companies where employees have, for a time at least, enjoyed unrestricted Web access, such specific policies may be resisted (as though browsing the Web on the company's dime is a right, just like selecting your own desktop design or installing your own games). But if the company has a preexisting general policy statement that asserts ownership of information

processing assets, any restrictions on how PCs may be used can immediately be vindicated and enforced because it is clearly in keeping with that policy.

On the other hand, you have to be realistic. The desktop computing environment is inherently difficult to control and so the most effective policies are those which are understood and accepted by those who must abide by them. Developing policy by consensus is clearly more effective in this environment than policy by decree. To this end, high-level policy statements which establish the company's right to control its own computers play an important psychological role.

Desktop Security Awareness

It is not enough to develop security policies for desktop systems. Users must be told what the policies are and trained to support them. The ideal situation is a self-regulating workforce so that, for example, when Fred in engineering brings to work a game on a floppy disk that his son brought home from school the night before, Mary will refuse to put it in her PC because she knows that (1) it is a violation of security policy, and (2) it exposes her PC, and thus the company LAN, to the risk of virus infection; and (3) LAN downtime and person-hours consumed by virus disinfection have a negative effect on company profitability, which in turn has a negative effect on her earnings and employment prospects.

Raising employee security awareness to this level requires a significant training effort, but it is money well spent relative to more technology-oriented solutions. In an age of universal computer literacy it would be foolish to rely solely upon high-tech security systems, since there will always be people with the skills to challenge such defenses. You can reduce the incentive to mount such challenges by eschewing policy dictation in favor of consensus-based policy making. If employees understand and thus "buy-in" to the policy, the technical defenses can be concentrated in the areas of greatest effectiveness.

Determining those areas is an ongoing process which depends upon a different type of security awareness: that which you cultivate as a security professional. It involves staying current with the latest trends in computer insecurity, for example, new virus outbreaks, newly discovered operating system vulnerabilities, and so on. You maintain this awareness by subscribing to industry publications, participating in online forums and mailing lists, attending security conferences, and networking with fellow security professionals.

PHYSICAL SECURITY: DESKTOPS AND LAPTOPS

Efforts to thwart computer equipment theft are a good illustration of the importance of security awareness. For example, do you know the total

value of desktop computer equipment that is stolen every year in North America? The answer, according to SAFEWARE, the Columbus, Ohio-based computer insurance specialist, is quite staggering: more than $1 billion. Consider some of the security implications of desktop computer theft:

- All data on a stolen hard drive that was not backed up is now lost.
- No data can be accessed in a timely manner while backups are restored to replacement equipment.
- Certain components, such a custom cables, are hard to replace if stolen.
- Most PC-based systems depend upon a very specific configuration of hardware and software which may be difficult to replicate on replacement systems.
- Unless it was encrypted, anyone who receives a stolen PC has access to the data stored on it.
- If the stolen PC is recovered it is very hard to know whether or not someone made a copy of the data that was stored on it.

Obviously, your information security policy should mandate that backups of all data be available at all times (this typically requires off-site backup storage as a defense against backup media being stolen along with the systems backed up thereon). However, even if you are in compliance with this lofty goal, backups cannot solve every security problem. If a competitor obtains copies of your trade secrets by stealing your computers, having a backup copy is not much consolation.[10]

Awareness of current trends in computer theft will not only help you plan countermeasures, but also help you refine policy and provide timely security awareness training. The first point to note is that personal computers are now a commodity, like VCRs, camcorders, and stereos. This means they can be turned into cash very quickly, making them a target for casual thieves and those supporting drug habits. Because of their higher value-to-weight ratio, notebook computers are very popular with this type of thief.

More organized felons will target notebooks at locations such as airports, where there are rich pickings. For example, a popular tactic in recent years has been for two-person teams to steal notebooks at security check points. One thief waits until a notebook-bearing bag is placed on the conveyor belt to the X-ray machine, then holds up the line going through the metal detector (not hard to do). The accomplice waiting on the other side of the check point simply picks up the bag and departs.

While desktop systems in offices are sometimes targeted by the “smash and grab for cash thief,” the more serious risk may be sophisticated criminals stealing to order. Such thieves tend to target high-end equipment like graphics work stations, large monitors, and production-quality typesetters

and color scanners. European offices seem to be particularly vulnerable due to the high demand and relative lack of resources in former Eastern bloc countries. On occasion, Scotland Yard has recovered trucks full of expensive Apple Macintosh desktop publishing equipment stolen to order and destined for Eastern Europe.

A slightly different combination of factors led to a rash of chip heists in the early 1990s. Shortages of memory chips resulted in high prices and led to several types of theft. Europe experienced a rash of thefts in which chips were removed from office systems. Employees arrived in the morning to find desktop computers torn apart (none too gracefully) and the memory chips removed. This represents a major blow to any organization (a charity for the elderly and the Automobile Association were two of the victims). No data processing can occur until the chips are replaced. Specification of chips for used equipment is no simple matter (there are many different types and many compatibility issues). Even if you can afford the high replacement cost there may be delays obtaining chips. After all, the motive for the theft was high prices caused by a shortage.

A different type of theft occurred in chip producing areas such as America's Silicon Valley and Scotland's Silicon Glen. This involved direct, and sometimes violent, attacks on chip factories and shipping facilities. However, the motivating factors were the same: memory chips are easily resold, hard to trace, and they can have a higher value-to-weight ratio than gold or platinum.

The point of these examples is that as an information systems security professional you need to be keenly aware of the current economics of both crime and computing. As this chapter is being written, memory prices are at an all-time low, reducing the incentive for chip theft, and possibly impacting your spending on countermeasures, relative to other threats. However, if prices suddenly rise again you will need to tighten security measures in this particular area.[11] Some specific microcomputer physical security measures to consider include:

1. Good site security: this not only protects against theft, but also against vandalism, unauthorized access, and media removal.
2. Case locks: these not only deter theft of internal components, but also protect BIOS-based security services, described elsewhere in this chapter.
3. Documentation: you need to keep detailed records of all your hardware and software, including serial numbers, purchase dates, invoices, and so on. These records will be invaluable if you ever have to prove loss or reclaim stolen items that have been recovered.
4. Insurance: computer equipment typically requires separate insurance or a special rider in your business insurance or office contents

policy. Note that home contents policies often exclude computers used for work.

5. Access controls and encryption: if a computer is stolen you would like to make it as difficult as possible for the person who ends up trying to use it to access the data that are stored on the system.

DESKTOP DATA BACKUP

Clearly, the single most effective technical strategy you can employ to defend the integrity and availability of computer-based data is making backup copies, often simply referred to as backup. This is standard doctrine for most information systems professionals, particularly those familiar with the mainframe environment, where backup is an integral part of computing. However, in the desktop environment, which is based on systems that have their origins in casual, even recreational use, the task of backing up is all too often neglected until it is too late.[12]

Backup Types and Devices

Most "live" data in use today are stored on hard disk drives. While the reliability of the hard disk devices found in desktop and laptop systems has steadily improved over the last decade, they are nevertheless mechanical devices quite capable of wearing out, sometimes prematurely, sometimes without warning. Furthermore, users are only human, often lacking in formal training. Sometimes they erase important files or records within files by mistake. Sometimes they delete data out of malice. Viruses and other malicious programs can destroy files. Making backup copies of all of the files that are on a hard disk is the best, and often the only, means of recovery from mechanical failure, user error, malevolent software, natural disaster, and physical theft.

Hard drives have finite storage capacity. Eventually you have to erase files from the hard disk to make way for more. You may need to keep copies of those "surplus" files, such as last year's bookkeeping ledger. These days some people use two computers, one on the desk at work, another that travels with the user or resides in the user's home. Thus we can identify at least four different types of file copying, as listed in Exhibit 23.1.

Backups=Copies of files made to defend against loss/corruption of originals
Archives=Copies of files made to relieve overcrowding on primary storage devices
Updates=Copies of files made to synchronize files between two machines
Duplicates=Copies of files made to provide other users with copies of programs or data

Exhibit 23.1. Four Different Types of File Copying

The main focus in this section is backups, but the other categories are also important. Updates that synchronize files between desktops and portable machines are a relatively recent concern and have implications for data integrity. An archive is a set of files that has been copied as an historical record. Typically these are files containing data that will not change, and immediate access to which is no longer required, such as properly aged accounting records. When the archive copy has been created the original can be erased, thus freeing up storage space. Several terms that are useful at this point are

- Primary storage — where frequently used software and data reside.
- Online storage — storage that is immediately available and randomly accessible; this includes removable media such as floppy diskettes.
- Removable media — any media that can be physically removed from the system, such as diskettes and CD-ROMs.
- Magnetic media — storage based on magnetic properties, such as hard drives, tapes, and floppies.
- Optical media — storage based on optical properties, such as CD-ROMs.
- Magneto-optical — storage based on a combination of magnetic and optical properties, like some high-capacity cartridge drives.
- Random vs. linear access — the ability to immediately access data regardless of their physical location on the media (e.g., a hard drive) as opposed to access which requires reading preceding data (e.g., a tape drive).
- Read only — the ability to read stored data but not change it.
- Write once, read many — the ability to record data in read only form and then read it multiple times (e.g., burning a CD-ROM).
- RAID — redundant array of inexpensive disks — a storage system which combines multiple disks managed as a single storage device, allowing disks to be "hot swapped," i.e., replaced without powering down or losing data.
- Jukebox — a storage system which combines multiple tapes or CD-ROM drives managed as a single storage device with automated media switching, providing large-scale storage or backup.

In the early days of personal computing the primary means of backup, software duplication, and archiving, was the floppy diskette. A floppy diskette can be described as randomly accessible removable media, with write many/read many, as well as read only capability (by physically adjusting the write-protect setting on the disk jacket you can write-protect the contents, although this is a reversible procedure, distinguishable from

Type	Capacity	Comments
Floppy diskettes	1.44 Mb	Standard equipment Low capacity, slow, cheap, tedious.
Tape drives e.g., Travan, Exabyte, DAT	400 Mb–9 Gb	Low media cost, highly automated, most widely used.
Removable cartridges e.g., Syquest, Jaz, Zip	200 Mb–4.6 Gb	High media cost, very fast, good for online systems.
CD-ROM	650 Mb	Low media cost, slow to make, convenient access.

Exhibit 23.2. Backup Options

WORM media that is physically impossible to overwrite). The floppy diskette has several benefits:

- Low cost for both drives and media
- Included as standard equipment on all machines
- Widespread compatibility between systems

Unfortunately, hard drive capacities and the complexity of both software and data have far outstripped the capacity of standard diskettes, while possible alternatives such as high-capacity cartridge drives and read/write optical media have so far failed to achieve anything like the same level of acceptance as standard equipment. The current options for backup are listed in Exhibit 23.2. Note that some of these removable media devices also work as primary storage, for active software and live data, as well as secondary or backup storage.

While constant improvements in performance, capacity, and pricing make "best buy" statements about storage devices imprudent, there are clearly some practical points that can be made. First of all, you need to match capacity and speed to need. For example, if a desktop machine uses about 600 megabytes of hard drive storage, 5 megabytes of which is updated every day, a CD-R drive might be worth considering as an alternative to tape. But tape would be better for a system that regularly stores twice as much data and updates data at a faster daily rate. For a network file server that stores several gigabytes of constantly changing data, you will probably want to use RAID for primary storage and a jukebox for constant backup.[13]

Boosting Backup

If desktop users are on a network, part of the backup problem has been solved. Any data they store on the file server will be backed up as part of normal network management (any network file server worthy of the name will have a built-in backup device, typically tape, and any network administrator worthy of the name will use it diligently). But unless the network

work stations are diskless, there will be a residual problem of local backup. It is possible to back up local work station storage through the file server, but this is not always practical (typically the work station must be on with the user logged in but not using the machine, an arrangement that has security implications). Besides, users may be keeping some data locally on removable media, such as diskettes.

What is required is a clear policy on local backup (as well as on the use of removable media). But how do you persuade users to do better in the backup department? Make it easier to do and make people want to do it. Making people want to do something is mainly a question of education. People need to be told why backups are important, and this means more than simply saying, "Because it is company policy." A positive approach is to educate, using scenarios in which backup saves the day. Users should be made aware of the variety of ways in which data can be lost or damaged. But don't dwell too long on the negative — emphasize the comfortable feeling that comes from knowing that you have current backups.

Making backup easy to do involves some decisions about hardware and software. What backup media will be used — floppy disks, tape, optical disks, cartridges? What backup software will be used? Will computers attached to a network be backed up independently or by the network? Will macros, batch files, or automated schedule programs be used to simplify the procedures? If so, who is responsible for creating and configuring these? Beyond these are questions such as how often backup should be done, what files should be backed up, and where will the backup media be stored? You should establish explicit guidelines on these matters so that users are clear about what their backup responsibilities are. Such rules and regulations can be incorporated into an education campaign. To summarize, a general improvement in backup habits is likely to occur if you:

1. Make backup a policy, not an option.
2. Make backup desirable.
3. Make backup easy.
4. Make backup mandatory.
5. Make sure users comply with backup policy.

Backup Strategy

There is no universal path to quick and easy backup. If there was, everyone would be taking it and cheerfully doing their daily backup. The user with unlimited resources has some excellent options, the most attractive probably being optical disks. But the whole culture of personal computers is shaped by economics and the inescapable fact is that most individuals and organizations do not have unlimited resources. To make effective use of time and money devoted to backup, a backup strategy should be developed. Consider what files need to be backed up, and how often the backup

should be performed. Begin by considering the type of backup that is needed.

Image Backup. Early personal computer tape drives could only perform a complete and total backup of every file on the hard disk, referred to as an image backup. This is a "warts and all" image, a track-by-track reading of the surface of the hard disk, including hidden and system files, even unused areas and cross-linked files. This caused problems when restoring data; for example, if the hard drive to which the data were being restored was not exactly the same make and model as the original. Some systems only allowed an image backup to be restored in its entirety, meaning that bad sectors were restored along with the good. But image backup has some advantages, such as speed. By treating the contents of the hard disk as a continuous stream of data bits, a lot of time that would otherwise be spent searching the disk for parts of specific files is saved. Recently, the use of image backup has been revived by more intelligent software that eliminates the shortcomings of early systems.

File-By-File. The alternative to an image backup is a file-by-file backup in which the user selects the directories and files to be backed up. The software then reads and writes each one in turn. While this may take longer than an image backup, it allows quick restoration of a single file or group of files. A file-by-file backup can also be faster than an image backup when only a small percentage of the hard disk has been used, or if the data on the hard disk are "optimized."[14] A file-by-file backup can be complete, including all of the files on the hard disk, but this is different from an image backup. In a file-by-file backup, the files are read individually rather than as a pattern on the disk.

Data Vs. Disk. When choosing the files to include in a backup, there is some logic in omitting program files because these already exist on the original program distribution disk(s). However, a fully functioning personal computer is constantly changing. Software is fine-tuned, utility programs are added, batch files and macros created, tool bars and icons are customized, and system files are tweaked for optimum performance. Recreating a system after a major crash involves a lot more than just copying back the data and reinstalling the programs. Numerous parameters, the right combinations of which were previously determined by considerable trial and error, need to be recreated. If you have no backup of configuration or user-preference files, getting the system back to normal can be quite a challenge. A good compromise is to make a complete backup at longer intervals, while backing up changing data files more frequently.

Now consider what you want to include when performing a data file backup. For example, are font files to be included? They seldom change but can take up a lot of space. You might want to omit them from a data file

backup. The same applies to spelling dictionaries and thesauri, which do not change. However, user-defined spelling supplements that are regularly updated might need to be included.

The method you use to include or exclude files from a backup operation will depend on the backup software you are using. For example, on the Macintosh, the operating system itself distinguishes between data/document files and program/application files, so backup software on the Mac often has a simple check box to include or exclude programs. Backup software on the PC often has include and exclude parameters based on file extensions. Program files can be excluded by specifying the extensions EXE and COM, plus BAT and SYS (as well as DLL on Windows systems). If you are consistent in your file naming, you might be able to group data files by specifying extensions such as DBF, XLS, DOC, and so on.

Incremental and Differential. An incremental backup involves backing up only those files that have changed since the last backup. The idea is that successive "all data files" backups are likely to include files that were already backed up. This slows down the backup process. Interim backups can be performed that only apply to files that have been added or modified since the last backup. Operating systems can do this by checking the status of files stored along with names and other directory information. Some backup software makes a distinction between incremental and differential backups; the latter is defined as all files that are new or modified since the last full backup. This differs from an incremental backup, which is all files that are new or modified since the last backup, either full or incremental.

Note that restoring from an incremental backup, as opposed to a full backup, may require more work. Several sets of media may be required, namely the previous full backup plus all incremental backups since then. On the other hand, restoring from a differential backup requires only the last full backup plus the last differential backup. However, differential backups take up more space and take longer to perform than incrementals. Basically, incrementals are better to systems that are heavily used, like file servers on a network, whereas differentials are more appropriate for single-user systems.

Backup Regimen

The timing of backups depends on how often the information on a system changes. A personal computer might operate purely as an information bank, perhaps used to look up pricing information that seldom changes — such a system only needs to be backed up when the information is updated. But a PC that records customer orders coming in as fast as they can be typed might have to be backed up at least once a day. Most systems are somewhere between these two extremes, but remember that frequency of file changes may not be a constant factor. For example, spreadsheets in the accounting department might change quite often while the annual budget

is being prepared, but remain unchanged the rest of the year. So, the backup regimen you implement will depend on how you use your computer. The three factors that need to be weighed against each other are:

- The amount of time and effort represented by changes to files.
- The amount of time and effort represented by backing up the files.
- The value of the contents of the files.

Careful consideration of work patterns is necessary to establish an appropriate backup regimen. You can combine the three levels of backup described earlier, based on three different intervals:

Interval 3	Total backup
Interval 2	Data file backup
Interval 1	Incremental data file backup

For example, you could do a total backup once a month, a total data file backup once a week, and an incremental data file backup every day. The main point is that every backup does not have to be complete or lengthy, and a schedule mixing complete and partial backups will require less time and so stand more chance of being adhered to. One important factor to bear in mind when designing your backup schedule is the ease with which the state of your data at a specific point in the past can be recreated. For example, suppose that a virus is discovered on a hard drive and many files have been infected. A process of deduction determines that the virus was probably introduced on Monday when an employee brought in a game on a floppy disk. If incremental backup is done daily with a full backup on Friday and today is Wednesday, then one option of dealing with the virus is to erase the hard disk and then restore the previous Friday's backup. Since viruses do not infect true data files you can then restore the data files from the Monday and Tuesday incremental backups.

But what if records were accidentally erased from a database on Tuesday, and this affected spreadsheets and reports created on Wednesday, yet the error was not discovered until the following Monday? You could not use the complete backup from the immediately preceding Friday to correct this problem. You would need the complete backup from the preceding Friday, plus the following Monday's incremental backup. If this sort of problem sounds challenging, that's because it is. Getting people to create backups is only part of the problem. Restoring systems and data from those backups is quite another.

Backup Handling and Storage

Consider the physical handling of the backup media. Where will it be stored? How many copies will there be? What makes a good off-site storage location? One possible media management program is to place backup copy 1 off-site (a bank, the manager's home, a different office of the same

company). Note that simply using a fireproof safe designed for important papers is not enough. Magnetic tapes give up the digital ghost at much lower temperatures than paper ignites — you want a safe that prevents internal temperature from rising above 125°F for at least 1 hour during exposure to fire at 1500°F. After a suitable interval you make backup copy 2, which is placed off-site, while backup 1 moves to on-site storage. After another interval, you reuse the backup 1 media to make backup 3, which is placed off-site while backup 2 is moved on-site. This means the off-site backup is always the most up-to-date.

For data-intensive operations, such as order processing where large amounts of data are added or altered every day, you can use a day-by-day backup schedule such as the six-way system. You begin by labeling six sets of media as Friday1, Friday2, Monday, Tuesday, Wednesday, and Thursday. On Friday afternoon, the operator goes to the backup storage cabinet and takes out the media marked Friday1. This is used to make a complete backup of the hard disk. The media is locked away over the weekend. On Monday afternoon, the operator goes to the media cabinet and gets out media marked Monday. This is used to make an incremental backup, overwriting the previous data on the media. The same thing happens on Tuesday through Thursday. Incremental backups are made each day on media marked for that day of the week.

When Friday rolls around again, the Friday2 media is used for a new complete backup. On Monday the incremental backup is made onto the Monday media, and so on, until Friday comes around again and you overwrite Friday1 with another complete backup. This system gives you a maximum archive period of two weeks. For example, on Fridays before you perform the Friday backup you have the ability to restore data from one or two Friday's ago. On any day of the week you can restore things to the way they were on same day of the previous week.

This system has several advantages. The time required for an incremental backup is generally far less than that for a full backup, making the daily routine less burdensome. Nevertheless, if restoration is required, a full set of data can be put together. If you simply use the same backup media every day, this type of recovery is not possible. A variation of this six-way routine, sometimes referred to as the father/son backup cycle, requires eight sets of media with the additional ones being called Friday3 and Friday4 so that your archive goes back a whole month.

Yet another backup cycle is the ten-way or grandfather/father/son system. This covers 12 weeks and allows you to delete data from your hard disk and retrieve it up to 3 months later. A variation of this scheme involves removing some of the complete backups from circulation at regular intervals for archive purposes, for example, once a month or once a quarter.

One advantage of this is a gradual replacement of media, which have a natural tendency to wear out from repeated use.

Give some thought to the time of day that backups are performed. It seems natural to do the backup at the end of the day, then lock the media away or take it off-site. Because some backup systems, such as tape units, allow backups to be triggered automatically, some people leave systems on overnight and have the backup performed under software control. This minimizes inconvenience to users, and leaving systems running is not considered detrimental to their health or reliability (although monitors should be turned down or off). However, even if the hardware performs reliably, there is a problem because the backup is being performed during a period of high risk.

Theft of computers, tampering with files, or disasters such as fires can progress with less chance of detection during the night. An unsupervised overnight backup operation is no protection against these threats. Indeed, if the backup media sits in the computer until a human operator arrives in the morning, it can make a nice present to someone looking to steal data. Doing backup first thing in the morning might seem like the answer, but again, an overnight attack threatens a whole day's worth of work. Besides, backup operations tend to tie up processing time and thus prevent systems from being used, which can make backing up in the morning counterproductive. One solution available to companies with an evening shift is to have them perform the backup and lock up the media before leaving. Indeed, with larger networks it will be necessary to budget staff specifically for this task.

Remote Backup Strategies

Off-site storage of backups is a strong defense against two serious threats, physical theft and natural disaster. However, some off-site storage options pose practical or tactical problems. Requiring staff to take backup media home with them imposes a considerable burden of responsibility, and requires a high degree of trust. Most banks are not set up to receive magnetic media for safe deposit outside normal banking hours. Fortunately, numerous companies now specialize in off-site storage of media, such as Arcus Data Security, DataVault, and Safesite Records Management.

Safesite's SafeNet service provides off-site storage and rotation of file server backup tapes. Outgoing tapes are placed in foam shipping trays and air-freighted overnight to secure vaults where they are bar coded and stored in a halon-protected environment that is fully temperature and humidity controlled. You pay a weekly fee for this service. Other companies operate at a local level, offering daily pickup and delivery of backup media according to standard rotation schedules. This has the added benefit of reinforcing backup regimes.

One step beyond physical off-site collection and delivery of backup media is remote off-site backup. In other words, your computers are backed up automatically, over phone lines, to a remote location, a strategy known as televaulting. This not only provides protection against theft and natural disasters at your site, it also provides insurance against errors and failures in your normal on-site backup systems. A pioneer and leading supplier of this type of service is Minneapolis-based Rimage Corporation (while the company headquarters are in Minneapolis, all its eggs are not in one basket — Rimage operates backup sites in New York and Atlanta, plus one near Los Angeles and another near San Francisco).

DEFEATING VIRUSES AND OTHER MALICIOUS CODE

One of the most persistent threats to the confidentiality, integrity, and availability of data entrusted to desktop systems, is malicious code, the most common form of which is the virus. A computer virus is self-replicating code designed to spread from system to system. Thousands of different viruses have been identified, although only a few hundred are active. This is software which can erase files, bring down networks, and waste a lot of person power and processing time. There are several types of programs, besides viruses, that can be grouped together as malicious code, or MC, although each type poses a different threat to the integrity and availability of your data.

The Malicious Code Problem

Based on numerous studies it is possible to say that malicious code has caused billions of dollars worth of damage and disruption over the last five years.[15] Malicious code has affected everything from corporate mainframes and networks to computers in homes, schools, and universities. Despite impressive advances in defensive measures, malicious programs continue to pose a major threat to information security. A key member of IBM's antivirus team, Alan Fedeli, uses the following as simple, working definitions of the three main problems for PC and LAN users:

- Virus: a program which, when executed, can add itself to another program, without permission, and in such a way that the infected program, when executed, can add itself to still other programs.
- Worm: a program which copies itself into nodes in a network, without permission.
- Trojan horse: a program which masquerades as a legitimate program, but does something other than what was expected, (as in the deceptive wooden horse used by the Greek army to achieve the fall of Troy).

Note that while viruses and worms replicate themselves, Trojan horses do not. Viruses and worms both produce copies of themselves but worms do so without using host files as carriers.

A fourth category of malicious code, the logic bomb, has historically been associated with mainframe programs but can also appear in desktop and network applications. A logic bomb can be defined as dormant code, the activation of which is triggered by a predetermined time or event. For example, a logic bomb might start erasing data files when the system clock reaches a certain date or when the application has been loaded × number of times. In practice, these various elements can be combined, so that a virus could gain access to a system via a Trojan, then plant a logic bomb, which triggers a worm.

The practical objection to viruses and worms, Trojan horses, and logic bombs, is that no programmer, however smart, can write code that will run benignly on every computer it encounters. Commercial software developers like Microsoft, which spend millions on software development and testing, cannot create such code, even when an elaborate installation program is used. The number of hardware permutations alone is staggering (with 12 alternatives in 12 categories you get 8,916,100,448,256 possible combinations). Quite simply, you cannot write benign code which can insert itself unannounced into every system without causing problems for at least some of those systems.

About Viruses

According to Dr. Peter Tippett, President of the National Computer Security Association, even if virus code does not try to cause harm, "most of the damage that viruses cause, day in and day out, relates to the simple fact that contamination by them must be cleaned up. The problem is that unless you search through all the personal computers at your site, as well as all the diskettes at your site, you can have no assurance that you have found all copies of the virus that may have actually infected only four or five PCs. Since viruses are essentially invisible the engineer must actually go looking for them on all 1000 PCs and 35,000 diskettes in an average corporate computer site. And if even a single instance of the virus is missed, then other computers will eventually be reinfected and the whole clean-up process must start again."

Further light is shed by IBM's Al Fedeli who notes that "While viruses exhibit many other characteristic behaviors, such as causing pranks, changing or deleting files, displaying messages or screen effects, hiding from detection by changing or encrypting themselves, modifying programs and spreading are the necessary and sufficient conditions for a program to be considered a virus." The very act of modifying files means that the presence of a virus causes disruption to normal operation, in addition to which the virus program can be written to carry out a specific task, like playing a tune at a certain time every day. In a mix of metaphors, such a virus task is referred to as a payload, and the event that releases or invokes it is referred

to as a trigger. This might be a date or action, such as booting up the machine. Some payloads are very nasty, such as corrupting the file allocation table (FAT) on a disk and thus rendering files inaccessible.

A lot of viruses attack operating system files, meaning that they have the potential to disrupt a wide range of users. Other viruses attack a particular application. Consider the virus that attacks dBASE data files, stored with the DBF extension. The virus reverses the order of bytes in the file as it is written to disk. The virus reverses them back to normal when the file is retrieved, making the change transparent to the casual user. However, if the file is sent to an uninfected user, or if the virus is inadvertently removed from the host system, the data are left in a scrambled state.

Before moving on to Trojan horses, it is important to point out that although some people say there are thousands of viruses to worry about, as of early 1997, only a few hundred were "in the wild." This term is reserved for viruses that have actually infected someone, somewhere. It is important to distinguish this small number of "in the wild" viruses from the much larger number of "in the zoo" viruses. We use this term to describe a virus that has never been seen in a real-world situation (believe it or not, some people who write viruses send them to antivirus researchers, which is one reason the population of the zoo far outnumbers that of the wild).[16]

The Trojan Horse

According to Rosenberger and Greenberg, "Trojan horse is a generic term describing a set of computer instructions purposely hidden inside a program. Trojan horses tell programs to do things you don't expect them to do." The original Trojan horse held enemy soldiers in its belly who thus gained entrance to the fortified city of Troy. In computer terms, a seemingly legitimate program is loaded by the user, but at some point thereafter malicious code goes to work, possibly capturing password keystrokes or erasing data.

An example appeared in 1995 when someone started distributing a file described as PKZIP 3.0, the long-awaited update of PKZIP version 2.04g, an excellent file archiving tool. Naturally, since the purpose of PKZIP is to compress and decompress files, version 2.04g was distributed as a self-extracting file. That is, it was executed as a program at the DOS prompt. PKZIP 3.0 was also made available on bulletin boards as an executable file, but it was not a self-extracting archive. Instead it was a Trojan horse that attempted to execute the DELTREE and FORMAT commands. Although clumsily written, it sometimes worked and some people lost data (one defense against such programs is to rename, remove, or relocate potentially destructive commands like FORMAT and DELTREE).

The Worm

According to virus experts Rosenberger and Greenberg, a worm is similar to a Trojan horse, but there is no "gift" involved: "If the Trojans had left that wooden horse outside the city, they wouldn't have been attacked from inside the city. Worms, on the other hand, can bypass your defenses without having to deceive you into dropping your guard." The classic example is a program designed to spread itself by exploiting bugs in a network operating software, spreading parts of itself across many different computers that are connected into a network. The parts remain in touch with, or related to, each other, thus giving rise to the term *worm*, a segmented insect. Naturally, this has a disruptive effect on the host computers, eating up empty space in memory and storage, and wasting valuable processing time.

The best-known example is the Internet worm which consumed so much memory space and processor time that eventually several thousand computers ground to a halt (the Morris/Internet worm has been exhaustively analyzed and documented on the Web). More destructive worms might erase files. Even without malicious intent, communications on the network are likely to be disrupted by any worm as it attempts to grow from one area to another. Most people agree that a worm is typified by independent growth rather than modification of existing programs. The difference between a worm and a virus might be characterized by saying a virus reproduces, while a worm grows.

The Code Bomb

One of the oldest forms of malicious programming is the creation of dormant code that is later activated or triggered by specific circumstances. Typical triggers are events such as a particular date or a certain number of system starts. Stories abound of disgruntled programmers planting logic bombs to get back at employers deemed to have been unfair. Several logic bombs have been planted in order to extort money. You have to pay up or find the malicious code and remove it. The latter option can be extremely costly when the system is a large mainframe computer.

Defenses Against MC

The layered approach to security that we advocate can provide a head start in defending against malicious code. To briefly reiterate the elements of this layered approach, they are

- Access control
  - Site — controlling who can get near the system.
  - System — controlling who can use the system.
  - File — controlling who can use specific files.

- System support
  - Power — keeping supply of power clean and constant.
  - Backup — keeping copies of files current.

The three access control items provide positive protection against infection, while the last item under System Support, backup, allows you to recover from a virus attack. However, we now add a third layer of System Support, namely Vigilance — keeping tabs on what enters or attempts to enter the system. By exercising vigilance, users and administrators alike can prevent, or at least minimize, the effects of malicious programming. To be vigilant, users need to know what they are defending against. This means:

- General training in malicious code awareness.
- Constant updating of defenses to remain effective against a threat which continues to evolve.
- An ongoing program of security checking, review, and retraining.

In the case of the most prevalent malicious code threat, viruses, vigilance means:

- Knowing what viruses are, the methods of attack they use, and what constitutes a healthy regimen of computer operation and maintenance.
- The use of hardware and/or software that prevents or warns of virus attacks (typically, software of this type needs to be updated on a regular basis in order to remain effective).
- Hardware and software buying choices might be affected, with systems and programs that are more inherently virus-free being preferred.

Staying Abreast

To be effective against malicious code you must keep abreast of the latest threats. Fortunately, this is now a lot easier than it used to be. There are a number of online sources that are sure to report new developments:

- NCSA forums on CompuServe
- NCSA pages on the Web
- Forum/Web page/BBS hosted by your antivirus vendor
- VIRUS-L news group

For the small/home office user we recommend checking in with one or more of these sources once a week. After all, it only takes a few minutes. For larger organizations we suggest that someone, probably on the support staff, be assigned the task of making a daily check.

Basic Rules

Being vigilant about the files that enter your system will go a long way towards protecting it from malicious code. If you use access controls to

extend that vigilance to the times when you are not around to oversee what is happening to your computer, you should avoid the immediate effects of malicious code attacks. To sum up the defensive measures discussed here, the following rules can be promulgated, first for the individual user, and then for the manager of users.

1. Observe site, system, and file access security procedures.
2. Always perform a backup before installing new software.
3. Only use reputable software from reputable sources.
4. Know the warning signs of a malicious program.
5. Use antivirus products to watch over your system.
6. Use an isolated machine to test software that might be suspect.

Rules for managers of users:

1. Make sure that access control and backup procedures are observed by all users.
2. Check all new software installations, floppy disks, and file transfers with an antivirus product.
3. Forbid the use of unchecked or unapproved software, floppy disks, or online connections.
4. Stay informed of latest developments in malicious programming, either through an alert service or by tasking in-house staff.
5. Keep all staff informed of latest trends in malicious code so that they know what to look for.
6. Make use of activity/operator logging systems so that you know who is using each system and what it is being used for.
7. Encourage the reporting of all operational anomalies and match these against known attacks.

Boot Sector Viruses

This type of infection hits your computer just as it loads the operating system. Most common on IBM-compatible machines, boot sector viruses can also be created for other systems (the "first" virus was an Apple II boot sector virus). Boot sectors are what get the operating system loaded into memory after you power-up the system (cold boot), or perform a hard reset (usually using a button on the front of the machine). On IBM-compatible machines, the instructions stored in the BIOS, which cannot themselves be infected by a virus since they are burned into ROM (Read Only Memory), load information from the Master Boot Sector and DOS Boot Sector into RAM, after performing the POST (Power On Self Test) and reading data, such as the time, from CMOS (which can be corrupted by viruses).

According to Virus Bulletin's description "boot sector viruses alter the code stored in either the Master Boot Sector or the DOS Boot Sector. Usually, the original contents of the boot sector are replaced by the virus

code…. Once loaded, the virus code generally loads the original boot code into memory and executes it, so that as far as the user is concerned, nothing is amiss." This might be accomplished by virus code in the boot sector that points to a different section of the disk. So the virus code is in memory and the user is none the wiser. The virus may then infect the boot sector of any floppy disk that is used in the machine's floppy disk drive, thus passing the infection on. While this is rather clever, it would seem to be an inefficient means of replicating now that so many people boot from a hard disk. If everyone cleaned their hard disk boot sector it would appear that extermination of boot sector viruses would be achievable.

Unfortunately, this overlooks the fact that there are boot sectors on ALL floppy disks, not just those that are bootable system disks. And we have all made the mistake of turning on or resetting a system with a floppy in drive A. If the floppy disk is not bootable, for example, if it is a data or program installation disk, we get the "Non-System disk or disk error. Replace and strike any key when ready" message. Alas, at that point the boot sector virus is already in memory. Indeed, that message is read onto the screen from the boot sector. Taking the floppy out and pressing "any key" will not clear the virus from memory, and besides, it may have already infected the hard disk. Note that the Macintosh uses a combination of hardware design and operating system software to spit out floppy disks when booting, thus considerably reducing the chances of this type of infection.

Even without the Mac's method of handling floppies, the solution appears quite simple: don't leave floppies in drive A, and if you do get the Non-System error message, reset the system instead of pressing "any key" when you get the message. Better still, if you have a newer BIOS that allows you to adjust the drive boot sequence, tell it to boot from C before A (this still allows you boot from a floppy if something happens to drive C). Well-known boot sector viruses include Michelangelo, Monkey.B, and perhaps the most widely occurring viruses of all time, Stoned and Form.

While at first it sounds like you could only catch a boot sector virus from a floppy disk, the threat is slightly more complex thanks to the folks who enjoy placing boot sector viruses in Trojan horse or "bait" files and then uploading them to bulletin boards. These files are designed to place the boot sector virus on your system when you execute them (ironically, these programs accomplish this task with a routine known as a "dropper," originally developed to allow the transfer of boot sector viruses between legitimate researchers and antivirus programmers).

Parasitic Viruses

More numerous than boot sector viruses but less prevalent, parasitic viruses are also referred to as file infectors, because they infect executable files. According to Virus Bulletin "they generally leave the contents of the

host program relatively unchanged, but append or prepend their code to the host, and divert execution flow so that the virus code is executed first. Once the virus code has finished its task, control is passed to the original program which, in most cases, executes normally." While such a complex operation sounds at first like it would be immediately noticeable to the user, this is often not the case since virus code is typically very compact. The temporary diversion of program flow is often indiscernible from normal operations.

Multipartite and Companion Viruses

You now know what boot sector and file infector viruses do. Put the two together and you have multipartite viruses, such as Tequila, which are capable of spreading by both methods. At the other end of the sophistication scale are companion viruses which take advantage of this simple fact about DOS: if you launch a program at the DOS prompt by entering its name, as in FORMAT, and DOS finds that there are two program files in the current directory, one called FORMAT.COM and the other called FORMAT.EXE, the COM file will be executed before the EXE file. A companion virus thus hides and spreads as a COM variant of a standard EXE file. Examples include the rare AIDS II and Clonewar viruses.

Other Types of Virus

Link viruses are a type of virus rare in the wild, despite the fact that they have considerable potential for spreading rapidly owing to the way they manipulate the directory structure of the media on which they are stored, pointing the operating system to virus code instead of legitimate programs. Academic viruses researchers and underground virus writers both spend a lot of time thinking about new ways in which viruses may be spread. This leads to many "in the zoo" or "in theory" viruses which exist more on paper than in practice. Several approaches to infection that fit into this category are source code and object code viruses. The idea behind a source code virus is to insert virus instructions into programs at the source code level, rather than through the compiled program.

A source code virus would add itself to the source code file, then get compiled into the executable file when the program code was compiled. From the complied program the virus code then seeks out further source code files to infect. This method of infection could be quite effective in some environments since most source code files have common and easily identifiable attributes, such as file extensions (like .C and .BAS). There is little evidence of such viruses on desktop machines, but widespread use of an interpreted language, like Microsoft Visual Basic, could make this an appealing path for infection.

To understand the object code virus, of which at least one example, Shifting_Objectives, has been discovered, you need to know that all of the source code for a complex program, such as Microsoft Windows or Microsoft Excel, is not compiled into one large EXE or COM file. Instead, these programs use sections of code, called objects, that are loaded into RAM and linked together only when they are needed. Programmers like to write code in the form of objects because these can be recycled very easily. For example, if treated as an object, the code required to create a dialog box can also be used in many places within a program, without the programmer having to code each dialog box individually. By infecting an object rather than an executable, the object code virus makes itself less open to normal methods of detection (for example, many antivirus strategies concentrate on protecting and monitoring executable files).

The term *kernel* is used to describe the core of the operating system. In DOS, for example, the kernel is stored in the hidden file IO.SYS. The idea behind a kernel infector, of which there are currently very few, is to operate at one level above the boot sector, but within the heart of the operating system, replacing the instructions in the real IO.SYS with its own agenda. This makes the virus more difficult to track than if it infected visible COM files such as COMMAND.COM. By loading its own code into memory ahead of the operating system the virus can achieve "stealthing" to avoid many traditional forms of virus detection.

Stealth and Polymorphism

Stealth viruses use traditional techniques for infection, such as boot sectors and executable files, but they have code which stays in memory to monitor and intercept operating system calls, thus disguising its presence. As Jonathan Wheat, one of the antivirus experts at NCSA puts it, "When the system seeks to open an infected file, the stealth virus leaps ahead, uninfects the file and allows the operating system to open it, so that all appears normal. When the operating system closes the file, the stealth virus reverses the actions, reinfecting the file. If you look at a boot sector on a disk infect by a stealth boot sector virus what you see looks normal, but it is not the real boot sector." Stealth viruses pose numerous problems for traditional antivirus products, which may even propagate the virus as they examine files when looking for infections.

The term *polymorphic* is used to describe computer viruses that mutate to escape detection by traditional antivirus software which compares suspect code to an inventory of known viruses. Polymorphic viruses can infect any type of host software. Polymorphic file viruses are most common, but polymorphic boot sector viruses have also been discovered (virus writers use a free piece of software called the Mutation Engine to transform simple

viruses into polymorphic ones, which ensures that polymorphic viruses are likely to further proliferate).

Some polymorphic viruses have a relatively limited number of variants or disguises, making them easier to identify. The Whale virus, for example, has 32 forms. Antivirus tools can detect these viruses by comparing them to an inventory of virus descriptions that allows for wildcard variations. Polymorphic viruses derived from tools such as the Mutation Engine are tougher to identify, because they can take any of four billion forms!

Macro Viruses

Viruses do not need to be written in assembly code or a higher language such as C. They can be written using any instruction set. Ask anyone who has worked with macros in programs such as 1-2-3 or Excel, WordPerfect, or Word, and you will discover that these work just like a programming language. As macros evolved from their origins in the 1970s in word processing (storing multiple keystrokes under one key) to spreadsheets in the early 1980s (enabling complex menu branches of conditional commands) they acquired a vital ingredient for virus making, automatic execution.

Of course, the purpose of automated operation was to enable the creation of easy-to-use, macro-driven applications for less-experienced users. In the mid to late 1980s this became a major activity within some organizations. Macro power increased, driven by power users of programs like 1-2-3 who worked hard to reduce complex operations, such as invoicing, to simple macro menus. Macros acquired the ability to execute operating system commands and further extended their power in the early 1990s when software designers introduced cross-application macro languages, such as WordBasic. The result is a class of computer file which appears at first to be a data file, but which may actually contain a program of macro commands.

This further blurred the distinction embodied in the oft-repeated advice that "your computer cannot be infected by a document" and "you can only be infected by programs." These statements only remain true if we carefully define documents to exclude those containing macros (and any other pseudo-language such as PostScript, which can trigger hardware events when transmitted to a printer) and define programs to include executable code in the widest sense (including ANSI codes, which could execute some unwanted actions if placed in e-mail that was displayed in text mode).

Ironically, Microsoft's domination of the software market in the mid 1990s provided the final ingredient for a "document" virus outbreak, that is, a universal, transplatform application — Microsoft Word. In late August of 1995 people learned that there was a dark side to the compatibility benefits of a *de facto* standard for word processing. A new virus came to light, capable of being spread through the exchange of Microsoft Word documents.

The virus, named Winword.Concept, replicates by adding internal macros to Word documents. If the virus is active on a system, an uninfected document can become infected simply by opening it and saving it using the "File Save As" menu option. Although Winword.Concept does not cause any intentional damage to the system, some users have reported problems when saving documents.

The macro virus becomes active when you open an infected document, doing so via Microsoft Word's "AutoOpen" macro, which executes each time you open a document. If you open an infected document with Word, the first thing the macro virus does is check the global document template, typically NORMAL.DOT, for the presence of either a macro named PayLoad or FileSaveAs. If either macro is found, the routine aborts and no infection of the global document template occurs. However, if these macros are not found, then several macros are copied to your global document template. During the course of copying the macros a small dialog box with an "OK" button appears on the screen. The dialog box simply contains the number "1" as its only text. The title bar of the dialog box indicates it is a Microsoft Word dialog box. This dialog will only be shown during the initial infection.

Once these macros are added to the global document template, they replicate by means of the virus version of "File Save" command. Consequently any document created using File Save As will contain this macro virus. An uninfected user can simply open the document and become infected. This can even happen while you are online to the World Wide Web, if you have your Web browser configured to use Word as the viewer for DOC files (the remedy is to use a viewer program such as Word Viewer, instead, as described later in this chapter). Note that the "PayLoad" macro contains the following text:

```
Sub MAIN

        REM That's enough to prove my point

End Sub
```

However, "PayLoad" is not executed at any time. Because of the flexibility of Microsoft's WordBasic macro language, almost anything could be performed here (including a file delete or other potentially damaging operating system commands). Also note that Word is available in many different languages, and in some versions the macro language commands have also been translated. This has the effect that macros written with the English version of Word will not work in, for example, the Finnish version of Word. The result is that users of such a national version of Word will not get infected by this virus. However, using an infected document in a translated version of Word will not produce any errors, and the infection will stay intact even if the document is re-saved. Under these circumstances

you should check for the presence of the virus in any case, in order not to spread infected DOC files further.

There are some preventative measures built into Word that are supposed to control automatic macros. For example, the Word for Windows manual states that if you hold down Shift while double-clicking the Word icon in Program Manager, then Word will start up with file-related "autoexecute" macros disabled. However, while this ought to inhibit the actuation of some macro viruses like WinWord.Nuclear, which relies on this feature, many users have found that it doesn't work. They also found that starting up Word with the command line WINWORD.EXE/m, which is supposed to achieve a similar effect, failed as well, as did holding down Shift while opening a document to disable any automatic macros in that file. Furthermore, many companies have invested a lot of development time in automatic Word macros to automate routine tasks. The best strategy for preventing infection is thus to scan all incoming documents. All products that achieve the NCSA's antivirus certification (listed at www.ncsa.com) are capable of spotting macro viruses.

ACCESS CONTROLS AND ENCRYPTION

Earlier it was noted that access controls and encryption are a defense against the compromise of data on stolen systems and storage media. For example, if a laptop system is stolen but the bulk of the data on the machine are stored in encrypted files, it is unlikely that the thief, or the person to whom the machine is fenced and ultimately sold, will gain access to the data.

Unfortunately, encryption is an example of security's two-edged sword. For example, the very feature that makes a notebook easier to secure physically (the small size — it can be locked away in an office drawer or a hotel-room safe) also makes it easier to run off with. Similarly, the technology that renders files inaccessible to the wrong people, encryption, can be abused to deny access to legitimate users (in the last 12 months we have received several calls from companies wanting help in retrieving their own data, encrypted by a disgruntled employee who refuses to share the password — payment is sometimes demanded, leading to the term *data ransoming*).

Nevertheless, it is better to use the digital protection schemes that are available than risk data loss or compromise. Start with the BIOS. Most laptops and desktops produced in recent years have a decent set of BIOS-based security features. For example, the trusty three-year-old Compaq Concerto on which this chapter is being written allows the user to "hot lock" with a single keystroke, preventing anyone from using the mouse or keyboard unless they can enter the correct PIN. This can be set to kick in at system startup, thus defending against a reboot attack. Beyond this, you

can disable the floppy drive, even block the ports, and all with a security program that has a Windows interface. Getting around this protection would require taking the machine apart and knowing just how to drain current from the CMOS.

Beyond BIOS-based protection you have the option of installing encryption software to scramble the contents of files so that they are useless to anyone who doesn't have the password/key. Encryption programs can operate at different levels. You can choose to encrypt just a few very valuable files on a file-by-file basis. This is simple and straightforward with something like Nortel Entrust Lite, McAfee's PC Secure, RSA's SecurPC, or Cobweb Application's KeyRing. These programs are particularly useful when you want to transmit files by e-mail, which remote users often need to do. If you routinely need to encrypt your e-mail messages, as opposed to file attachments, then PGPMail or ConnectSoft's Email Connection may be the way to go (the latter supports the S/MIME standard and requires a password before you can even run the program).

The next level of encryption is a designated area on the hard disk, in which all files stored are automatically encrypted. This is possible with programs like Utimaco's Safe Guard Easy products, which perform on-the-fly encryption. In other words, encryption and decryption are made part of the normal file save and open process. This can be more convenient in that constant entering of passwords is not required, but then again, if the master password is compromised the attacker may gain access to more data than if each file had a separate password. Program's like Symantec's Norton Your Eyes Only can actually encrypt everything on the entire hard disk, if that is what you want to do.

If you do use encryption you will need to take passwords seriously. The use of a master password, which unlocks all files you have encrypted, can simplify this, but it also increases the amount you have riding on one single password. Separate passwords for each file presents a management problem. Then there is the dilemma of easy-to-remember passwords, like your name, being easy for interlopers to guess, vs. long, obscure, and hard to crack passwords that you are tempted to write down, and thus compromise, just because they are hard to remember.

Also, there is the temptation to use the same password in different situations, which can lead to compromise. For example, it is relatively easy to crack the standard Windows 95 screen-saver password. So, you shouldn't use the same password for the screen-saver that you use for network login or sensitive file encryption (alternatively, you can use a more powerful screen-saver, such as Cobweb Application's HideThat).

Several encryption solutions attempt to go beyond passwords. For example, Fischer International offers a hardware key that fits inside a

floppy disk drive. Companies like Chrysalis and Telequip make PCMCIA cards that not only store encryption keys but also perform encryption calculations, thus mitigating some of the performance hit that encryption can impose. Encryption programs like Entrust can store passwords on floppy disks, which allows them to be kept separate from the computer where the encrypted files are stored. Keep that in your pocket when you leave your laptop behind and at least you will know that nobody can get to your files, even if they steal your machine.

DEFENDING THE LAN

The first personal computer networks were installed in the mid 1980s, allowing users to share, for purposes of efficiency, productivity and cost-saving, their storage devices, printers, and software. Naturally, these networks started out small, hence the term local area network. They were often informal, employed by a group of users who knew and trusted each other, and so people paid little attention to the security implications of this new type of computing.

Peer-to-Peer Networks

Typical of this phase of networking is the peer-to-peer network, in which each computer on the network has an equal ability to make its resources available to all the others. Examples are Appletalk, standard on the Apple Macintosh since 1984, Microsoft Windows for Workgroups, and Novell Personal NetWare. Microsoft continues to provide peer-to-peer networking in Windows 95 and Windows NT Workstation. The ease with which users of peer-to-peer networks can share files and printers is both appealing and alarming.

If you work with a small group of trusted colleagues, this approach to networking can be both convenient and efficient. But as such networks grow, systems become harder to manage, and trust is spread thinner. Access is difficult to control, because the network operating system was not designed with control in mind. All connections between a peer-to-peer network and other systems, such as the Internet or a dial-up line for a remote user are a security threat. For example, unless specific and nonobvious precautions are taken, any machine on a Windows 95 peer-to-peer network which dials out to the Internet immediately creates a path by which any other system on the Internet can access your shared resources.[17]

Server-Based Networks

Novell's main Netware product has always been a server-based network operating system and this path was followed by IBM, and later Microsoft (in the form of Microsoft LAN Manager which has evolved into Windows NT Server). Note that PCs connected to a network file server as clients act as

work stations, not terminals. In other words, they do not give up their ability to locally input, process, store, and output. Furthermore, unless they are logged onto the network, the network cannot have any effect on their security, which has serious implications. For example, when a PC has been logged off, the network operating system cannot control access to directories on its hard drive or prevent the user running locally stored applications.

Similarly, the network file server may scan both server and client directories for malicious code, but it cannot scan clients when they are not clients, that is, when they are logged off. This means that viruses can still infect machines that are part of the network. When an infected local machine later logs onto the network, it can spread the virus to the server.

While it is typical for the network file server to require that only authorized users, with valid users name and passwords, be allowed to use network resources, the network itself cannot identify users who do not log on. Theft, destruction, or corruption of data that are stored locally on a client is thus entirely possible, unless additional controls are in place. However, some interesting variations are possible when PCs are networked. For example, it is possible to configure desktop machines so that they cannot be operated unless they are logged onto the network. This can be achieved by extending the BIOS-based security described earlier (other examples of enhanced BIOS include alerting the network if the PC is logged off or disconnected).

Network Computers

If access to local storage is also blocked at the BIOS level, or removed completely, then the desktop computer becomes a truly dedicated client, useless without its properly authenticated network connection. Of course, some might argue that the machine is no longer a "personal computer," but from a security perspective the response is likely to be "so what?" In fact, today's networking technology allows the network to provide users with their own server-based storage and their own customized applications and settings, without the need for local storage. This facilitates centralized management of security tasks such as backup, authentication, and malicious code scanning.

The personal computer (PC) is thus transformed into the network computer (NC), a reincarnation of the diskless work stations that flopped in the 1980s. Back then, server-based software was far less exciting than the code you could run on stand-alone desktop machines, which were first adopted by eager do-it-yourself programmers who were people with a natural aptitude for productive use of the technology. Now that more than 50% of the workers in America have to use a computer of some kind, there is less need for each one of those computers to be personally managed and controlled.

From a security and management perspective, the NC is clearly a step forward, a cost-effective one at that. It is not unreasonable to suggest that individuals who still need or want a truly personal computer can either use their own machine at home, or use a nonnetworked system at the office. In any event, organizations should not lose sight of the fact that the "personal" computers it provides to its employees are actually the property of the organization, which is free to control the manner in which they are used, particularly when some uses such as Web surfing can increase risks to valuable data, not to mention the negative impact on productivity.

Network Security Implications

Constant improvements in hardware and software enabled LANs to grow in size and power. By the early 1990s some LANs had evolved into mission-critical information systems. The security implications increased dramatically but, even when network managers have had time to think about these implications, they have often lacked the resources and tools with which to address them. Furthermore, because many of these PC-based networks resembled the familiar paradigm of a powerful central computer supporting numerous, less powerful machines, many people assumed that the security problems could be solved in familiar ways, such as (1) give users password protected network accounts and don't let anyone log onto the network unless they can supply a valid account name and password; and (2) perform regular backups.

In practice, (2) has been easier to achieve than (1), but in a typical LAN environment (2) offers less protection than you might expect. The reason is simple. As was noted earlier, desktop computers are computers, they are not terminals. A desktop computer runs its own operating system under local control, does its own processing, has its own storage and its own input and output capabilities. Of course, you can try and make a desktop computer emulate a terminal, but unless you turn it into a terminal it will still be a computer.

Of course, there are many positive reasons for increased intercomputer communications, such as:

- Cost savings from sharing resources
- Productivity gains from faster, better communications and information sharing.

There are also potential security benefits. Any serious network operating system, or NOS, contains security features, and every NOS is more mindful of security than the popular desktop operating systems. The centralized storage of information that comes with server-based networking makes that information easier to protect, at least in terms of backup.

But these gains come with risks attached. Connecting two computers opens up a new front for the attacker who can exploit the connection, either to get at the data being transferred, or to penetrate one or more of the connected systems. Simply put, establishing a connection between two or more computers means:

- More to lose.[18]
- More ways to lose it.

The increase in potential gains from a single successful penetration of security makes the connected computer a far more promising target for the attacker. You still have to worry about in-house interlopers, both the merely curious and the seriously fraudulent, as well as disgruntled employees for whom intercomputer connections are a target for belligerence. But you also need to consider outside hackers, both amateur and professional, who live and breathe intercomputer communications.[19] The security implications of networking personal computers can be assessed as two different factors:

- The multiplication factor: normal security problems associated with an unconnected computer system are multiplied by a factor, roughly equal to the number of computer systems connected together.
- The channel factor: a new security area created by opening up channels of communications between computer systems, providing access into a computer through one port or another.

Taken together the multiplication and channel factors create the unique set of security problems normally referred to as network security. However, the term "manifold security" might better describe the situation confronting those responsible for securing personal computers which need to communicate, because, despite the existence of a substantial body of knowledge that deals with the protection of networks of large computer systems, much of it cannot be applied directly to personal computers. There are major differences in design and application. Personal computers are rarely located in secure or controlled environments. Neither personal computer hardware, nor the operating systems that control it, offer much in the way of built-in access control, particularly when it comes to connections with other hardware.

The Multiplication Factor

The security of computers that are connected has to start with individual computer security. You cannot combine a number of insecure computers into a network and create a secure system from the top down (unless you remove all local storage and processing, which in effect reduces the personal computer to a dumb terminal). While the network operating system will provide security measures, these are defeated or weakened if the

individual systems are not secure. If someone has uncontrolled use of a PC connected to a network, they have an excellent platform from which to attack the network, not to mention data that have already been transferred from the network to your PC (after all, the whole point of client/server computing is to make valuable data available on the desktop).

Even if the network is securely configured it cannot protect the PC that is not logged on. This problem is not likely to disappear any time soon, given that the default as-delivered state of most PCs continues to be unlocked and unprotected. Consider Windows 95, the first major new desktop operating system in many years. It contains plenty of hooks to which network security features can be attached, but it offers no serious stand-alone security. The point is clear: intercomputer security begins with everything in the chapter so far, from boot protection to backups, theft prevention to power conditioning, access control to virus prevention. According to the layered approach that this book advocates, each computer connected to another must be

- Protected by site, system, and file access control.
- Supported by suitable power and data backup facilities.
- Watched over by a vigilant operator/administrator.

The multiplication factor implies that protecting two computers is at least twice as difficult at protecting one. For example, a network can actually increase the damage and disruption that a virus can cause. The potential fall-out from the errors, omissions, and malicious actions of individual users is magnified when they are network users. Typically, a higher degree of user supervision is required; however, this is not always forthcoming. Users accustomed to the freedom and independence of stand-alone computing may find it irksome to submit to the rules for network users.

The Channel Factor

In previous chapters, you have seen how the layered approach to security is built up. So far, the concern has been the protection of personal computers as separate entities, vulnerable to abuse by users putting information in or taking it out via disk, screen, and keyboard. The layered approach to stand-alone security can be summarized like this:

- Access control
  - Site — controlling who can get near the system.
  - System — controlling who can use the system.
  - File — controlling who can use specific files.
- System support
  - Power — keeping supply of power clean and constant.

- Backup — keeping copies of files current.
- Vigilance — keeping tabs on what enters and leaves the system.

This arrangement needs to be expanded whenever a computer system is connected to another system. Intercomputer connection opens a channel of communication between machines. This adds a third layer, channel protection, which can be divided into three areas:

- Channel control
- Channel verification
- Channel support

Channel Control

A connection between two computers is one more way for an attacker to steal, delete, and corrupt information, or otherwise undermine normal operations. To prevent a channel of communication from becoming an avenue of attack, you need to control who can:

- Open a channel.
- Use a channel.
- Close a channel.

Clearly the first step is to ensure that proper site and system access controls are in place. The next step is to decide who needs to use a particular channel and then restrict access to authorized users. In network terms, this might be a matter of using password-controlled log-on procedures, or two-part token authentication. Password protection can be used for mainframe connections as well. Most commercial online services require an account number and password for access, and these should be closely guarded. However, system access control should be particularly tight on all personal computers equipped with modems.

Channel Verification

To be on the safe side, you should think of a channel of communication as a path through enemy territory. Whatever passes along that route runs the risk of being ambushed. Secure communications involves ongoing verification of:

- The identity of users.
- The integrity of data.
- The integrity of the channel.

Users of a communication channel should be required to identify themselves, whether the connection is a network hookup, a modem, or a mainframe link. When you are on the receiving end of intercomputer communications, that is, acting as the host for users calling in, you need to

be able to verify the claimed identity. Network nodes need to be able to verify the legitimacy of packets received.

One of the most important requirements for secure communications between computers is verification of identity. On a local area network, this might mean that each user has an ID number and a password, both of which must be entered before log-in can be completed. Of course, entry of a valid ID number/password combination does not guarantee the identity of the person using them, but the network software will tell the administrator who claims to be using the system. In small sites, a tour of the LAN can provide visual verification of these claims. In large installations, where the administrator might not be expected to put a name to every face, assistance might be provided in the form of photo-ID tags or biometric controls.

When data are being transferred via a communications channel, they are subject to possible distortion, tampering, or theft. Verifying the integrity of the channel means making sure that this does not happen. Most communications software includes some form of error checking. At a rudimentary level, this can check that the amount of data received matches the amount transmitted. More sophisticated methods confirm details of the transmission.

Verifying the integrity of the channel also means making sure nobody is listening in, or preventing the theft of anything useful if someone is. This is best accomplished by encryption. You will need to assess the likelihood of anyone attempting to intercept or overhear your communications. If the risk is high enough, then you can encrypt important communications, using a variety of devices. Some software systems encrypt all network and telephone line traffic. Hardware encryption/decryption devices can be placed at each end of a communications link. Some of these are combined with data verification systems.

Channel Support

Intercomputer communications can only be established when a large number of different parameters are properly coordinated. Once established, communications need to be maintained. This requires a high degree of reliability in communications hardware and software. The need for reliability and protection centers on those components that serve more than one user, in proportion to the number of users served. For example, in a local area network where one personal computer is acting as a file server for others, disruption or failure of the server can have far greater consequences than the breakdown of a single personal computer working on its own. Once established, channels of communication must be supported, or else those tasks that depend upon them will be jeopardized.

Business Recovery for LANs and Desktop Systems

One of the biggest challenges facing information systems professionals today is the recovery of desktop/LAN-based systems following disasters such as fires and floods (for more about the topic of business continuity planning, see Domain 8). As noted earlier in this chapter, a significant percentage of mission-critical applications are now running on desktop systems, which are inherently more complex when it comes to recovery. Unlike mainframe systems, which tend to conform to certain standards as far as equipment and code are concerned, and can thus be duplicated by a hot site with relative ease, each LAN represents a unique configuration of hardware and software.

The configuration of a particular LAN server, and the personal computer clients that it serves, may have been tweaked and fine-tuned over a long period of time. It is seldom possible to simply take the server backup tapes, load them onto a different server, and bring up the system. There are simply too many variables. There are some steps you can take to minimize these problems:

1. Carefully document the current LAN hardware and software, including all configuration settings.
2. Use "standard" equipment and configurations wherever possible.
3. Document the minimum configuration required to restore essential data and services on a replacement LAN.
4. Use server-mirroring, fault-tolerant hardware, and redundant disk arrays.

SECURE REMOTE ACCESS AND INTERNET CONNECTION

One of the most revolutionary, and largely unforeseen, implications of personal computer technology has been the emergence of the home office and the mobile worker. Invariably, users who are on the road need to call home, and so do their computers. Laptops like to link up with head office systems to update databases and download e-mail. A growing army of work-at-home telecommuters need some sort of remote access to their employer's systems. The technology with which to create these connections has been around for some time, and so has the subtle art of subverting it for nefarious purposes, or mere curiosity.

It might be hard to understand, but some people get a genuine thrill simply being "in" someone else's computer system. Remote access points are still a popular way of getting in. (Given the number of frustrating hurdles that you sometimes have to clear in order to establish a legitimate connection, it might be hard to imagine someone doing this for fun; however, at that precise moment when you finally get your own e-mail after hours of

dropped connections and redials, it is possible to sense something of the kick you get from hacking into someone else's system.)

Recent publicity about computer break-ins over the Internet has tended to overshadow hacking in through remote access points such as those provided for telecommuters, maintenance people, and field staff. However, this form of penetration is still used. Typically, it starts with a war dialer, a piece of software running on a modem-equipped PC, which automatically calls all of the phone numbers in a certain range, such as 345-0000, 345-0001 to 347-9999. The software records which numbers are answered by a modem. This gives the hacker a list of numbers worth testing for further access.

One technique that can reduce the risk of being found by such a technique is to set your modem to answer only after four or five rings — since the default operation of war dialers is geared toward speed, they may not linger that long at unanswered numbers. Of course, there are less technically sophisticated ways of getting phone numbers for computers, such as downloading lists of such numbers that are routinely shared on hacker bulletin boards, or digging through company trash for discarded phone directories.

Technically speaking you have several options for remote access. The most basic is a modem on your desktop machine which answers calls from the modem on your laptop. With "remote control" software running at both ends, the laptop user can operate the desktop machine as though seated at it. This remote control technology was popular early on in PC development since it kept to a minimum the data that needed to be sent over the phone at slow modem speeds. Later, when desktop machines were networked, the remote laptop user was able to control the desktop machine while it was logged into the network, thus giving network access.

With faster modems it became possible to log a remote caller directly into the network as a remote node. In other words, the laptop becomes a work station on the network. This is typically more convenient for the user, but it may be more expensive since the laptop needs to have its own licensed copy of the networked applications (instead of borrowing them from the desktop). However, network managers have tended to prefer remote node access because it is easier to manage, and this in turn provides security benefits. The remote machine has to prove its identity to the more demanding network server, rather than a mere desktop work station.

Recently, we have seen big strides towards consolidating remote network access, with special servers designed to run either remote node or remote control access in a tightly controlled manner. Typical methods for protecting a modem connection that is providing remote access are password protection and call-back. A simple form of the latter approach is for

the remote user to dial into the modem at the office, which then hangs up and calls the remote user back. The idea is to prevent people establishing connections from unauthorized numbers, but hackers have found that it is possible to fool the modem at the office into thinking it has dropped the connection, so that the call-back never really takes place. The addition of a password requirement at the time of call-back reduces the chances of this type of hack succeeding.

The call-back approach can be hard to scale when the number of remote users starts to grow, and the cost of long distance calls to all those users starts to add up. An alternative is to provide a toll-free number for remote users to dial into, which is answered by a remote access server. This is a combined hardware and software solution that creates a special node on the network with the ability to receive and authenticate multiple incoming calls. The connection should be authenticated by something stronger than an ordinary password, such as a one-time password generated by a smart card.

For example, modem-maker U.S. Robotics uses the SecurID system on its Total Control Enterprise Network Hub remote access server. To access the server the user enters a PIN followed by the code displayed on the SecurID card issued to that user. The code displayed on the card changes every 60 seconds, in sync with the company's ACE/Server authentication server at the office. Other options for two-factor authentication (something you know, like a PIN, plus something you have, like a token) include requiring special PCMCIA cards holding encrypted keys to be present in the remote laptop before the connection can be made.

The number of users who dial into the office is bound to increase as companies expand the use of telecommuting and virtual offices. This will continue to provide a possible channel for penetration of internal systems. But improvements in remote access servers supported by two-factor authentication systems have the potential to make such penetration increasingly difficult. Two developments that need to be watched carefully are the shift towards using the Internet for remote access to in-house databases, and public key-based digital certificates as a means of authentication.

SUMMARY

In less than two decades the microcomputer has risen from the basement workshop and the garage benchtop to become the dominant force in computer hardware. While mainframes and minicomputers continue to anchor many systems, particularly in areas such as online transaction processing, the shift towards client/server solutions based on what are, in essence, microcomputers, shows no signs of abating.

We are only just beginning to come to terms with the information security implications of this phenomenon.[20] The process starts with an understanding of the desktop computer environment. Experience has shown that you cannot simply take big-system security practices and impose them on desktop machines. We have to develop security policies and procedures that are appropriate for the desktop. We have to implement those policies and procedures by educating users about security. We might not like it, but the fact is personal computers will never be secure unless the personnel who use them also secure them.

There are alternative strategies. For example, you can emasculate the PC and make it an NC, controlled and secured by a server that is treated like a mainframe, even if it is just a beefed up PC. Whether this option will find favor, either in corporate information systems or cubicle-land, remains to be seen.

Footnotes

1. As someone you call when you get one of these headaches, I can attest to the increased frequency of the calls and the growing severity of the headaches. The opening comments in this chapter were shaped by participation in security assessments at a number of major U.S. and international corporations during the last 12 months. For a collection of recent infosec-related statistics, visit http://www.theroyfamily.com/security.html.
2. For more detailed statement of this position and its weaknesses, see *The NCSA Guide to PC and LAN Security*, McGraw-Hill, New York, 1996.
3. For example, many new PCs today have BIOS-based boot protection, but there are plenty still in use that do not.
4. Examples of this are legion, from Aldrich Ames, the CIA spy, to lists of AIDS patients made public in Florida, to company secrets valued at millions of dollars in cases brought by American Airlines and Merrill-Dow.
5. About 76% of survey respondents said they were running "mission critical" applications on local area networks. Ernst & Young survey of 1,271 technology and business executives, January, 1995.
6. For example, a modest 486 and a modem is all it takes to mount a very effective denial of service attack on a Web site, mail gateway, or even an Internet Service Provider such as the New York provider, PANIX, which was disrupted for more than a week in 1996.
7. "After 1998, the widespread availability of inexpensive disruptive technology and the broadening base of home computer users will put threat capabilities into the hands of a wider, less-privileged class, dramatically increasing the risk for intermediate-size organizations (0.8 probability)." Gartner Group.
8. For example, instructions for mounting the type of attack suffered by PANIX were posted on the Internet and recently an easy-to-use Windows attack program was released.
9. For example, it is relatively easy to configure a dumb terminal so that the screen is the only output device which is ideal for transitory lookup access to confidential data, such as medical records. But it is relatively difficult to lobotomize a PC so that it cannot retain or redirect whatever data it receives. I still meet mainframe-oriented systems people who have not yet grasped this distinction.
10. "Someone broke into the offices of Interactive Television Technologies, Inc. in Amherst, New York, and stole three computers containing the plans, schematics, diagrams and specifications for proprietary Internet access technology still in development but conservatively valued at $250 million." Reuters, 1996.
11. For example, case locks, building locks, increase surveillance.

12. A few years ago a manufacturer of data backup tapes, 3M Corp., did a survey about backup regimes and found that, of those respondents who regularly performed backups, some 80 percent only started to do so *after* they had lost data through lack of backup.
13. A tape jukebox can cycle through multiple tapes and backup RAID data that is mirrored and not being accessed.
14. The term "optimized" refers to organizing data on the disk so that files are stored in contiguous sectors, in logical order for the most efficient retrieval. The term "defragmented" is used to describe the process of rearranging files so that they are stored in contiguous sectors.
15. One of the most comprehensive studies is the one performed by NCSA, available at their Web site, www.ncsa.com.
16. A list of current "in the wild" viruses can be found at www.ncsa.com/virus/wildlist.html. The list is maintained independently for the computing community by Joe Wells, with the help of over 40 volunteers around the world.
17. For a test, point your Web browser to www.omna.com/yes/mwc/info, a page that tells you how your Windows 95 machine is configured.
18. A 1993 study by Infonetics Research of San Jose, California found that when companies experienced losses due to LAN outages, the average amount per company, including lost revenues and productivity, was $7.5 million.
19. Remember that hacker Kevin Mitnik's first arrest was for stealing manuals from a Pacific Bell switching station — that was in 1981, when he was 17.
20. See footnote 7.

Reflections on Database Integrity

William Hugh Murray

THIS CHAPTER DISCUSSES THE CONCEPT OF DATABASE INTEGRITY. It contrasts this concept to those of data integrity and database management system integrity. The purpose of the discussion is to arrive at a set of recommendations for the owners and operators of such databases on how to preserve that integrity.

CONCEPTS AND DESCRIPTIONS

This section sets forth some definitions and concepts that describe and bound the issue of database integrity.

Integrity

Integrity is the property of being whole, complete, and unimpaired; free from interference or contamination; unbroken; in agreement with requirements or expectation.

Data can be said to have integrity when it is internally consistent (e.g., the books are in balance) and when it describes what it intends (e.g., the books accurately reflect the performance and condition of the business). A system can be said to have integrity when it performs according to a complete specification most of the time, fails in a predictable manner, presents sufficient evidence of its failure to permit timely and effective corrective action, and permits orderly recovery.

Database

For purposes of this discussion, a database can be defined as a monolithic collection of related or interdependent data elements. Alternatively, it is a monolithic collection of information represented in coded data elements and specific relationships between those data elements. A database is usually intended to be shared across users, uses, or applications.

The abstraction of *database* is relatively novel, no older than the modern computer. Until the appearance of database management software for the microcomputer, perhaps a decade ago, it was esoteric. Analogous collections of data, such as the books of account for a business, existed before the computer. The term can properly be applied to most of the data that is usually recorded on such media as ledger cards or 3×5 cards. However, it is usually reserved for the most formal, rigorous, and systematic of such collections.

Information in a database can be explicitly represented in the form of coded data elements; employee name is a common example. However, there is other information in the database in the form of associations, both explicit and implicit, between the data elements.

Relationships are special kinds of associations between the data elements. For example, the various fields in an employee database record are related logically in much the same way as they are related on a piece of paper. The meaning and identity of each field is determined, in part, by this context. This information is at least as important as that in the data elements themselves.

The relationships can be expressed in the data itself (relational), in the arrangement or order of the elements within the database (structured), or in meta-data, data about the data, that explicitly describes or encodes the relationships (e.g., indexed or object oriented). While databases can be characterized by how the relationships are primarily expressed, in practice, all databases use a combination of these mechanisms. For example, in those databases known as *relational,* some relationships are expressed in the structure (i.e., tables and views), some in the data (i.e., references to other tables), and some in meta-data, the names of the columns.

Database Integrity

A database can be said to have integrity when it preserves the information in the data, that is, when both the data and the relationships are maintained. Database integrity is about the integrity of the records. The integrity of the database is separate from, and can be contrasted to that of the data, on the one hand, and of the database management system on the other.

Database Management System

For our purposes, a database management system is a generalized, abstract, and automated mechanism for creating, maintaining, storing, preserving, and presenting a database to, and on behalf of, applications.

Database managers are often characterized by the name of the mechanism on which they primarily rely to describe the relationships among the

data elements. Thus, database managers in which the relationship between two data elements is normally implied in the data itself, for example, the content of a data element (two employee records have the same department number), or the ordering of the data (employee A precedes B in the sort order of the name field) can be called *relational database managers*. Those in which the relationship is implied by how the two elements are physically stored, (for example, all employees in the same department are stored together, or employee A is always stored before B) can be referred to as *structured database managers*.

Relational Integrity

Relational integrity is the aspect of database integrity that deals with the preservation of the special relationships between the data elements.

Referential integrity is an example and a special case of relational integrity A reference is a relationship in which a value in one record points to another record, usually of another record type. For our purposes, it is an example and illustration of what it might mean to say that a database has integrity to the extent that relationships are preserved.

Consider the case of an employee record with a department number in it that refers to a department record. If the department number in the employee record is *N*, then referential integrity requires that there be a department record for department *N*. It would prohibit the creation of an employee record with a department number for which there was no corresponding department record, the deletion of department record *N* as long as any employee record pointed to it, and more than one department record *N* for the employee record to point to.

It should be noted that this kind of integrity is optional. That is, the condition could exist, coincidentally or accidentally, without any declaration, commitment, or enforcement. Likewise, it can be implemented and enforced either by using applications or the database management system. As a rule, it is preferable to have it implemented in the database management system so that the mechanism can be shared across applications and so that one using application need not rely on another.

METHODS

This chapter section discusses some of the methods for implementing database managers and preserving the integrity of the database.

Localization

By definition, a database is a monolith. That is, all of its elements and all of its relationships are essential to its identity. If any element or relationship is lost or broken, then the identity and the integrity are destroyed.

Of course, this is separate from the physical database manager, which might contain two or more independent databases. However, all other things being equal, keeping the elements of the database together helps preserve its integrity. Therefore, most database managers strive to keep the database together.

Single Owning Process

An important form of localization is the single owning process. Because a database is a monolith, there must be a single process that can see all of it, manage it, and have responsibility for its integrity. This owning process is usually the database manager. An implication is that a database manager is usually a single process.

Redundancy

To make the database more reliable than the media and devices on which it is stored, most database managers apply some kind of redundant data. The data is recorded in more than the minimum number of bits otherwise required to express it.

Dynamic Error Detection and Correction

Often, redundancy takes the form of error detection and correction codes. The data is recorded in codes that make the alteration of a bit obvious and its timely and automatic correction possible. One such code is *parity*, in which an additional bit is added to each frame of 7 or 8 bits to make the frame conform to some arbitrary rule such as *odd* or *even.* A variance from the rule signals the alteration of a bit. Some codes are so powerful as to permit the automatic detection and correction of multiple bit errors. These codes can be implemented in both the storage device (i.e., below the line) or in the database manager (above the line between software and hardware only mechanisms).

Duplication

Redundancy can be carried as far as one or more complete copies of the database or its elements. Such copies can be either inside or outside the database manager. Because relationships are usually best known to the database manager, they are best preserved using the duplication facilities that are provided by it.

Mirroring

One form of duplication is mirroring, in which two synchronized copies of the data are maintained. Mirroring is done internal to a mechanism; the copy is not visible from outside it. For example, a file manager can mirror files. It will apply changes to both copies, satisfy requests from either, but

conceal the existence of the second copy to processes outside itself. Mirroring can be done on the same device or on a different one. When done on a single device, mirroring protects against a media failure or a limited failure of the device (e.g., a bad track). When done across devices, it protects against a general device failure.

Backup

Backup copies of the database are made independent of the database manager. Among other losses, these copies are specifically intended to protect against damage that might occur to the data if the manager should fail or become corrupt.

Such copies can be prepared automatically by the database manager, or by using utilities or other program processes that are independent of the mechanism itself. Of course, although intended to protect against database manager failures, the use of an independent backup system may itself be a threat to the integrity of the database. It is difficult for an independent system to know and enforce the rules that the database manager itself enforces.

Checkpoints and Journals

A checkpoint is a special case of a backup copy. It is taken at a particular point in time. For example, the initial state of the database, even if empty, is a checkpoint. Checkpoints are used in conjunction with a journal or log of all update activity subsequent to the checkpoint to reconstruct the database. This mechanism preserves both integrity and currency.

Reconstruction

Such secondary copies can be employed to reconstruct the database, even from massive failures. However, this means that, at least under some circumstances, the integrity of the database will depend on the integrity of these copies.

Compartmentation

To compartmentalize is to place things into segregated compartments. The intent is to contain the effects of what happens in one compartment in such a way as to limit the impact on other compartments. For example, one might run multiple small database managers, in preference to a single large one, so as to limit the impact of a failure.

Segregation and Independence

Database management systems often implement segregation and independence of sub-processes to preserve integrity. For example, they may

isolate the process that does an update, from that which checks to see that it was done correctly, from the one that attempts corrective action. The purpose is to minimize the chances that the same fault will affect all three.

Encapsulation

The database manager can be viewed as a package, container, or capsule, one role of which is to protect the database from any outside interference or contamination. Encapsulation can be either physical or logical. For a database manager, physical encapsulation might be provided by placing it in a separate computer. Logical encapsulation might be provided by placing it in an isolated and protected process within an environment provided by a shared computer and its operating system. Logical encapsulation may also be provided, in part, and in static conditions, by the use of secret codes.

Most database management systems provide some encapsulation of the databases they contain. Object-oriented database management systems do so, by definition, explicitly and globally. Increasingly, one sees database managers themselves being encapsulated in their own hardware.

Hiding

Capsules hide or conceal their contents so that they cannot be seen or addressed from the outside. While this does not make the database safer from destruction, it does protect it from unauthorized disclosure and from malicious, but covert, change. Hiding can be implemented in many ways; the most common are by means of process-to-process isolation, data typing and type managers, and by the use of secret codes.

Binding

Binding is used to resolve and fix, for example, a data characteristic or reference, so as to resist later change. In computer science, one speaks of early and late binding. For example, in some programming, symbolic names are bound, that is, resolved so as to resist later change at compile time, while in others the same characteristic may not be bound until execution time.

Many structured database management systems can bind relationships in the database at programming time or at load time. This tends to improve both the integrity and performance at the expense of loss of flexibility and increased maintenance cost. Relational database managers also employ binding of table existence at creation time.

Binding applies only within the environment in which it takes place. If data or databases are removed from the database manager, then characteristics are no longer bound or reliable.

Atomic Update

Atomic update means that any change to the database takes place completely or not at all. There are no partial updates. This includes both data elements and relationships. Most database managers implement this by maintaining the ability to "roll back" any partial updates that they are unable to complete.

Locking

One potential threat to the integrity of a database results from concurrent use by two or more processes. For example, where two users make changes to a database, there is some potential that the second change will overwrite the first. Database management systems are expected to provide mechanisms, such as locking, that resist such problems.

Locking is a mechanism that database managers employ to ensure that partially updated elements and relationships are not used. It involves marking the element as "in use" or "asking for the lock" for all elements involved in an update. The mechanism will not permit a second use of an element that is in use and will not begin an update until is can obtain the locks for all elements involved. However, locking is ordinarily a logical, rather than physical mechanism. It is usually just a bit or flag that is set by locking or unlocking.

Locking may come in several levels of transparency and granularity. Ideally, locking would be automatic and transparent to all users or using processes. However, this might have unnecessary performance impact. For example, for maximum transparency, a database management system might restrict access from application B to any data that A is looking at, on the assumption that A might elect to update it. Thus, B will see a performance penalty even if he does not care about potential updates.

Performance might also require that B's access be limited to only the smallest element that A might update. B should not be restricted from an entire table simply because A is interested in a single row of the table. Thus, maximum performance requires that both A and B declare their intent.

Access Control

Access control is a mechanism provided by the database management system to enable the owners and managers of the database to control which users or using processes can alter the database, its elements, or

its relationships. These controls are most likely to be included in database management systems intended for use by multiple users. It is an integrity mechanism in that it reduces the size of the population that can alter the database to the intended population. It can also be used to enforce dual controls intended to resist errors and malice.

Privileged Controls

Most database management systems, particularly those that provide access controls, provide what can be referred to as privileged controls. These controls are intended for use by the managers of the system. They are intended for use to exercise ultimate control, particularly to remedy unusual situations. Two unusual situations are of particular interest. The first is to override the access controls. This capability may be necessary to avoid a deadlock situation. The second is the use of such privilege to repair the database itself. In the early days of structured databases, such controls were frequently used to "repair broken chains."

It should be noted that such privilege includes the ability to contaminate or interfere with the database.

Reconciliation

Reconciliation refers to an act or process that brings the database into harmony or consistency; that is, the act or process of checking the database against expectation and correcting for variances. Normally, database management systems perform this kind of checking on a routine, automatic, frequent, and repetitive, if not quite continuous, basis. For example, after making a WRITE request to another process (e.g., the file system), the database manager can make an immediate inspection to satisfy itself that the request completed correctly. The routine and automatic nature of this activity, among other things, distinguishes it from recovery. Another is that it relies almost exclusively on internal resources.

Recovery

Recovery is the integrity mechanism of last resort, the one that is used when the database is broken beyond the ability of any other mechanism to repair it. It is usually externally invoked and relies on external resources such as backup copies of the data. While it must bring the database back to a state of integrity, it may do so at the expense of currency or even lost data.

CONCLUSIONS

Database integrity is essential. If one cannot rely on the data, it is useless. Integrity is easier to preserve than to recreate. No single tool or

mechanism is sufficient unto itself. Database management systems will employ a variety of tools, and owners and managers will compensate for the inherent limitations of the database managers by employing tools that are completely external to it.

At least four things are necessary to preserve the integrity of a database:

1. One must preserve both the data elements and the relationships among them.
2. One must understand and exploit the mechanisms provided by the database management systems.
3. One must not compromise any of these mechanisms, either in the way one uses them or external to them.
4. One must understand the limitations of the database management system and compensate for them.

A simple copy of the data elements may not preserve the information contained in the relationships. For example, if a structured database contains information about the relationships in the physical location of the data within the device, then a copy of the data can preserve the relationships only if it is on an identical device.

Because all database management systems employ a combination of mechanisms to implement relationships and because most of these mechanism are concealed, management or operational procedures that bypass the database management system are suspect. On the other hand, if there are no measures taken to preserve integrity that are independent of the database management system, then a failure of the mechanism can destroy the database.

It should be noted that the most robust database managers so encapsulate the database that they cannot be bypassed. Any attempt to do so will result, at best, in the distortion of the database, and, at worst, in the destruction of the database and the database management system. Most of these systems will also provide one or more built-in mechanisms for creating external representations of the database.

One final issue is that of scale. Most databases are relatively small when compared to the systems and devices on which they reside. However, many of the most important databases are very large and span tens or even hundreds of devices. In such databases, information about relationships can span many devices. The integrity of the database requires the preservation of the devices and their relationship to each other.

On the other hand, it is common in these databases to create external copies by backing up the devices rather than the database or even the files. Such backups are device and device field dependent. While they provide adequate protection against the failure of one or two devices,

recovery from the destruction of the entire environment might require the complete replication of the environment. Timeliness may require that this be done in days or even hours. Thus, in exactly the databases in which it may be most urgent to have device-independent backups, it may be least likely to have them.

RECOMMENDATIONS

This chapter section sets forth recommendations for preserving the integrity of databases. These include some recommendations for using the database management system and some for compensating for its limitations.

1. Choose a database manager whose characteristics, features, and properties are sufficiently robust for the intended application and environment. Consider the size of the database and its importance to the enterprise.
2. Use the database management system according to directions. Note and respect all limitations.
3. Place the database and its manager in a robust environment.
4. Provide adequate resources (e.g., mirror files, devices, and control units) as indicated by the application and environment.
5. Prefer monolithic databases for integrity. Use distributed database managers only to the extent justified by major differences in performance.
6. For integrity, prefer a one-to-one relationship between a database, a database management system, and a processor. Share only to the extent indicated by major economies of scale. Keep in mind that today's computer systems can be more readily scaled to their applications. Large-scale sharing no longer offers the economies that it used to.
7. Prefer relational and object-oriented databases for integrity. Prefer structured databases for performance.
8. Applications and users should check those behaviors of the database manager that they rely on.
9. Limit access to the database and to elements within it to the minimum number of known users and processes consistent with the application.
10. Apply access controls in such a way as to involve multiple people in sensitive updates to the database.
11. Involve multiple people in the use of privileged or potent controls.
12. Keep multiple backup copies and generations of the data, including checkpoints and journals of update activity.
13. Prefer device-independent backups, particularly for databases that span multiple devices.

14. For device independence, prefer to make backups with services provided by the database manager. Use independent mechanisms for performance.
15. Prefer to make backups with services provided by the database manager for preservation of relationships. Prefer backups made by other means for independence and to protect against failure in the mechanism.
16. To protect external copies of the database, involve multiple people in their custody.
17. Check integrity after recovery and before use. Remember that even normal use of a corrupt database may spread the damage and that using bad data may result in serious damage to the enterprise.

Firewalls, Ten Percent of the Solution: A Security Architecture Primer

Chris Hare, CISSP, CISA

A solid security infrastructure consists of many components that, through proper application, can reduce the risk of information loss to the enterprise. This article examines the components of an information security architecture and why all the technology is required in today's enterprise.

A principal responsibility of the management team in any organization is the protection of enterprise assets. First and foremost, the organization must commit to securing and protecting its intellectual property. This intellectual property provides the organization's competitive advantage. When an enterprise loses that competitive advantage, it loses its reason for being an enterprise.

Second, management must make decisions about what its intellectual property is, who it wants to protect this property from, and why. These decisions form the basis for a series of security policies to fulfill the organization's information protection needs.

However, writing the policies is only part of the solution. In addition to developing the technical capability of implementing these policies, the organization must remain committed to these policies, and include regular security audits and other enforcement components into its operating plan. This is similar to installing a smoke alarm: if you do not check the batteries, how will you know it will work when you need it?

There are many reasons why a corporation should be interested in developing a security architecture including:

- Telecommunications fraud
- Internet hacking
- Viruses and malicious code
- War dialing and modem hacking
- Need for enhanced communications
- Globalization
- Cyber-terrorism
- Corporate espionage
- E-commerce and transaction-based Web sites

Telecommunications fraud and Internet and modem hacking are still at the top of the list for external methods of attacking an organization. Sources of attack are becoming more sophisticated and know no geographical limits. Consequently, global attacks are more predominant due to the increased growth in Internet connectivity and usage.

With business growth has come the need for enhanced communications. No longer is remote dial-up sufficient. Employees want and need high-speed Internet access, and other forms of services to get their jobs done, including videoconferencing, multimedia services, and voice conferencing. Complicating the problem

is that many corporate networks span the globe, and provide a highly feature-rich, highly connected environment for both their employees and for hackers.

The changes in network requirements and services has meant that corporations are more dependent on technologies that are easily intercepted, such as e-mail, audio conferencing, videoconferencing, cellular phones, remote access, and telecommuting. Employees want to access their e-mail and corporate resources through wireless devices, including their computers, cell phones, and personal digital assistants such as the PalmPilot and Research in Motion (RIM) BlackBerry.

With the Information Age, more and more of the corporation's knowledge and intellectual capital are being stored electronically. Information technology is even reported as an asset on the corporation's financial statements. Without the established and developed intellectual capital, which is often the distinguishing factor between competitors, the competitive advantage may be lost.

Unfortunately, the legal mechanisms are having difficulty dealing with this transnational problem, which affects the effectiveness and value of the legislation — expertise of law enforcement, investigators, and prosecutors alike. This legal ineffectiveness means that companies must be more diligent at protecting themselves because these legal deficiencies limit effective protection.

Add to this legal problem the often limited training and education investment made to maintain corporate security and investigative personnel in the legal and information technology areas. Frequently, the ability of the hacker far surpasses the ability of the investigator.

Considering the knowledge and operational advantages that a technology infrastructure provides, the answer is this: the corporation requires a security infrastructure because the business needs one.

Over the past 15 years, industry has experienced significant changes in the business environment. Organizations of all sizes are establishing and building new markets. Globalization has meant expanding corporate and public networks and computing facilities to support marketing, sales, and support staff. It addition to the geographical and time barriers, enterprises are continually faced with cultural, legal, language, and ethical issues never before considered.

In this time frame, we have also seen a drive toward electronic exchange of information with suppliers and customers, with E-commerce and transaction-based Web sites being the growth leaders in this area.

This very competitive environment has forced the enterprise to seek efficiencies to drive down product costs. The result of this activity has been to outsource noncore activities, legacy systems, consolidation of workforces, and a reduction in nonessential programs.

The mobile user community reflects the desire to get closer to our customer for improved responsiveness (e.g., automated sales force). In addition, legislation and the high cost of real estate have played a role in providing employees with the ability to work from home.

The result of these trends is that information is no longer controlled within the confines of the data center, thereby making it easier to get access to, and less likely that this access would be noticed.

Where Are the Risks?

The fact is that firewalls provide the perimeter security needed by today's organizations. However, left on their own, they provide little more than false assurance that the enterprise is protected. Indeed, many organizations believe the existence of a firewall at their perimeter is sufficient protection. It is not!

The number of risks in today's environment grows daily. There have been recent documented instances in which members of some of these areas, such as outsourced consultants, have demonstrated that they are more a risk than some organizations are prepared to handle. For example, *Information Week* has reported cases where outsourced consultants have injected viruses into the corporate network. A few of the many risks in today's environment include:

- Inter-enterprise networking with business partners and customers
- Outsourcing
- Development partners
- Globalization
- Open systems
- Access to business information
- Research and development activities

- Industrial and economic espionage
- Labor unrest
- Hacking
- Malicious code
- Inadvertent release or destruction of information
- Fraud

These are but a few of the risks to the enterprise the security architecture must contend with. Once the organization recognizes that the risk comes from both internal and external sources, the corporation can exert its forces into the development of technologies to protect its intellectual property.

As one legitimate user community after another have been added to the network, it is necessary to identify who can see what and provide a method of doing it. Most enterprises have taken measures to address many of the external exposures, such as hacking and inadvertent leaks, but the internal exposures, such as industrial or economic espionage, are far more complex to deal with. If a competitor really wants to obtain valuable information, it is easier and far more effective to plant someone in the organization or engage a business partner who knows where the information can be found.

Consider this: the FBI estimates that 1 out of every 700 employees is actively working against the company.

Establishing the Security Architecture

The architecture of the security infrastructure must be aligned with the enterprise security policy. If there is no security policy, there can be no security infrastructure. As security professionals, we can lead the best technologists to build the best and most secure infrastructure; however, if it fails to meet the business goals and objectives, we have failed. We are, after all, here to serve the interests of the enterprise — not the other way around.

The security architecture and resulting technology implementation must, at the very least, meet the following objectives:

- It must not impede the flow of authorized information or adversely affect user productivity.
- It must protect information at the point of entry into the enterprise.
- It must protect the information throughout its useful life.
- It must enforce common processes and practices throughout the enterprise.
- It must be modular to allow new technologies to replace existing ones with as little impact as possible.

Enterprises and their employees often see security as a business impediment. Consequently, they are circumvented in due course. For security measures to work effectively, they must be built into operating procedures and practices in such a way that they do not represent an "extra effort." From personal experience, this author has seen people spend up to ten times the effort and expense to avoid implementing security.

The moment the security infrastructure and technology are seen, *or perceived*, to impact information flow, system functionality, or efficiencies, they will be questioned and there will be those that will seek ways to avoid the process in the interest of saving time or effort. Consequently, the infrastructure must be effective, yet virtually transparent to the user.

Once data has entered the system, it must be assumed that it may be input to one or more processes. It is becoming impractical to control the use of all data elements at the system layer; therefore, any data that is considered sensitive, or can only be "seen" by a particular user community, must be appropriately protected at the point of entry to the network or system and, most importantly, wherever it is subsequently transferred. This involves the integration of security controls at all levels of the environment: the network, the system, the database, and the application.

A centralized security administration system facilitates numerous benefits, both in terms of efficiency and consistency. Perhaps the most significant advantage is knowing who has access to what and if, for whatever reason, access privileges are to be withdrawn, that can be accomplished for all systems expeditiously.

Quite clearly, it is not economically feasible to rewrite existing applications or replace existing systems. Therefore, an important aspect of the security architecture must be the ability to accommodate the existing infrastructure. Along the same lines of thinking, the size of existing systems and the population using them precludes a one-time deployment plan. A modular approach is an operational necessity.

The infrastructure resulting from the architecture must also provide specific services and meet additional objectives, including:

- Access controls
- Authorization
- Information classification
- Data integrity

Achieving these goals is not only desirable, it is possible with the technology that exists today. It is highly desirable to have one global user authentication and authorization system or process, a single encryption tool, and digital signature methodology that can be used consistently across the enterprise for all applications. Authenticating the user does not necessarily address the authorization criteria; it may prove that you are who you say you are but does not dictate what information can be accessed and what can be done with it.

Given the inter-enterprise electronic information exchange trend, one can no longer be certain that the data entering the corporate systems is properly protected and stored at the points of creation. Data that is submitted from unsecured areas represents a number of problems, primarily related to integrity, the potential for information to be modified (e.g., the possibility of the terminal device being "spoofed," collecting data, modifying it, and retransmitting it as if from the original device), and confidentiality (e.g., "shoulder surfing").

Unfortunately, one cannot ignore the impact of government in our infrastructure. In some way or another, domestic and foreign policies regarding what one can and cannot use do have an effect. Consider one of the major issues today being the use of encryption. The United States limits the export of encryption to a key length, whereas other governments (e.g., France) have strict rules regarding the use of encryption and when they require a copy of the encryption key.

In addition, governments also impose import and export restrictions on corporations to control the movement of technology to and from foreign countries. These import/export regulations are often difficult to deal with due to the generalities in the language the government uses, but they cannot be ignored. Doing so may result in the corporation not being able to trade with some countries, or lose its ability to operate.

An Infrastructure Model

The security infrastructure must be concerned with all aspects of the information, and the technology used to create and access it, including:

- Physical security for the enterprise and security devices
- Monitoring tools
- Public network connectivity
- Perimeter access controls
- Enterprise WAN and LAN
- Operating systems
- Applications
- Databases
- Data

This also does not discount the need for proper policies and an awareness program as discussed earlier. The protection objects listed above, if viewed in a reverse order (Exhibit 121.1), provides an outside in view to protecting the data.

What this model also does is incorporate the elements of physical security and awareness, including user training, which are often overlooked. Without the user community understanding what is expected from them in the security model, it will be difficult — if not impossible — to maintain.

The remainder of this article focuses on the technology components and how to bring them together in a sample architecture model.

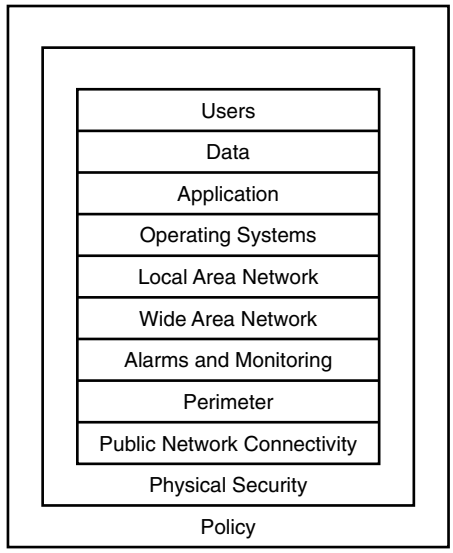

EXHIBIT 121.1 The Infrastructure Model.

Establishing the Perimeter

The 1980s brought the development of the microcomputer, and despite its cost, many enterprises that were mainframe oriented could now push the work throughout the enterprise on these lower-cost devices. Decentralization of the computing infrastructure brought several benefits and, consequently, several challenges.

As connectivity to the Internet increased, a new security model was developed. This consisted of a "moat," where the installation of a firewall provided protection against unauthorized access. Many organizations then, as today, took the approach that information contained within the network was available for any authorized employee to access. However, this open approach meant that the enterprise was dependent upon other technology such as network encryption devices to protect the information and infrastructure.

The consequence many organizations have witnessed with this model is that few internal applications and services made any attempt to operate in a secure fashion. As the number of external organizations connected to the enterprise network increases, the likelihood of the loss of intellectual property also increases.

With the knowledge that the corporate network and intellectual property were at risk, it was evident that a new infrastructure was required to address the external access and internal information security requirements.

Security professionals around the globe have embarked on new technology and combinations. Consequently, it is not uncommon for the network perimeter to include:

- Screening or filter routers
- Firewalls
- Protected external networks
- Intrusion detection systems

When assembled, the perimeter access point resembles the diagram in Exhibit 121.2.

The role of the screening or filter router between the external network and the firewall is to limit the types of traffic allowed through, thereby reducing the quantity of network traffic visible to the firewall. This establishes the first line of defense. The firewall can then respond more effectively to the traffic that is allowed through by the filter router. This first filter router performs the ingress traffic filtering, meaning it limits the traffic inbound to your network based on the filter rules.

Traditionally, enterprises have placed their external systems such as Web and FTP servers outside their firewall, which is typically known as the DMZ (demilitarized zone). However, placing the systems in this

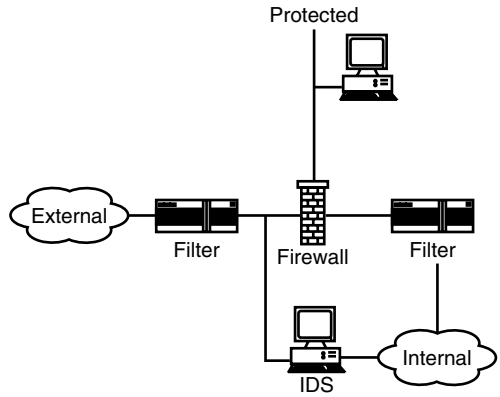

EXHIBIT 121.2 Perimeter Access Point.

manner exposes them to attack from the external network. An improved approach is to add additional networks to the firewall for these external systems. Doing so creates a protected network, commonly known as a service network or screened subnet.

The filters on the external filter router should be written to allow external connections to systems in the protected network, but only on the allowed service ports. For example, if there is a Web server in the protected network, the filter router can be designed to send all external connection requests to the Web server to only the Web server. This prevents any connections into the internal network due to an error on the firewall.

Note: The over use of filters on routers can impact the overall performance of the device, increasing the time it takes to move a packet from one network to another. For example, adding a single rule: <any IP address> to <any IP address> adds ten percent to the processing load on the router CPU. Consequently, router filter rules, although recommended, must be carefully engineered to not impede network performance.

The firewall is used to create the screened or protected subnet. A screened subnet allows traffic from the external network into the screened subnet, but not directly into the corporate network. Additionally, firewall rules are also used to further limit the types of traffic allowed into the screened subnet, or into the internal network.

Should a system in the protected network require access into the internal network, the firewall provides the rules to do so, and limits the protocols or services available into the internal network.

The second filter router between the firewall and the internal network is used to limit outbound traffic to the external network. This is particularly important to prevent network auto-discovery systems such as HP Openview from trying to use its auto-discovery features to map the entire Internet. This filter router can also allow other traffic that the enterprise does not want sent out to the Internet to be blocked. This is egress filtering, or using the router to limit the traffic types being sent to the external network. Some enterprises combine both filters on one router, which is acceptable depending on the ultimate architecture implemented.

The final component is an intrusion detection system (IDS) to identify connection attempts or other unauthorized events and information. Additionally, content filtering systems can be used to scan for undesirable content in various protocols such as Web and e-mail. Many vendors offer solutions for both, including those that can prevent the distribution of specific types of attachments in e-mail messages. E-mail attachment scanning should also be implemented in the enterprise to prevent the distribution of attachments such as malicious code within the enterprise.

The Network Layer

The network layer addresses connectivity between one user, or system, and another for the purposes of information exchange. In this context, information may be in the form of data, image, or sound and may be transmitted using copper, fiber, or wireless technologies. This layer will include specific measures to address intra- and inter-enterprise information containment controls, the use of private or public services, protocols, etc.

Almost all enterprises will have some level of connectivity with a public data network, be it the Internet or other value-added networks. The security professional must not forget to examine all network access points and connectivity with the external network points and determine what level of protection is needed. At very least, a screening router must be used. However, in some cases, external legislation determines what network access control devices are used and where they must be located.

The enterprise wide area network (WAN) is used to provide communications between offices and enterprise sites. Few enterprises actually maintain the WAN using a leased line approach due to the sheer cost of the service and associated management. Typically, WAN services are utilized through public ATM or Frame Relay networks. Although these are operated and managed by the public telecommunications providers, the connectivity is private due to the nature of the ATM and Frame Relay services.

Finally, the local area network (LAN) used within each office provides network connectivity to each desktop and workstation within the enterprise. Each office or LAN can be used to segregate users and departments through security domains (see Exhibit 121.3).

In this case, the security professional works with the network engineering teams to provide the best location for firewalls and other network access devices such as additional filter routers. Utilizing this approach can prevent sensitive traffic from traveling throughout the network and only be visible to the users who require it. Additionally, if the information in the security domain requires it, network and host-based IDSs should be used to track and investigate events in this domain.

Finally, the security professional should recommend the use of a switched network if a shared media such as coaxial or twisted-pair media is used. Traditional shared media networks allow any system on the network to see all network traffic. This makes it very easy for a sniffer to be placed on the network and packets collected, including password and sensitive application data. Use of a switched network makes it much more difficult, although not impossible.

Other controls should be used in the design of the LAN. If the enterprise is using DHCP, any person who connects to the LAN and obtains an IP address can gain access to the enterprise network. For large enterprises, it is unrealistic to attempt to implement MAC level controls due to the size of the network. However, public areas such as lobbies and conference rooms should be set up in one of the following manners:

- No live network jacks
- DHCP on a separate subnet and security domain
- Filtered traffic

The intent of these controls is to prevent a computer in a conference room from being able to participate fully on the network, and only offer limited services. In this context, security domains can be configured to specifically prevent access to other parts of the network or specific systems based on the source IP address.

Other LAN-based controls for network analysis and reporting, such as Nicksun Probe and NetVCR, provide network diagnostics, investigation, and forensics information. However, on large, busy networks, these provide an additional challenge, that being the disk space to store the information for later analysis.

Each of the foregoing layers provides the capability to monitor activities within that layer. Monitoring systems will be capable of collecting information from one or more layers, which will trigger alarm mechanisms when certain undesirable operational or security criteria are met. The alarm and monitoring tools layer will include such things as event logging, system usage, exception reporting, and clock synchronization.

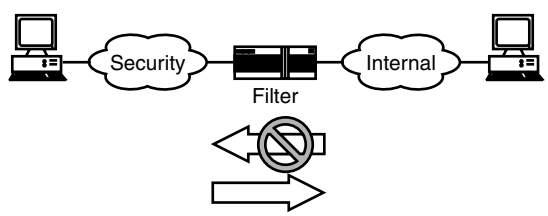

EXHIBIT 121.3 Local Area Network with Security Domains.

Physical Security

Physical security pertains to all practices, procedures, and measures relating to the operating environment, the movement of people, equipment or goods, building access, wiring, system hardware, etc. Physical security elements are used to ensure that the corporate assets are not subjected to unwarranted security risks. Items addressed at this layer include secure areas, security of equipment off-premises, movement of equipment, and secure disposal of equipment.

The physical security of the following network access control devices, is paramount to ensuring the ongoing protection of the network and enterprise data:

- Firewall
- IDS
- Filter routers
- Hubs
- Switches
- Cabling and
- Security systems

Should these systems not be adequately protected, a device could be installed and no one would notice. Physical security controls for these devices should include locked cabinets and cable conduits, to name only two.

System Controls

Beyond the network are the systems and applications that users use on a daily basis to fulfill enterprise business objectives. The protection of the operating system, the application proper, and the data are just as important as the network.

Fundamentally, information security is in the hands of the users. Regardless of the measures that may be implemented, carelessness on the part of individuals involved in the preparation, consolidation, processing, recording, or movement of information can compromise any or all security measures. This layer then looks at the human-related processes, procedures, and knowledge related to developing a secure environment, such as user training, information security training and awareness, and security policies and procedures.

Access to the environment must be controlled through a coordinated access control program, as discussed later in this article. Access control provides the control mechanisms to limit access to systems, applications, data, or services to authorized people or systems. It includes, for example, identification of the user, their authorization, and security practices and procedures. Examples of items that would be included in access control systems include identification and authentication methods, privilege management, and user registration. One could argue that privilege management is part of authorization; however, it should be closely coupled to the authentication system.

The operating system controls provide the functionality for applications to be executed and management of system peripheral units, including connectivity to network facilities. A heterogeneous computing environment cannot be considered homogeneous from a security perspective because each manufacturer has addressed the various security issues in a different manner. However, within your architecture, the security professional should establish consistent operating system baselines and configurations to maintain the overall environment.

Just as the security professional will likely install a network-based intrusion detection system, so too should host-based systems be considered for the enterprise's critical systems and data. Adding the host-based element provides the security professional with the ability to monitor for specific events on the system itself that may not be monitored by or captured through a network-based intrusion detection system.

The data aspect of the architecture addresses the measures taken to ensure data origination authenticity, integrity, availability, non-repudiation, and confidentiality. This layer will address such things as database management, data movement and storage, backup and recovery, and encryption. Depending on the applications in use, a lot of data is moved between applications. These data transfers, or interfaces, must be developed appropriately to ensure that there is little possibility for data compromise or loss while in transit.

The application and services layer addresses the controls required to ensure the proper management of information processing, including inputs and outputs, and the provision of published information exchange services.

Establishing the Program

The security architecture must not only include the elements discussed so far, but also extend into all areas to provide an infrastructure providing protection from the perimeter to the data. This is accomplished by linking security application and components in a tightly integrated structure to implement a security control infrastructure (see Exhibit 121.4).

The security control infrastructure includes security tools and processes that sit between the application and the network. The security control infrastructure augments or, ideally, replaces some of the control features in the applications — mostly user authentication. This means that the application does not maintain its own view of authentication, but relies on the security control infrastructure to perform the authentication. The result is that the user can authenticate once, and let the security control infrastructure take over. This allows for the eventual implementation of a single sign-on capability.

A centralized tool for the management of individual user and process privileges is required to enable the security control infrastructure to achieve this goal. The centralized user management services interact with the control infrastructure to determine what the user is allowed to do. Control infrastructure and other services within it depend on the existence of an enterprisewide privilege database containing the access and application rights for every user.

The result is a security infrastructure that has the ability to deliver encryption, strong authentication, and a corporate directory with the ability to add single sign-on and advanced privilege management in the future.

The Corporate Directory

The corporate directory, which is a component of the security control infrastructure, contains elements such as:

- Employee number, name, department, and other contact information
- Organizational information such as the employee's manager and reporting structure
- Systems assigned to the employee
- User account data
- E-mail addresses
- Authorized application access
- Application privileges
- Authentication information, including method, passwords, and access history
- Encryption keys

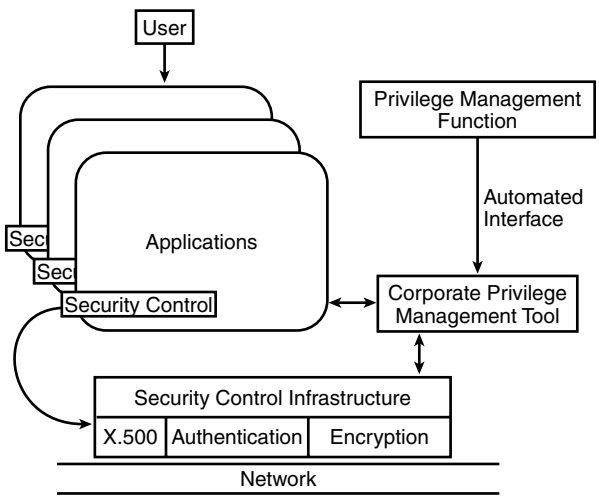

EXHIBIT 121.4 Security Control Infrastructure.

All of this information is managed through the enterprise user and privilege management system to provide authentication information for network, system, and application access on a per-user basis (see Exhibit 121.5).

With the wide array of directory products available today, most enterprises will not have to develop their own technology, but are best served using X.500 directory services as they provide Lightweight Directory Access Protocol (LDAP) services that can be used by many of today's operating systems, including Windows 2000.

The enterprise directory can be used to provide the necessary details for environments that cannot access the directory directly, such as NIS and non-LDAP-ready Kerberos implementations.

Using the enterprise privilege management applications, a new user can be added in a few minutes, with all the necessary services configured. New applications and services can be added at any time. Should an employee no longer require access to specific applications or application privileges, the same tool can be used to remove them from the enterprise directory, and subsequently the application itself.

A major challenge for many enterprises is removing user access when that user's employment ends. The enterprise directory removes this problem because the information can be removed or invalidated within the directory, thereby preventing the possibility of the employee's access remaining active and exposing the company beyond the user's final day of work.

Authentication Systems

There are many different identification and authentication systems available, including passwords, secure tokens, biometrics, and Kerberos to name a few (see Exhibit 121.6). The enterprise must ultimately decide what authentication method makes sense for its own business needs, and may require multiple systems for different information types within the enterprise. However, the common thread is that in today's environment, the simple password is just not good enough anymore.

When a user authenticates to a system or application, his credentials are validated against the enterprise directory, which then makes the decision to allow or deny the user's access request. The directory can also provide authorization information to the requesting application, thereby limiting the access rights for that user. Using this methodology, the exact authentication method is irrelevant and could be changed at any time. For example, using a password today could be replaced with a secure token, biometrics, or Kerberos at any time, and multiple authentication technologies can easily co-exist within the enterprise.

However, one must bear in mind that user authentication is only one aspect. A second aspect concerns authentication of the information. This is achieved through the use of a digital signature, which provides the authentication and integrity of the original message.

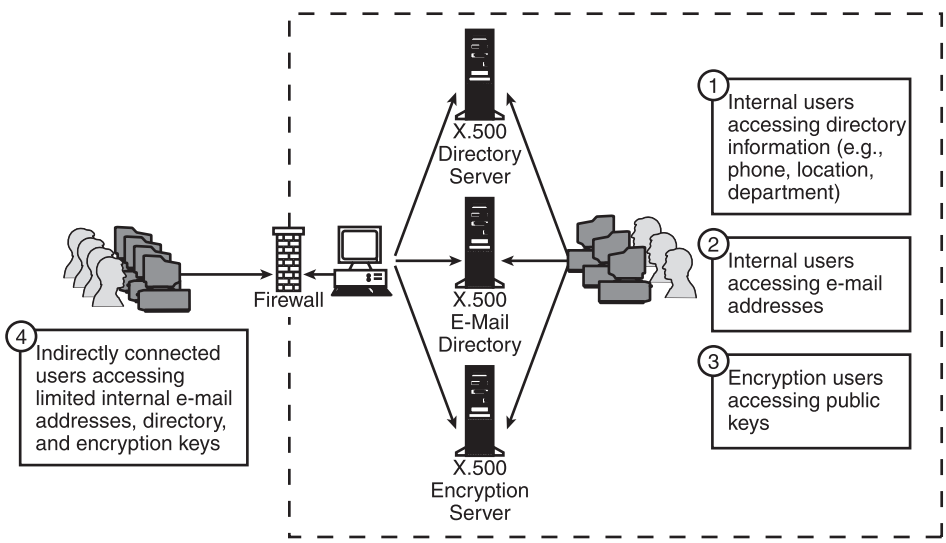

EXHIBIT 121.5 Authentication Information for Network, System, and Application Access.

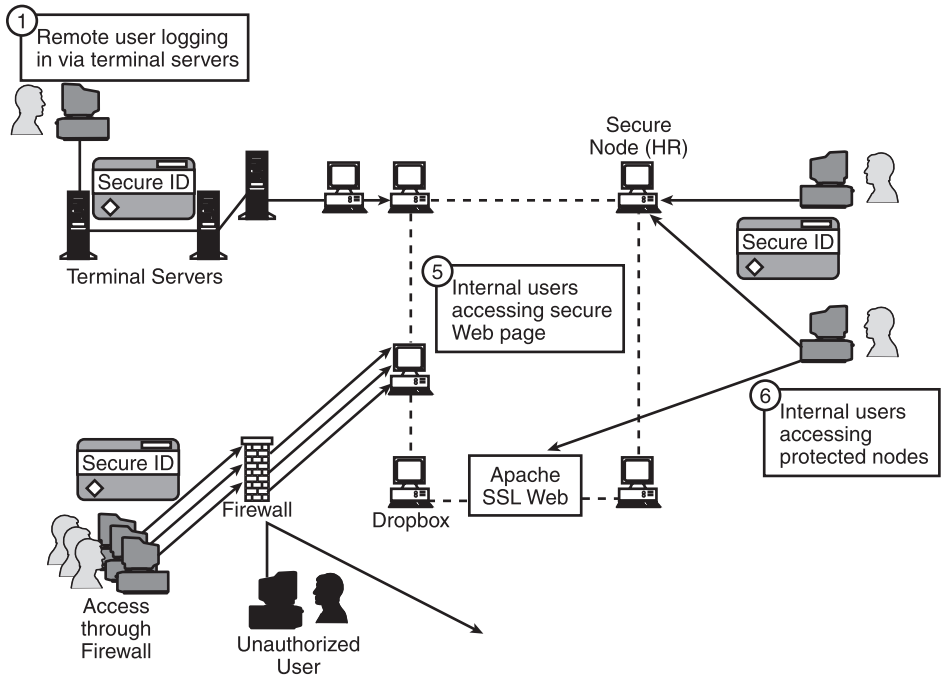

EXHIBIT 121.6 Authentication Systems.

It is important to remember that no authentication method is perfect. As security professionals, we can only work to establish even greater levels of trust to the authenticating users.

Encryption Services

Encryption is currently the only way to ensure the confidentiality of electronic information. In today's business environment, the protection of enterprise and strategic information has become a necessity. Consequently, the infrastructure requirements include encryption and digital signatures (see Exhibit 121.7).

Encryption of files before sending them over the Internet is essential, given the amount of business and intellectual property stolen over the Internet each year. The infrastructure must provide for key management, as well as the ability to handle keys of varying size. For example, global companies may require key management abilities for multiple key sizes.

Encryption of enterprise information may be required within applications. However, without a common application-based encryption method, this is difficult to achieve. Through the use of virtual private network (VPN) technologies, however, one can construct a VPN within the enterprise network for the protection of specific information, regardless of the underlying network technologies. Virtual private networking is also a critical service when sessions are carried over insecure networks such as the Internet.

In addition, the mobile user community must be able to protect the integrity and confidentiality of its data in the event a computer is stolen. This level of protection is accomplished with more than encryption, such as disk and system locking tools.

Customer and Business Partner Access

The use of the security infrastructure allows for the creation of secure environments for information exchange. One such example is the customer access network (see Exhibit 121.8) or those entry points where nonenterprise employees such as customers and suppliers can access the enterprise network and specific resources. In our global community, the number of networks being connected every day continues to grow. However, connecting one's corporate network to "theirs" also exposes one to all of the other networks "they" are connected to.

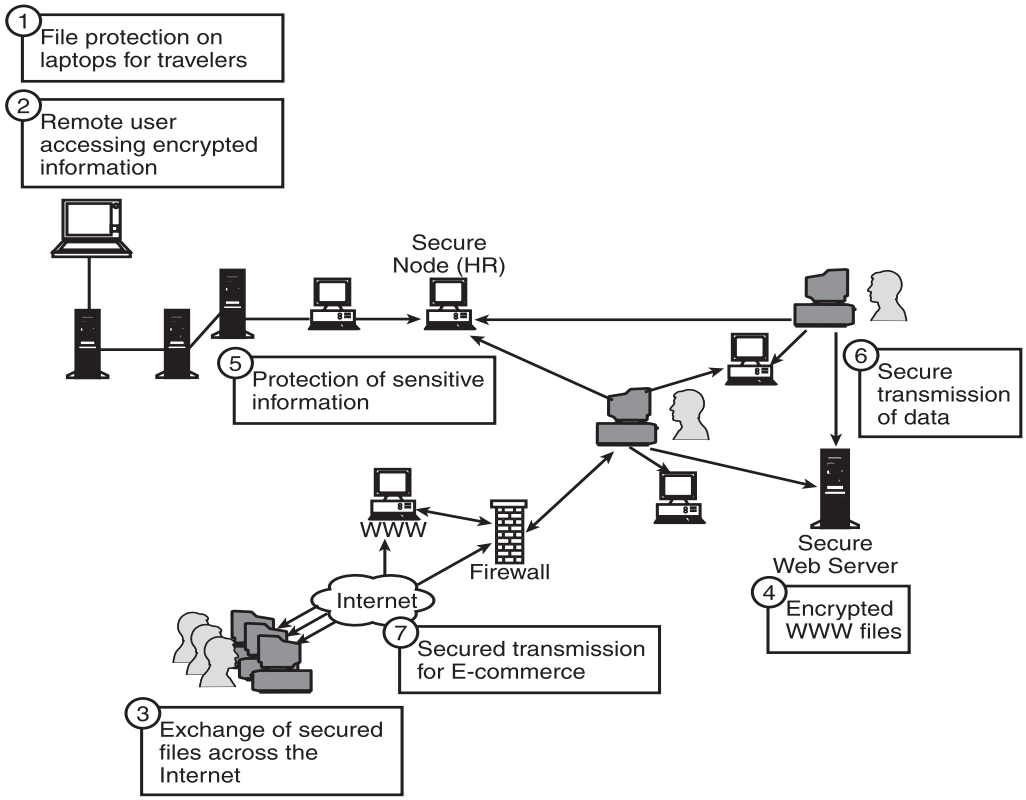

EXHIBIT 121.7 Encryption Services.

Through the deployment of customer access networks, the ability to provide connectivity with security is achieved.

The customer access network is connected to the customer network and to one's corporate network, configured to prevent access between connected partners, and includes a firewall between it and the corporate network. In fact, the customer may also want a firewall between its network and the access point.

With VPN technologies, the customer access network may not be extremely complicated, but does result in a VPN endpoint and specific rules within the VPN device for restricting the protocol types and destinations that the customer is permitted to access.

The rules associated with the individual customer should be stored in the enterprise directory to allow easy setup and removal of the VPN access rules and keys. The real purpose behind the customer access network is not only to build a bridge between the two networks, but also to build a secure bridge.

Conclusion

This article focused on the technologies and concepts behind a security infrastructure. There are other elements that ideally should be part of the security infrastructure, including:

- Desktop and server anti-virus solutions
- Web and e-mail content filtering
- Anti-spam devices

At the same time, however, one's infrastructure must be designed at the conceptual level using the business processes and needs, and not be driven by the available technology. The adage that "the business must drive

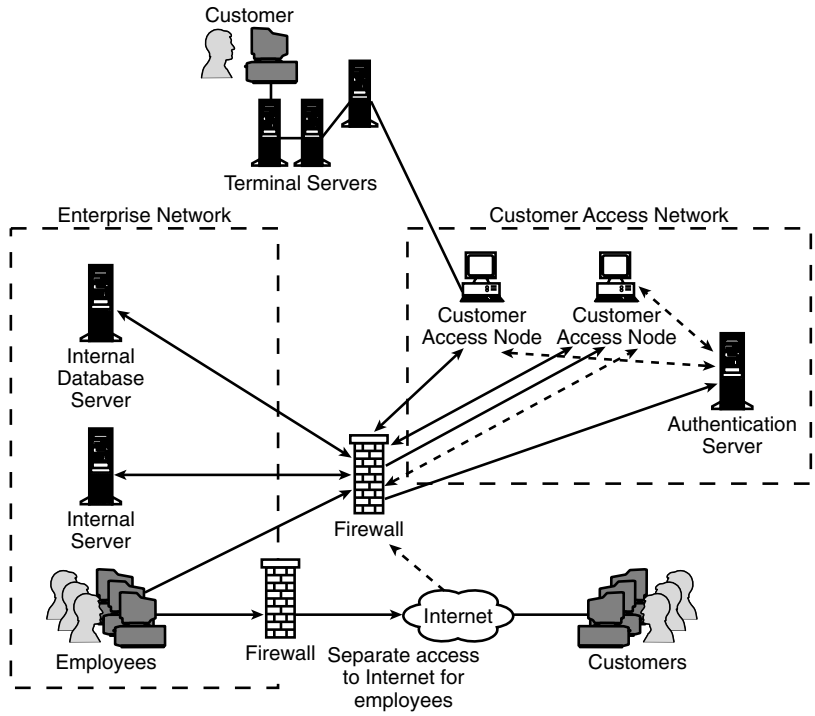

EXHIBIT 121.8 Customer Access Network.

the technology" is especially true. Many security and IT professionals forget that their jobs are dependent upon the viability and success of the enterprise — they exist to serve the enterprise, and not the other way around!

Many infrastructure designers are seduced by the latest and greatest technology. This can have dire consequences for the enterprise due to unreliable code or hardware. Additionally, one nevers knows when one has something that works because one is constantly changing it. To make matters worse, because the users will not know what the "flavor of the week" is, they will simply refuse to use it.

Through the development of a security infrastructure that is global in basis and supported by the management structure, the following benefits are realized:

- The ability to encourage developers to include security in the early stages of their new products or business processes
- The risk and costs associated with new ventures or business partners are reduced an order of magnitude from reactive processes
- Centralized planning and operations with an infrastructure responsive to meeting business needs
- Allow business application developers to deliver stronger controls over stored intellectual capital
- The risks associated with loss of confidentiality are minimized
- A strengthening of security capabilities within the installed backbone applications (e.g., e-mail, servers, Web)
- The privacy and integrity associated with the corporation's intellectual capital are increased
- The risks and costs associated with security failures are reduced

In short, we have created a security infrastructure, which protects the enterprise assets, is manageable, and is a business enabler.

Above all this, the infrastructure must allow the network users, developers, and administrators to contribute to the corporation's security by allowing them to "do the right thing."

122

The Reality of Virtual Computing

Chris Hare, CISSP, CISA

A major issue in many computing environments is accessing the desktop or console display of a different graphical-based system than the one you are using. If you are in a homogeneous environment, meaning you want to access a Microsoft Windows system from a Windows system, you can use applications such as Timbuktu, pcAnywhere, or RemotelyPossible.

In today's virtual enterprise, many people have a requirement to share their desktops or allow others to view or manipulate it. Many desktop-sharing programs exist aside from those mentioned, including Microsoft NetMeeting and online conferencing tools built into various applications.

The same is true for UNIX systems, which typically use the X Windows display system as the graphical user interface. It is a simple matter of running the X Windows client on the remote system and displaying it on the local system.

However, if you must access a dissimilar system (e.g., a Windows system from a UNIX system) the options are limited. It is difficult to find an application under UNIX that allows a user to view an online presentation from a Windows system using Microsoft PowerPoint. This is where Virtual Network Computing, or VNC, from AT&T's United Kingdom Research labs, enters the picture.

This chapter discusses what VNC is, how it can be used, and the security considerations surrounding VNC. The information presented does get fairly technical in a few places to illustrate the protocol, programming techniques, and weaknesses in the authentication scheme. However, the corresponding explanations should address the issues for the less technical reader.

What Is VNC?

The Virtual Network Computing system, or VNC, was developed at the AT&T Research Laboratories in the United Kingdom. VNC is a very simple graphical display protocol allowing connections from heterogeneous or homogeneous computer systems.

VNC consists of a server and a viewer, as illustrated in Exhibit 122.1. The server accepts connection requests to display its local display on the viewer.

The VNC services are based on what is called a *remote framebuffer* or RFB. The framebuffer protocol simply allows a server to update the framebuffer or graphical display device on the remote viewer. With total independence from the graphical device driver, it is possible to represent the local display from the server on the client or viewer. The portability of the design means the VNC server should function on almost any hardware platform, operating system, windowing system, and application.

Support for VNC is currently available for a number of platforms, including:

- Servers:
  - UNIX (X Window system)
  - Microsoft Windows

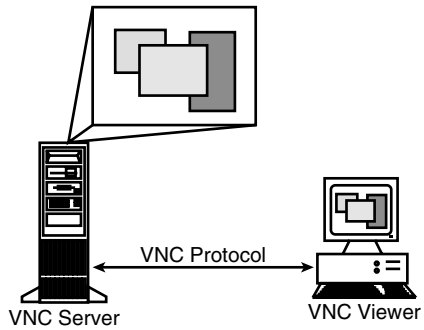

EXHIBIT 122.1 The VNC components.

  - Macintosh
- Viewers:
  - UNIX (X Window System)
  - Microsoft Windows
  - Macintosh
  - Java
  - Microsoft Windows CE

VNC is described as a thin client protocol, making very few requirements on the viewer. In this manner, the client can run on the widest range of hardware. There are a number of factors distinguishing VNC from other remote display systems, including:

- VNC is stateless, meaning you can terminate the session and reconnect from another system and continue right where you left off. When you connect to a remote system using an application such as a PC X Server and the PC crashes or is restarted, the X Window system applications running terminate. Using VNC, the applications remain available after the reboot.
- The viewer is a thin client and has a very small memory footprint.
- VMC is platform independent, allowing a desktop on one system to be displayed on any other type of system, including Java-capable Web browsers.
- It can be shared, allowing multiple users the ability to view and share a single desktop at the same time. This can be useful when needing to perform presentations over the network.
- And, best of all, VNC is free and distributed under the standard GNU General Public License (GPL).

These are some of the benefits available with VNC. However, despite the clever implementation to share massive amounts of video data, there are a few weaknesses, as presented in this chapter.

How It Works

Accessing the VNC server is done using the VNC client and specifying the IP address or node name of the target VNC server as shown in Exhibit 122.2.

The window shown in Exhibit 122.2 requests the node name or IP address for the remote VNC server. It is also possible to add a port number with the address. The VNC server has a password to protect unauthorized access to the server. After providing the target host name or IP address, the user is prompted for the password to access the server, as seen in Exhibit 122.3.

The Microsoft Windows VNC viewer does not display the password when the user enters it, as shown in Exhibit 122.4. However, the VNC client included in Linux systems does not hide the password when the user enters it. This is an issue because it exposes the password for the server to public view. However, because there is no user-level authentication, one could say there is no problem. Just in case you missed it, *there is no user-level authentication*. This is discussed again later in this chapter in the section entitled "Access Control."

EXHIBIT 122.2 The X Windows VNC client.

EXHIBIT 122.3 Entering the VNC server password.

EXHIBIT 122.4 The UNIX VNC client displays the password.

The VNC client prompts for the password after the connection is initiated with the server and requests authentication using a challenge–response scheme. The challenge–response system used is described in the section entitled "Access Control."

Once the authentication is successful, the client and server then exchange a series of messages to negotiate the desktop size, pixel format, and the encoding schemes. To complete the initial connection setup, the client requests a full update for the entire screen and the session commences. Because the client is stateless, either the server or the client can close the connection with no impact to either the client or server.

Actually, this chapter was written logged into a Linux system and using VNC to access a Microsoft Windows system that used VNC to access Microsoft Word. When using VNC on the UNIX- or Linux-based client, the user sees the Windows desktop as illustrated in Exhibit 122.5.

The opposite is also true — a Windows user can access the Linux system and see the UNIX or Linux desktop as well as use the features and functionality offered by the UNIX platform (see Exhibit 122.6). However, VNC is not limited to these platforms, as mentioned earlier and demonstrated later.

However, this may not be exactly what the Linux user was expecting. The VNC sessions run as additional displays on the X server, which on RedHat Linux systems default to the TWM Window Manager. This can be changed; however, that is outside the topic area of this chapter.

EXHIBIT 122.5 The Windows desktop from Linux.

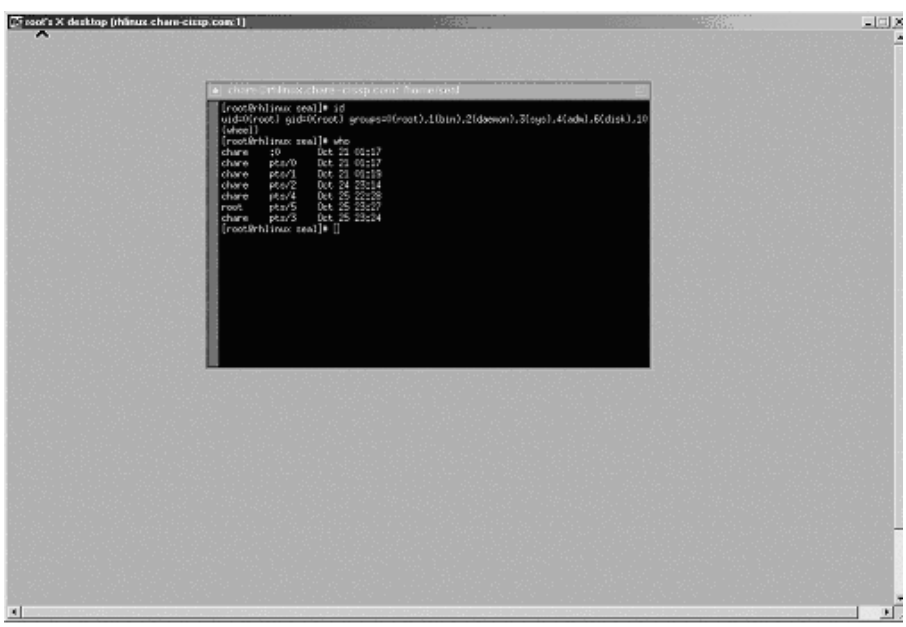

EXHIBIT 122.6 The TWM Window Manager from Windows.

Network Communication

All network communication requires the use of a network port. VNC is a connection-based TCP/IP application requiring the use of network ports. The VNC server listens on two ports. The values of these ports depend on the access method and the display number.

The VNC server listens on port 5900 plus the display number. WinVNC for Microsoft Windows defaults to display zero, so the port is 5900. The same is true for the Java-based HTTP port, listening at port 5800 plus the display number. This small and restrictive Web server is discussed more in the section entitled "VNC and the Web."

If there are multiple VNC servers running on the same system, they will have different port numbers because their display number is different, as illustrated in Exhibit 122.7.

There is a VNC server executed for each user who wishes to have one. Because there is no user authentication in the VNC server, the authentication is essentially port based. This means user chare is running a VNC server, which is set up on display 1 and therefore port 5901. Because the VNC server is running at user chare, anyone who learns or guesses the password for the VNC server can access chare's VNC server and have all of chare's privileges.

Looking back to Exhibit 122.6, the session running on the Linux system belonged to root as shown here:

```
[chare@rhlinux chare]$ ps -ef | grep vnc
root20368    10 23:21 pts/100:00:00 Xvnc :
   1 -desktop X -httpd/usr/s
chare20476204360 23:25 pts/300:00:00 grep vnc
[chare@rhlinux chare]$
```

In this scenario, any user who knows the password for the VNC server on display 1, which is port 5901, can become root with no additional password required. Because of this access control model, good-quality passwords must be used to control access to the VNC server; and they must be kept absolutely secret.

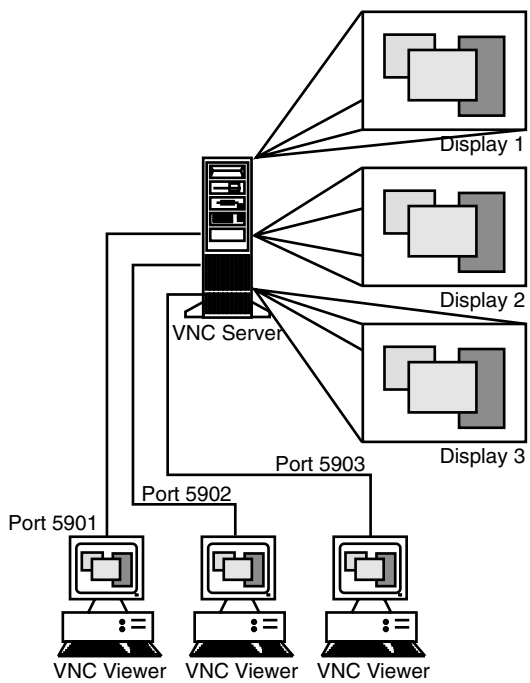

EXHIBIT 122.7 Multiple VNC servers.

As mentioned previously, the VNC server also runs a small Web server to support access through the Java client. The Web server listens on port 58xx, where xx is the display number for the server. The HTTP port on the Web server is only used to establish the initial HTTP connection and download the applet. Once the applet is running in the browser, the connection uses port 59xx. The section entitled "VNC and the Web" describes using the VNC Java client.

There is a third mode, where the client listens for a connection from the server rather than connecting to a server. When this configuration is selected, the client listens on port 5500 for the incoming connection from the server.

Access Control

As mentioned previously, the client and server exchange a series of messages during the initial connection setup. These protocol messages consist of:

- ProtocolVersion
- Authentication
- ClientInitialization
- ServerInitialization

Once the ServerInitialization stage is completed, the client can send additional messages when it requires and receive data from the server.

The protocol version number defines what level of support both the client and server have. It is expected that some level of backward compatibility is available because the version reported should be the latest version the client or server supports. When starting the VNC viewer on a Linux system, the protocol version is printed on the display (standard out) if not directed to a file.

Using a tool such as tcpdump, we can see the protocol version passed from the client to the server (shown in bold text):

```

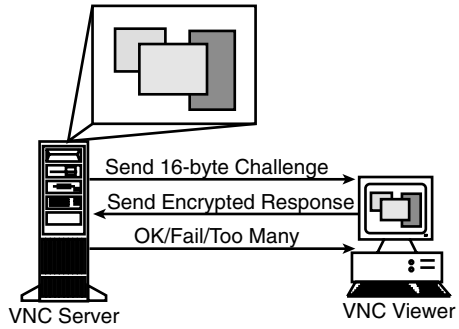

EXHIBIT 122.8 The VNC authentication challenge–response.

With the protocol version established, the client attempts to authenticate to the server. The password prompt shown in Exhibit 122.3 is displayed on the client, where the user enters the password.

There are three possible authentication messages in the VNC protocol:

1. *Connection Failed.* The connection cannot be established for some reason. If this occurs, a message indicating the reason the connection could not be established is provided.
2. *No Authentication.* No authentication is needed. This is not a desirable option.
3. *VNC Authentication.* Use VNC authentication.

The VNC authentication challenge–response is illustrated in Exhibit 122.8.

The VNC authentication protocol uses a challenge–response method with a 16-byte (128-bit) challenge sent from the server to the client. The challenge is sent from the server to the client in the clear. The challenge is random, based on the current time when the connection request is made. The following packet has the challenge highlighted in bold.

```
14:36:08.908961 < alpha.5900 > rhlinux.chare-cissp.com.

          ^Y] ..
```

The client then encrypts the 16-byte challenge using Data Encryption Standard (DES) symmetric cryptography with the user-supplied password as the key. The VNC DES implementation is based upon a public domain version of Triple-DES, with the double and triple length support removed. This means VNC is only capable of using standard DES for encrypting the response to the challenge. Again, the following packet has the response highlighted in bold.

```
14:36:11.188961 < rhlinux.chare-cissp.com.2058 >

```

The server receives the response and, if the password on the server is the same, the server can decrypt the response and find the value issued as the challenge. As discussed in the section "Weaknesses in the VNC Authentication System" later in this chapter, the approach used here is vulnerable to a man-in-the-middle attack, or a cryptographic attack to find the key, which is the password for the server.

Once the server receives the response, it informs the client if the authentication was successful by providing an *OK*, *Failed*, or *Too Many* response. After five authentication failures, the server responds with *Too Many* and does not allow immediate reconnection by the same client.

The *ClientInitialization* and *ServerInitialization* messages allow the client and server to negotiate the color depth, screen size, and other parameters affecting the display of the framebuffer.

As mentioned in the "Network Communication" section, the VNC server runs on UNIX as the user who started it. Consequently, there are no additional access controls in the VNC server. If the password is not known to anyone, it is safe. Yes and no. Because the password is used as the key for the DES-encrypted response, the password is never sent across the network in the clear. However, as we will see later in the chapter, the challenge–response method is susceptible to a man-in-the-middle attack.

The VNC Server Password

The server password is stored in a password file on the UNIX file system in the ~/.vnc directory. The password is always stored using the same 64-bit key, meaning the password file should be protected using the local file system permissions. Failure to protect the file exposes the password, because the key is consistent across all VNC servers.

The password protection system is the same on the other supported server platforms; however, the location of the password is different.

The VNC source code provides the consistent key:

```
/*
•We use a fixed key to store passwords, because we assume
•that our local file system is secure but nonetheless
•don't want to store passwords as plaintext.
*/

unsigned char fixedkey[8] = {23,82,107,6,35,78,88,7};
```

This fixed key is used as input to the DES functions to encrypt the password; however, the password must be unencrypted at some point to verify authentication.

The VNC server creates the ~/.vnc directory using the standard default file permissions as defined with the UNIX system's umask. On most systems, the default umask is 022, making the the ~/.vnc directory accessible to users other than the owner. However, the password file is explicitly set to force read/write permissions only for the file owner; so the chance of an attacker discovering the password is minimized unless the user changes the permissions on the file, or the attacker has gained elevated user or system privileges.

If the password file is readable to unauthorized users, the server password is exposed because the key is consistent and publicly available. However, the attacker does not require too much information, because the functions to encrypt and decrypt the password in the file are included in the VNC source code. With the knowledge of the VNC default password key and access to the VNC server password file, an attacker can obtain the password using 20 lines of C language source code.

A sample C program, here called attack.c, can be used to decrypt the VNC server password should the password file be visible:

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/types.h>
#include <sys/stat.h>
#include <vncauth.h>
#include <d3des.h>
main( argc, argv)
      int argc;
      char **argv;
{
   char *passwd;
   if (argc < = 1)
      {
      printf ("specify the location and name of a VNC
         password file\n");
      exit(1);
      }
   /* we might have a file */
   passwd = vncDecryptPasswdFromFile(argv[1]);
   printf ("passowrd file is%s\n," argv[1]);
   printf ("password is%s\n," passwd);
   exit(0);
}
```

Note: Do not use this program for malicious purposes. It is provided for education and discussion purposes only.

Running the attack.c program with the location and name of a VNC password file displays the password:

```
[chare@rhlinux libvncauth]$./attack $HOME/.vnc/passwd
passowrd file is/home/chare/.vnc/passwd
password is holycow
```

The attacker can now gain access to the VNC server. Note, however, this scenario assumes the attacker already has access to the UNIX system.

For the Microsoft Windows WinVNC, the configuration is slightly different. Although the methods to protect the password are the same, WinVNC uses the Windows registry to store the server's configuration information, including passwords. The WinVNC registry entries are found at:

- *Local machine-specific settings:*
  HKEY_LOCAL_MACHINE\Software\ORL\WinVNC3\
- *Local default user settings:*
  HKEY_LOCAL_MACHINE\Software\ORL\WinVNC3\Default
- *Local per-user settings:*
  HKEY_LOCAL_MACHINE\Software\ORL\WinVNC3\<*username*>
- *Global per-user settings:*
  HKEY_CURRENT_USER\Software\ORL\WinVNC3

The WinVNC server password will be found in the local default user settings area, unless a specific user defines his own server. The password is stored as an individual registry key value as shown in Exhibit 122.9.

Consequently, access to the registry should be as controlled as possible to prevent unauthorized access to the password.

The password stored in the Windows registry uses the same encryption scheme to protect it as on the UNIX system. However, looking at the password shown in Exhibit 122.9, we see the value:

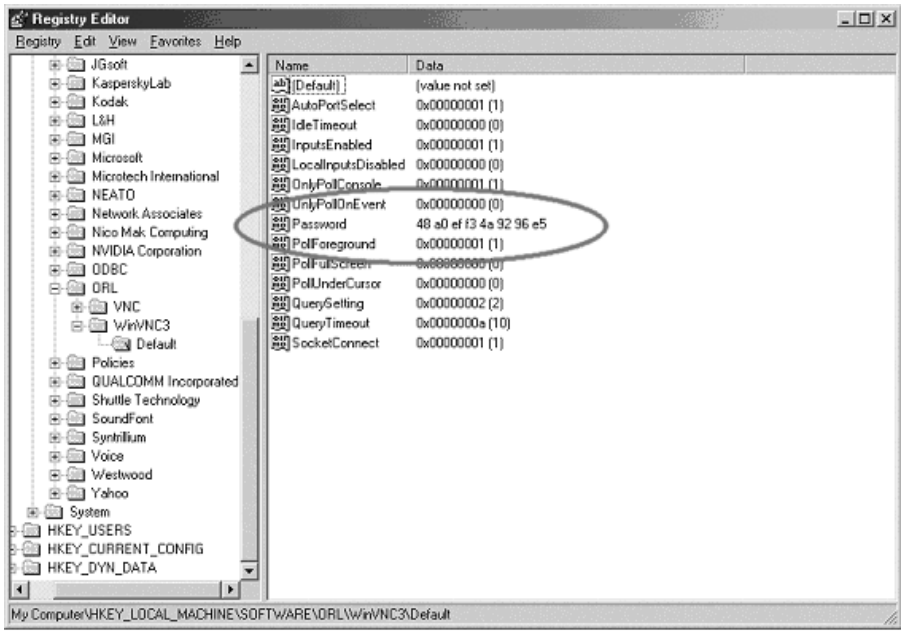

EXHIBIT 122.9 WinVNC Windows registry values.

```
48 a0 ef f3 4a 92 96 e5
```

and the value stored on UNIX is:

```
a0 48 f3 ef 92 4a e5 96
```

Comparing these values, we see that the byte ordering is different. However, knowing that the ordering is different, we can use a program to create a binary file on UNIX with the values from the Windows system and then use the attack.c program above to determine the actual password. Notice that because the password values shown in this example are the same, and the encryption used to hide the passwords is the same, the passwords are the same.

Additionally, the VNC password is limited to eight characters. Even if the user enters a longer password, it is truncated to eight. Assuming a good- quality password with 63 potential characters in each position, this represents only 63^8 possible passwords. Even with this fairly large number, the discussion thus far has demonstrated the weaknesses in the authentication method.

Running a VNC Server under UNIX

The VNC server running on a UNIX system uses the X Window System to interact with the X-based applications on UNIX. The applications are not aware there is no physical screen attached to the system. Starting a new VNC server is done by executing the command:

```
vncserver
```

on the UNIX host. Because the vncserver program is actually written in Perl, most common problems with starting vncserver are associated with the Perl installation or directory structures.

Any user on the UNIX host can start a copy of the VNC server. Because there is no user authentication built into the VNC server or protocol, running a separate server for each user is the only method of providing limited access. Each vncserver has its own password and port assignment, as presented earlier in the chapter.

The first time a user runs the VNC server, he is prompted to enter a password for the VNC server. Each VNC server started by the same user will have the same password. This occurs because the UNIX implemen-

tation of VNC creates a directory called .vnc in the user's home directory. The .vnc directory contains the log files, PID files, password, and X startup files. Should the user wish to change the password for the VNC servers, he can do so using the `vncpasswd` command.

VNC Display Names

Typically the main display for a workstation using the X Window System is display 0 (zero). This means on a system named *ace*, the primary display is ace:0. A UNIX system can run as many VNC servers as the users desire, with the display number incrementing for each one. Therefore, the first VNC server is display ace:1, the second ace:2, etc. Individual applications can be executed and, using the DISPLAY environment variable defined, send their output to the display corresponding to the desired VNC server.

For example, sending the output of an xterm to the second VNC server on display ace:2 is accomplished using the command:

```
xterm -display ace:2 &
```

Normally, the `vncserver` command chooses the first available display number and informs the user what that display is; however, the display number can be specified on the command line to override the calculated default:

```
vncserver :2
```

No visible changes occur when a new VNC server is started, because only a viewer connected to that display can actually see the resulting output from that server. Each time a connection is made to the VNC server, information on the connection is logged to the corresponding server log file found in the $HOME/.vnc directory of the user executing the server. The clog file contents are discussed in the "Logging" section of this chapter.

VNC as a Service

Instead of running individual VNC servers, there are extensions available to provide support for VNC under the Internet Super-Daemon, inetd and xinetd. More information on this configuration is available from the AT&T Laboratories Web site.

VNC and Microsoft Windows

The VNC server is also available for Microsoft Windows, providing an alternative to other commercial solutions and integration between heterogeneous operating systems and platforms. The VNC server under Windows is run as a separate application or a service. Unlike the UNIX implementation, the Windows VNC server can only display the existing desktop of the PC console to the user. This is a limitation of Microsoft Windows, and not WinVNC. WinVNC does not make the Windows system a multi-user environment: if more than one user connects to the Windows system at the same time, they will all see the same desktop.

Running WinVNC as a service is the preferred mode of operation because it allows a user to log on to the Windows system, perform his work, and then log off again.

When running WinVNC, an icon as illustrated in Exhibit 122.10 is displayed. When a connection is made, the icon changes color to indicate there is an active connection.

The WinVNC properties dialog shown in Exhibit 122.11 allows the WinVNC user to change the configuration of WinVNC. All the options are fully discussed in the WinVNC documentation.

With WinVNC running as a service, a user can connect from a remote system even when no user is logged on at the console. Changing the properties for WinVNC when it is running as a service has the effect of changing the service configuration, also known as the default properties, rather than the individual user properties. However, running a nonservice mode WinVNC means a user must have logged in on the console and started WinVNC for it to work correctly. Exhibit 122.12 illustrates accessing WinVNC from a Linux system while in service mode.

Aside from the specific differences for configuring the WinVNC server, the password storage and protocol-level operations are the same, regardless of the platform. Because there can be only one WinVNC server running at a time, connections to the server are on ports 5900 for the VNC viewer and 5800 for the Java viewer.

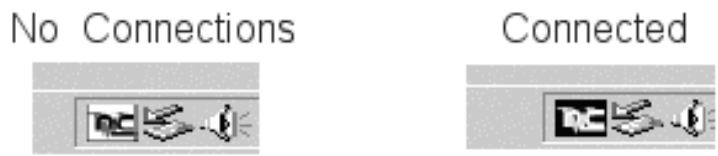

EXHIBIT 122.10 WinVNC system tray icons.

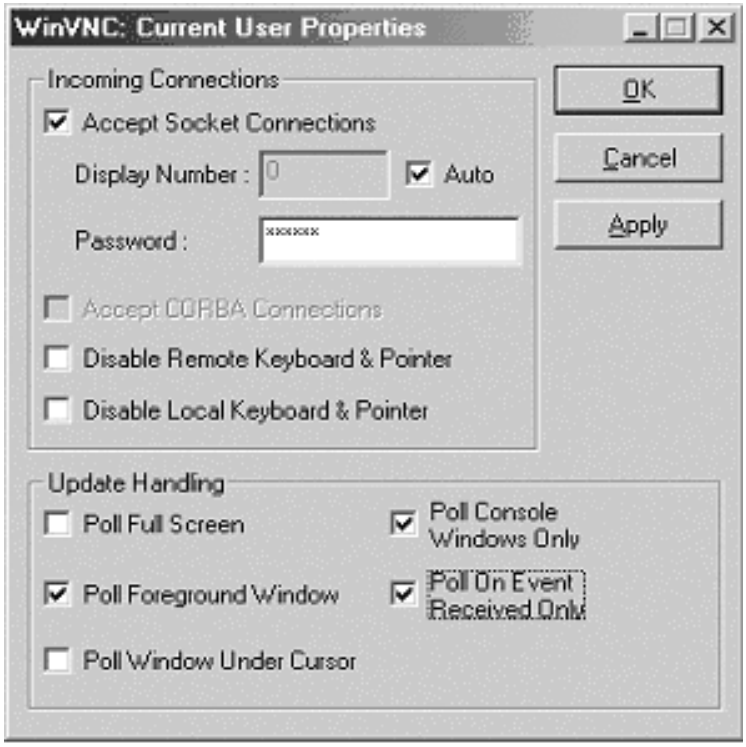

EXHIBIT 122.11 The WinVNC Properties dialog.

VNC and the Web

As mentioned previously, each VNC server listens not only on the VNC server port but also on a second port to support Web connections using a Java applet and a Web browser. This is necessary to support Java because a Java applet can only make a connection back to the machine from which it was served.

Connecting to the VNC server using a Java-capable Web browser to:

```
http://ace:5802/
```

loads the Java applet and presents the log-in screen where the password is entered. Once the password is provided, the access controls explained earlier prevail. Once the applet has connected to the VNC server port, the user sees a display resembling that shown in Exhibit 122.13.

With the Java applet, the applications displayed through the Web browser can be manipulated as if they were displayed directly through the VNC client or on the main display of the workstation.

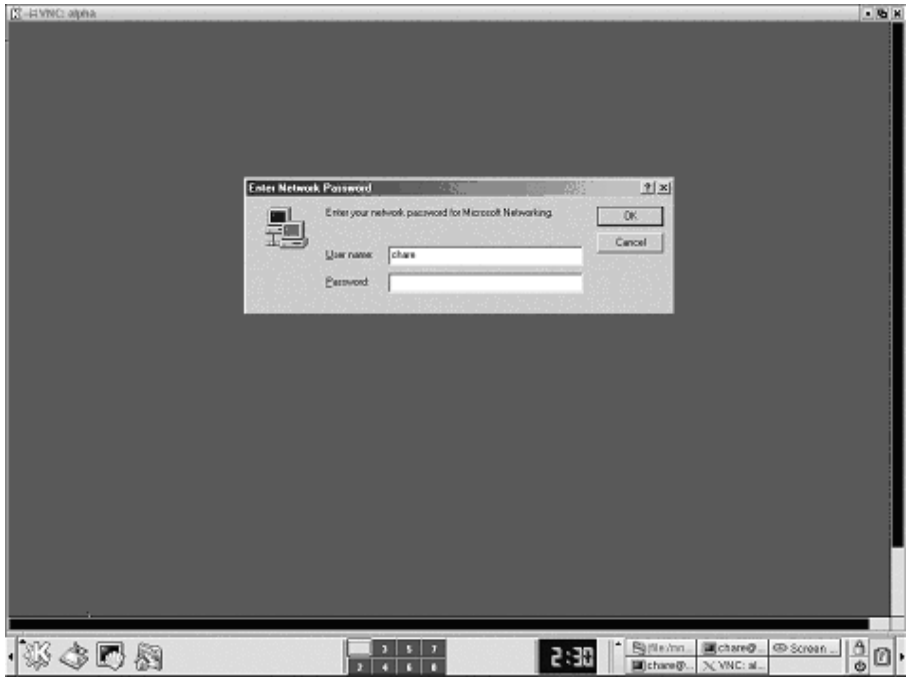

EXHIBIT 122.12 Accessing WinVNC in service mode.

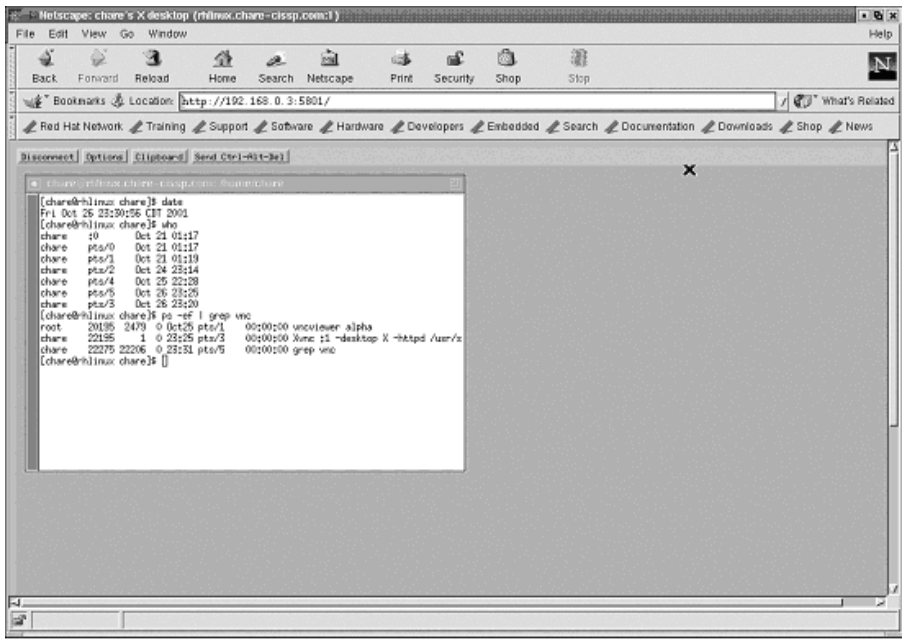

EXHIBIT 122.13 A VNC connection using a Java-capable Web browser.

Logging

As with any network-based application, connection and access logs provide valuable information regarding the operation of the service. The log files from the VNC server provide similar information for debugging or later analysis. A sample log file resembles the following. The first part of the log always provides information on the VNC server, including the listing ports, the client name, display, and the URL.

```
26/10/01 23:25:47 Xvnc version 3.3.3r2
26/10/01 23:25:47 Copyright © AT&T Laboratories Cambridge.
26/10/01 23:25:47 All Rights Reserved.
26/10/01 23:25:47 See http://www.uk.research.att.com/
   vnc for information on VNC
26/10/01 23:25:47 Desktop name 'X' (rhlinux.chare-cissp.com:1)
26/10/01 23:25:47 Protocol version supported 3.3
26/10/01 23:25:47 Listening for VNC connections on TCP port 5901
26/10/01 23:25:47 Listening for HTTP connections on TCP port 5801
26/10/01 23:25:47  URL http://rhlinux.chare-cissp.com:5801
```

The following sample log entry shows a connection received on the VNC server. We know the connection came in through the HTTPD server from the log entry. Notice that there is no information regarding the user who is accessing the system — only the IP address of the connecting system.

```
26/10/01 23:28:54 httpd: get '' for 192.168.0.2
26/10/01 23:28:54 httpd: defaulting to 'index.vnc'
26/10/01 23:28:56 httpd: get 'vncviewer.jar' for 192.168.0.2
26/10/01 23:29:03 Got connection from client 192.168.0.2
26/10/01 23:29:03 Protocol version 3.3
26/10/01 23:29:03 Using hextile encoding for client 192.168.0.2
26/10/01 23:29:03 Pixel format for client 192.168.0.2:
26/10/01 23:29:03  8 bpp, depth 8
26/10/01 23:29:03  true colour: max r 7 g 7 b 3, shift r 0 g 3 b 6
26/10/01 23:29:03 no translation needed
26/10/01 23:29:21 Client 192.168.0.2 gone
26/10/01 23:29:21 Statistics:
26/10/01 23:29:21  key events received 12, pointer events 82
26/10/01 23:29:21  framebuffer updates 80, rectangles 304, bytes 48528
26/10/01 23:29:21    hextile rectangles 304, bytes 48528
26/10/01 23:29:21  raw bytes equivalent 866242, compression ratio
 17.850354
```

The log file contains information regarding the connection with the client, including the color translations. Once the connection is terminated, the statistics from the connection are logged for later analysis, if required.

Because there is no authentication information logged, the value of the log details for a security analysis are limited to knowing when and from where a connection was made to the server. Because many organizations use DHCP for automatic IP address assignment and IP addresses may be spoofed, the actual value of knowing the IP address is reduced.

Weaknesses in the VNC Authentication System

We have seen thus far several issues that will have the security professional concerned. However, these can be alleviated as discussed later in the chapter. There are two primary concerns with the authentication. The first is the man-in-the-middle attack, and the second is a cryptographic attack to uncover the password.

The Random Challenge

The random challenge is generated using the rand(3) function in the C programming language to generate random numbers. The random number generator is initialized using the system clock and the current system time. However, the 16-byte challenge is created by successive calls to the random number generator, decreasing the level of randomness on each call. (Each call returns 1 byte or 8 bits of data.)

This makes the challenge predictable and increases the chance an attacker could establish a session by storing all captured responses and their associated challenges. Keeping track of each challenge–response pair can be difficult and, as discussed later, not necessary.

The Man-in-the-Middle Attack

For the purposes of this illustration, we will make use of numerous graphics to facilitate understanding this attack method. The server is system S, the client is C, and the attacker, or man in the middle, is A. (This discussion ignores the possibility the network connection may be across a switched network, or that there are ways of defeating the additional security provided by the switched network technology.)

The attacker A initiates a connection to the server, as seen in Exhibit 122.14. The attacker connects, and the two systems negotiate the protocols supported and what will be used. The attacker observes this by sniffing packets on the network.

We know both the users at the client and server share the DES key, which is the password. The attacker does not know the key. The password is used for the DES encryption in the challenge–response.

The server then generates the 16-byte random challenge and transmits it to the attacker, as seen in Exhibit 122.15. Now the attacker has a session established with the server, pending authorization.

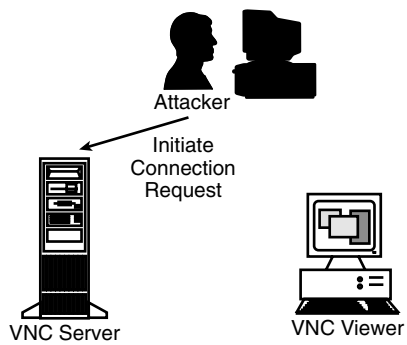

EXHIBIT 122.14 Attacker opens connection to VNC server.

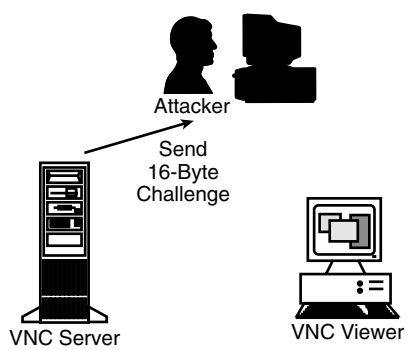

EXHIBIT 122.15 Server sends challenge to attacker.

At this point, the attacker simply waits, watching the network for a connection request to the same server from a legitimate client. This is possible as there is no timeout in the authentication protocol; consequently, the connection will wait until it is completed.

When the legitimate client attempts a connection, the server and client negotiate their protocol settings, and the server sends the challenge to the client as illustrated in Exhibit 122.16. The attacker captures the authentication request and changes the challenge to match the one provided to him by the server.

Once the attacker has modified the challenge, he forges the source address and retransmits it to the legitimate client. As shown in Exhibit 122.17, the client then receives the challenge, encrypts it with the key, and transmits the response to the server.

The server receives two responses: one from the attacker and one from the legitimate client. However, because the attacker replaced the challenge sent to the client with his own challenge, the response sent by the client to server does not match the challenge. Consequently, the connection request from the legitimate client is refused.

However, the response sent does match the challenge sent by the server to the attacker; and when the response received from the attacker matches the calculated response on the server, the connection is granted. The attacker has gained unauthorized access to the VNC server.

Cryptographic Attacks

Because the plaintext challenge and the encrypted response can both be retrieved from the network, it is possible to launch a cryptographic attack to determine the key used, which is the server's password. This is easily done through a brute-force or known plaintext attack.

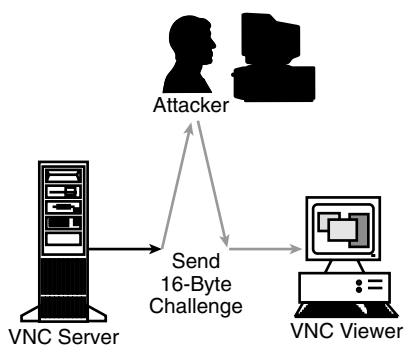

EXHIBIT 122.16 Attacker captures and replaces challenge.

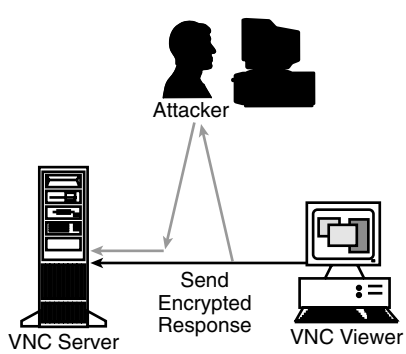

EXHIBIT 122.17 Attacker and client send encrypted response.

A brute-force attack is the most effective, albeit time-consuming method of attack. Both linear cryptanalysis, developed by Lester Mitsui, and differential cryptanalysis, developed by Biham and Shamir, are considered the two strongest analytic (shortcut) methods for breaking modern ciphers; and even these have been shown as not very practical, even against Single-DES.

The known plaintext attack is the most advantageous method because a sample of ciphertext (the response) is available as well as a sample of the plaintext (the challenge). Publicly available software such as *crack* could be modified to try a dictionary and brute-force attack by repeatedly encrypting the challenge until a match for the response is found. The nature of achieving the attack is beyond the scope of this chapter.

Finding VNC Servers

The fastest method of finding VNC servers in an enterprise network is to scan for them on the network devices. For example, the popular nmap scanner can be configured to scan only the ports in the VNC range to locate the systems running it.

```
[root@rhlinux chare]# nmap -p "5500,5800-5999" 192.168.0.1-5
Starting nmap V. 2.54BETA29 (www.insecure.org/nmap/)
All 201 scanned ports on gateway (192.168.0.1) are: filtered
Interesting ports on alpha (192.168.0.2):
(The 199 ports scanned but not shown below are in state: closed)
Port       State   Service
5800/tcp   open    vnc
5900/tcp   open    vnc

Interesting ports on rhlinux.chare-cissp.com (192.168.0.3):
(The 199 ports scanned but not shown below are in state: closed)
Port       State   Service
5801/tcp   open    vnc
5901/tcp   open    vnc-1

Nmap run completed — 5 IP addresses (3 hosts up) scanned in 31 seconds
[root@rhlinux chare]#
```

There are other tools available to find and list the VNC servers on the network; however, nmap is fast and will identify not only if VNC is available on the system at the default ports but also all VNC servers on that system.

Improving Security through Encapsulation

To this point we have seen several areas of concern with the VNC environment:

- There is no user-level authentication for the VNC server.
- The challenge–response system is vulnerable to man-in-the-middle and cryptographic attacks.
- There is no data confidentiality built into the client and server.

Running a VNC server provides the connecting user with the ability to access the entire environment at the privilege level for the user running the server. For example, assuming root starts the first VNC server on a UNIX system, the server listens on port 5901. Any connections to this port where the remote user knows the server password result in a session with root privileges.

We have seen how it could be possible to launch a man-in-the-middle or cryptographic attack against the authentication method used in VNC. Additionally, once the authentication is completed, all the session data is unencrypted and could, in theory, be captured, replayed, and watched by malicious users. However, because VNC uses a simple TCP/IP connection, it is much easier to add encryption support with Secure Sockets Layer (SSL) or Secure Shell (SSH) than, say, a telnet, rlogin, or X Window session.

Secure Shell (SSH) is likely the more obvious choice for most users, given there are clients for most operating systems. SSH encrypts all the data sent through the tunnel and supports port redirection; thus, it can be easily

supported with VNC. Furthermore, although VNC uses a very efficient protocol for carrying the display data, additional benefits can be achieved at slower network link speeds because SSH can also compress the data.

There are a variety of SSH clients and servers available for UNIX, although if you need an SSH server for Windows, your options are very limited and may result in the use of a commercial implementation. However, SSH clients for Windows and the Apple Macintosh are freely available. Additionally, Mindbright Technology offers a modified Java viewer supporting SSL.

Because UNIX is commonly the system of choice for operating a server, this discussion focuses on configuring VNC with SSH using a UNIX-based system. Similar concepts are applicable for Windows-based servers, once you have resolved the SSH server issue. However, installing and configuring the base SSH components are not discussed in this chapter.

Aside from the obvious benefits of using SSH to protect the data while traveling across the insecure network, SSH can compress the data as well. This is significant if the connection between the user and the server is slow, such as a PPP link. Performance gains are also visible on faster networks, because the compression can make up for the time it takes to encrypt and decrypt the packets on both ends.

A number of extensions are available to VNC, including support for connections through the Internet superserver inetd or xinetd. These extensions mean additional controls can be implemented using the TCP Wrapper library. For example, the VNC X Window server, Xvnc, has been compiled with direct support for TCP Wrappers.

More information on configuring SSH, inetd, and TCP Wrappers is available on the VNC Web site listed in the "References" section of this chapter.

Summary

The concept of thin client computing will continue to grow and develop to push more and more processing to centralized systems. Consequently, applications such as VNC will be with the enterprise for some time. However, the thin client application is intended to be small, lightweight, and easy to develop and transport. The benefits are obvious — smaller footprint on the client hardware and network, including support for many more devices including handheld PCs and cell phones, to name a few.

However, the thin client model has a price; and in this case it is security. Although VNC has virtually no security features in the protocol, other add-on services such as SSH, VNC, and TCP Wrapper, or VNC and xinetd provide extensions to the basic VNC services to provide access control lists limited by the allowable network addresses and data confidentiality and integrity.

Using VNC within an SSH tunnel can provide a small, lightweight, and secured method of access to that system 1000 miles away from your office. For enterprise or private networks, there are many advantages to using VNC because the protocol is smaller and more lightweight than distributing the X Window system on Microsoft Windows, and it has good response time even over a slower TCP/IP connection link. Despite the security considerations mentioned in this chapter, there are solutions to address them; so you need not totally eliminate the use of VNC in your organization.

123

Overcoming Wireless LAN Security Vulnerabilities

Gilbert Held

The IEEE 802.11b specification represents one of three wireless LAN standards developed by the Institute of Electrical and Electronic Engineers. The original standard, which was the 802.11 specification, defined wireless LANs using infrared, Frequency Hopping Spread Spectrum (FHSS), and Direct Sequence Spread Spectrum (DSSS) communications at data rates of 1 and 2 Mbps. The relatively low operating rate associated with the original IEEE 802.11 standard precluded its widespread adoption.

The IEEE 802.11b standard is actually an annex to the 802.11 standard. This annex specifies the use of DSSS communications to provide operating rates of 1, 2, 5.5, and 11 Mbps.

A third IEEE wireless LAN standard, IEEE 802.11a, represents another annex to the original standard. Although 802.11- and 802.11b-compatible equipment operate in the 2.4-GHz unlicensed frequency band, to obtain additional bandwidth to support higher data rates resulted in the 802.11a standard using the 5-GHz frequency band. Although 802.11a equipment can transfer data at rates up to 54 Mbps, because higher frequencies attenuate more rapidly than lower frequencies, approximately four times the number of access points are required to service a given geographic area than if 802.11b equipment is used. Due to this, as well as the fact that 802.11b equipment reached the market prior to 802.11a devices, the vast majority of wireless LANs are based on the use of 802.11b compatible equipment.

Security

Under all three IEEE 802.11 specifications, security is handled in a similar manner. The three mechanisms that affect wireless LAN security under the troika of 802.11 specifications include the specification of the network name, authentication, and encryption.

Network Name

To understand the role of the network name requires a small diversion to discuss a few wireless LAN network terms. Each device in a wireless LAN is referred to as a station, to include both clients and access points. Client stations can communicate directly with one another, referred to as *ad hoc* networking. Client stations can also communicate with other clients, both wireless and wired, through the services of an access point. The latter type of networking is referred to as infrastructure networking.

In an infrastructure networking environment, the group of wireless stations to include the access point form what is referred to as a basic service set (BSS). The basic service set is identified by a name. That name, which is formally referred to as the service set identifier (SSID), is also referred to as the network name.

One can view the network name as a password. Each access point normally is manufactured with a set network name that can be changed. To be able to access an access point, a client station must be configured

with the same network name as that configured on the access point. Unfortunately, there are three key reasons why the network name is almost valueless as a password. First, most vendors use a well-known default setting that can be easily learned by surfing to the vendor's Web site and accessing the online manual for their access point. For example, Netgear uses the network name "Wireless." Second, access points periodically transmit beacon frames that define their presence and operational characteristics to include their network name. Thus, the use of a wireless protocol analyzer, such as WildPackets' Airopeek or Sniffer Technologies' Wireless Sniffer could be used to record beacon frames as a mechanism to learn the network name.

A third problem associated with the use of the network name as a password for access to an access point is the fact that there are two client settings that can be used to override most access point network name settings. The configuration of a client station to a network name of "ANY" or its setting to a blank can normally override the setting of a network name or an access point.

Exhibit 123.1 illustrates an example of the use of SMC Networks' EZ Connect Wireless LAN Configuration Utility program to set the SSID to a value of "ANY." Once this action was accomplished, this author was able to access a Netgear wireless router/access point whose SSID was by default set to a value of "Wireless." Thus, the use of the SSID or network name as a password to control access to a wireless LAN needs to be considered as a facility easily compromised, as well as one that offers very limited potential.

Authentication

A second security mechanism included within all three IEEE wireless LAN specifications is authentication. Authentication represents the process of verifying the identity of a wireless station. Under the IEEE 802.11 standard to include the two addenda, authentication can be either open or shared key. Open authentication in effect means that the identity of a station is not checked. The second method of authentication, which is referred to as shared key, assumes that when encryption is used, each station that has the correct key and is operating in a secure mode represents a valid user. Unfortunately, as soon noted, shared key authentication is vulnerable because the Wired Equivalent Privacy (WEP) key can be learned by snooping on the radio frequency.

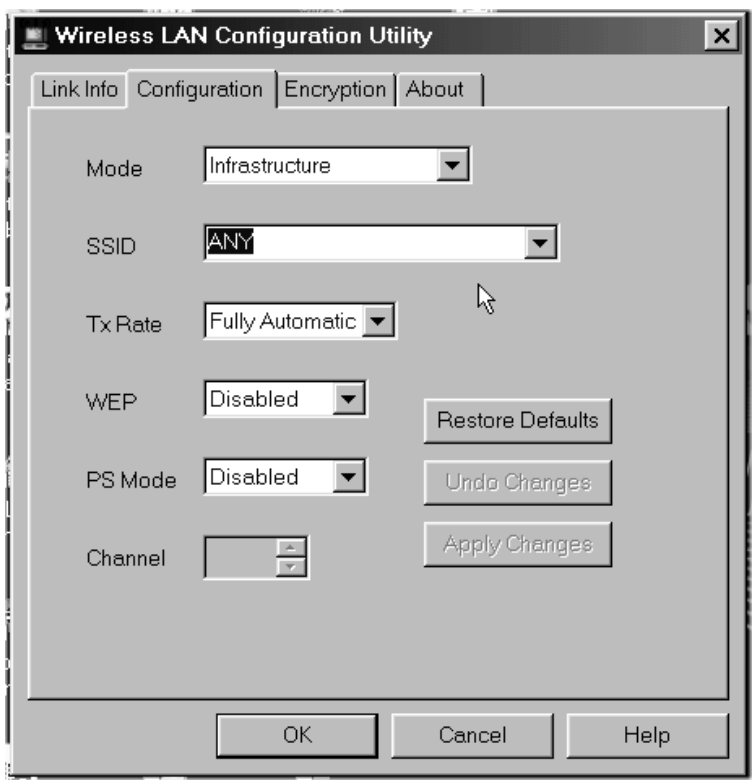

EXHIBIT 123.1 Setting the value of the SSID or network name to "ANY".

Encryption

The third security mechanism associated with IEEE 802.11 networks is encryption. The encryption used under the 802.11 series of specifications is referred to as WEP. The initial goal of WEP is reflected by its name. That is, its use is designed to provide a level of privacy equivalent to that occurring when a person uses a wired LAN. Thus, some of the vulnerabilities uncovered concerning WEP should not be shocking because the goal of WEP is not to bulletproof a network. Instead, it is to simply make over-the-air transmission difficult for a third party to understand. However, as we will note, there are several problems associated with the use of WEP that make it relatively easy for a third party to determine the composition of network traffic flowing on a network.

Exhibit 123.2 illustrates the drop-down list of the WEP field of SMC Networks' Wireless Configuration Utility program. Note that, by default, WEP is disabled; and unless you alter the configuration on your client stations and access points, any third party within transmission range could use a wireless LAN protocol analyzer to easily record all network activity. In fact, during the year 2001, several articles appeared in *The New York Times* and *The Wall Street Journal* concerning the travel of two men in a van from one parking lot to another in Silicon Valley. Using a directional antenna focused at each building from a parking lot and a notebook computer running a wireless protocol analyzer program, these men were able to easily read most network traffic because most networks were set up with WEP disabled.

Although enabling WEP makes it more difficult to decipher traffic, the manner by which WEP encryption occurs has several shortcomings. Returning to Exhibit 123.2, note that the two WEP settings are shown as "64 Bit" and "128 Bit." Although the use of 64- and 128-bit encryption keys may appear to represent a significant barrier to decryption, the manner by which WEP encryption occurs creates several vulnerabilities. An explanation follows.

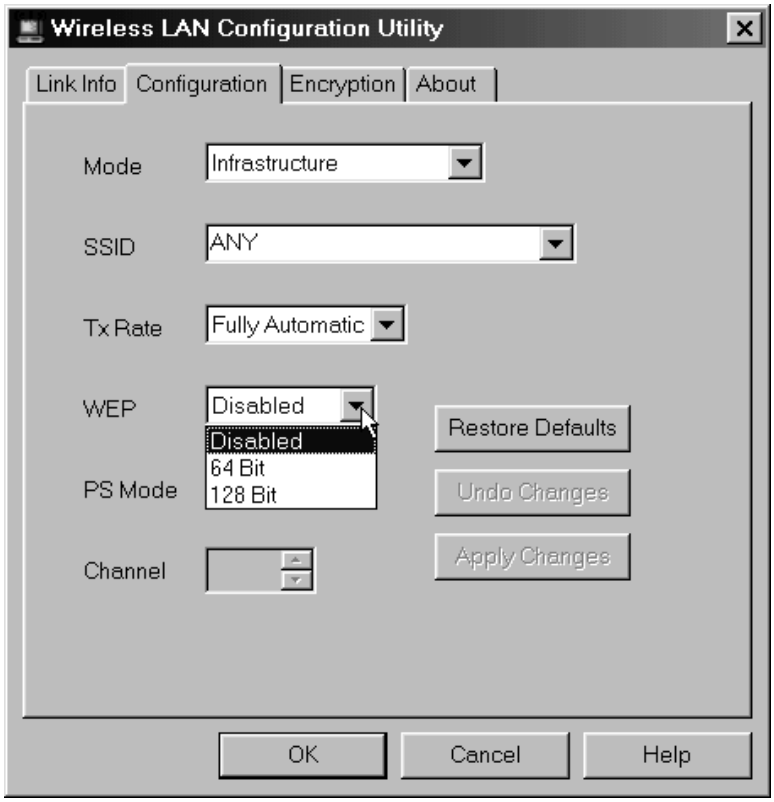

EXHIBIT 123.2 WEP settings.

EXHIBIT 123.3 Creating a WEP encryption key.

WEP encryption occurs via the creation of a key that is used to generate a pseudo-random binary string that is modulo-2 added to plaintext to create ciphertext. The algorithm that uses the WEP key is a stream cipher, meaning it uses the key to create an infinite pseudo-random binary string.

Exhibit 123.3 illustrates the use of SMC Networks' Wireless LAN Configuration Utility program to create a WEP key. SMC Networks simplifies the entry of a WEP key by allowing the user to enter a passphrase. Other vendors may allow the entry of hex characters or alphanumeric characters. Regardless of the manner by which a WEP key is entered, the total key length consists of two elements: an initialization vector (IV) that is 24 bits in length and the entered WEP key. Because the IV is part of the key, this means that a user constructing a 64-bit WEP key actually specifies 40 bits in the form of a passphrase or 10 hex digits, or 104 bits in the form of a passphrase or 26 hex digits for a 128-bit WEP key.

Because wireless LAN transmissions can easily be reflected off surfaces and moving objects, multiple signals can flow to a receiver. Referred to as multipath transmission, the receiver needs to select the best transmission and ignore the other signals. As one might expect, this can be a difficult task, resulting in a transmission error rate considerably higher than that encountered on wired LANs. Due to this higher error rate, it would not be practical to use a WEP key by itself to create a stream cipher that continues for infinity. This is because a single bit received in error would adversely affect the decryption of subsequent data.

Recognizing this fact, the IV is used along with the digits of the WEP key to produce a new WEP key on a frame-by-frame basis. Although this is a technically sound action, unfortunately the 24-bit length of the IV used in conjunction with a 64- or 104-bit fixed length WEP key causes several vulnerabilities. First, the IV is transmitted in the clear, allowing anyone with appropriate equipment to record its composition along with the encrypted frame data. Because the IV is only 24 bits in length, it will periodically repeat. Thus, capturing two or more of the same IVs and the encrypted text makes it possible to perform a frequency analysis of the encrypted text that can be used as a mechanism to decipher the captured data. For example, assume one has captured several frames that had the same IV. Because "e" is the most common letter used in the English language followed by the letter "t," one would begin a frequency analysis by searching for the most common

letter in the encrypted frames. If the letter "x" was found to be the most frequent, there would be a high probability that the plaintext letter "e" was encrypted as the letter "x." Thus, the IV represents a serious weakness that compromises encryption.

During mid-2001, researchers at Rice University and AT&T Laboratories discovered that by monitoring approximately five hours of wireless LAN traffic, it became possible to determine the WEP key through a series of mathematical manipulations, regardless of whether a 64-bit or 128-bit key was used. This research was used by several software developers to produce programs such as Airsnort, which enables a person to determine the WEP key in use and to become a participant on a wireless LAN. Thus, the weakness of the WEP key results in shared key authentication being compromised as a mechanism to validate the identity of wireless station operators. Given an appreciation for the vulnerabilities associated with wireless LAN security, one can now focus on the tools and techniques that can be used to minimize or eliminate such vulnerabilities.

MAC Address Checking

One of the first methods used to overcome the vulnerabilities associated with the use of the network name or SSID, as well as shared key authentication, was MAC address checking. Under MAC address checking, the LAN manager programs the MAC address of each client station into an access point. The access point only allows authorized MAC addresses occurring in the source address field of frames to use its facilities.

Although the use of MAC address checking provides a significant degree of improvement over the use of a network name for accessing the facilities of an access point, by itself it does nothing to alter the previously mentioned WEP vulnerabilities. To attack the vulnerability of WEP, several wireless LAN equipment vendors introduced the use of dynamic WEP keys.

Dynamic WEP Keys

Because WEP becomes vulnerable by a third party accumulating a significant amount of traffic that flows over the air using the same key, it becomes possible to enhance security by dynamically changing the WEP key. Several vendors have recently introduced dynamic WEP key capabilities as a mechanism to enhance wireless security. Under a dynamic key capability, a LAN administrator, depending on the product used, may be able to configure equipment to either exchange WEP keys on a frame-by-fame basis or at predefined intervals. The end result of this action is to limit the capability of a third party to monitor a sufficient amount of traffic that can be used to either perform a frequency analysis of encrypted data or to determine the WEP key in use. Although dynamic WEP keys eliminate the vulnerability of a continued WEP key utilization, readers should note that each vendor supporting this technology does so on a proprietary basis. This means that if one anticipates using products from multiple vendors, one may have to forego the use of dynamic WEP keys unless the vendors selected have cross-licensed their technology to provide compatibility between products. Having an appreciation for the manner by which dynamic WEP keys can enhance encryption security, this discussion of methods to minimize wireless security vulnerabilities concludes with a brief discussion of the emerging IEEE 802.1x standard.

The IEEE 802.1x Standard

The IEEE 802.1x standard is being developed to control access both to wired and wireless LANs. Although the standard was not officially completed during early 2002, Microsoft added support for the technology in its Windows XP operating system released in October 2001.

Under the 802.1x standard, a wireless client station attempting to access a wired infrastructure via an access point will be challenged by the access point to identify itself. The client will then transmit its identification to the access point. The access point will forward the challenge response to an authentication server located on the wired network. Upon authentication, the server will inform the access point that the wireless client can access the network, resulting in the access point allowing frames generated by the client to flow onto the wired network.

Although the 802.1x standard can be used to enhance authentication, by itself it does not enhance encryption. Thus, one must consider the use of dynamic WEP keys as well as proprietary MAC address checking or an 802.1x authentication method to fully address wireless LAN security vulnerabilities.

Formulating an Enterprise Information Security Architecture

Mollie E. Krehnke, CISSP, IAM and David C. Krehnke, CISSP, CISM, IAM

Introduction

Ours is a connected world, and a dependent world. The condition and livelihood of any organization is dependent on the integrity, availability, and confidentiality of information obtained from or protected from other sources. Today, organizations are at greater risk and their security stance against malicious actors, in the form of individuals, criminal cartels, terrorists, or nation-states, will affect the well-being of many persons, other companies, and perhaps the nation. These organizations often depend upon cyberspace — hundreds of millions of interconnected computers, servers, routers, switches, and fiber-optic cables that allow our critical infrastructures to work.[1]

Threat Opportunities Abound

Individuals and organizations with malicious intent will use any means to disrupt business processes; obtain the data the information systems create, maintain, and transmit; and acquire the power that the information systems and associated networks possess for other unauthorized acts. Malicious actors have the intent (political, economic, national security), the tools (widely available), and the targets (many and well-known vulnerabilities). Malicious actors also have the time and the financial resources necessary to implement attacks. These attacks can have serious consequences, such as disruption of critical operations, causing loss of revenue and intellectual property, or loss of life. Such attacks could use any available cyber resources, including computers located in homes or small businesses to initiate attacks on critical infrastructure organizations — exploiting weaknesses, disrupting communications, hindering defensive or offensive responses, or delaying emergency responders.

Vulnerabilities result from weaknesses in technology and improper implementation and oversight of technological products.[2] The majority of vulnerabilities can be mitigated through good security practices, although such practices must go beyond mere installation, and include proper training, operation, regular patching, and virus updates. The vulnerabilities within an organization can be used to mount an attack against that organization or against other organizations.

Responding to an Increasing Threat

The cyberspace vulnerabilities must be addressed at an individual level and an organizational level. "Each American who depends on cyberspace must secure the part that they own or for which they are responsible."[3]

Likewise, each organization must establish and maintain an effective enterprise information security architecture that contributes to its own security, its employees, customers, business partners — and that of the nation.

The effective deployment of security for an enterprise is dependent on the business functions of the enterprise. To gain business commitment, the security functions determined to be necessary must support the business functions of the organization and provide "added value." The provision of added value in the form of enterprise information security is dependent upon many factors: accurate identification of business functions; configuration and management of the existing and planned resources (e.g., networks and technologies); business and security infrastructures; enterprise business processes; people (employees, business partners, and vendors); physical security of facilities, equipment, and remote sites; and associated security or security-supporting policies and processes. The mere presence of certain security mechanisms will not guarantee an acceptable level of risk for the enterprise. Therefore, an enterprise information security architecture must be defined, installed, monitored, assessed, and upgraded on a periodic basis to ensure that the security architecture is appropriate for the enterprise. The major key to successful implementation of security is the commitment of upper management.

Architectural Design Concepts

Association of Business Functions to Security Services

To add value to an organization's business functions, those functions must be understood. A business will have documentation that presents an overview of those functions. Certain individuals will be good resources as well, and should be delighted to discuss security from an added-value standpoint. Business unit managers who oversee specific lines of business (business domains) and subject matter experts can support the documentation of business functions and provide the business perspective to the sequencing of automated and nonautomated processes to address the business mission. The business functions to be addressed also have to be viewed in light of capital planning, enterprise engineering, and program management.

Exhibit 124.1 presents an approach for enterprise architecture development. If such an architecture exists for the enterprise, then the creation of a security architecture has a firm foundation. Business functions and associated business processes, data and data flows, applications and associated functionality, present technology architecture, business locations, business partners and vendors, and strategic goals to support the business mission may already exist — in some form.

The three-to-five-year target enterprise architecture is a good resource for determining future goals of the organization that will have to be addressed from a security standpoint. Any goals beyond that timeframe will not be as useful for the establishment of an effective information security architecture — technology, customer focus, and external requirements are key drivers in this architecture and they are not easily defined beyond that time with any accuracy.

Association of Enterprise Architecture to Information Security Architecture

The target enterprise architecture can provide answers to the following questions that will be invaluable to the enterprise security architecture initiative:

- What are the strategic business objectives of the organization?
- What information is needed to support the business?
- What applications are needed to provide information?
- What technology is needed to support the applications?
- What is the needed level of interoperability between the data sources and the users of the data?
- What information technology is needed to support the enterprise's technical objective?
- What systems are going to be replaced in the near term? In the long term? What systems are going to be migrated to the new enterprise architecture?
- What risks are associated with the current sequencing plan?
- What alternatives are currently available if funding or resources are delayed?
- What are the budgetary and territorial concerns?

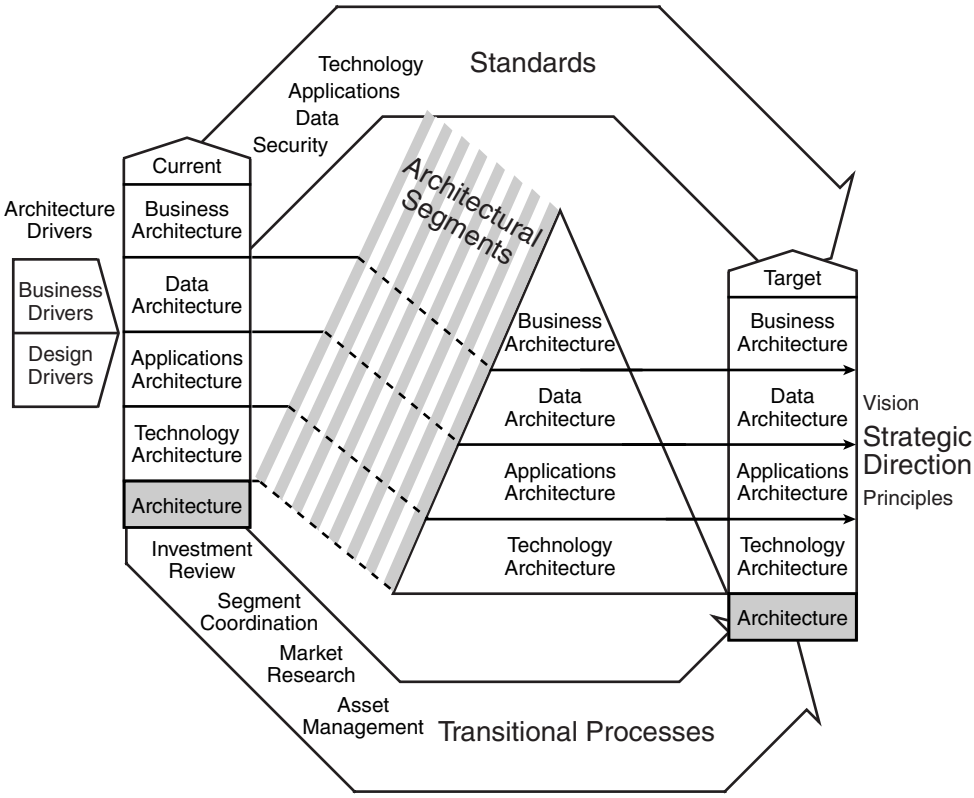

EXHIBIT 124.1 Structure of the Federal Enterprise Architecture Framework. (*Source:* A Practical Guide to Federal Enterprise Architecture, Chief Information Officer Council, Version 1.0, February 2001, Figure 6, Structure of the FEAF Components.)

The enterprise architecture can be managed as "a program that facilitates systematic agency [business] change by continuously aligning technology investments and projects with agency mission needs."[4] There are going to be areas in which the enterprise architecture information, such as data information and flows, can move directly into an enterprise information security architecture as factors in establishing processes and functionality. There will be others, such as the identification of the business areas or information needs with the greatest potential payoff for the enterprise, which will have to be tempered with other security considerations. Although an organization certainly wants to address these high payoff areas in terms of information availability, integrity, and confidentiality, there may be other less "visible" areas that have higher areas of risk that will also have to be appropriately addressed in order to ensure the security of all business functions.

General Enterprise Architecture Principles

Federal agencies are now required to establish an enterprise architecture that will be used to streamline the collection, storage, and analysis of information, and the provision of applicable information to the general public. The process for the identification and documentation of information required to establish a federal enterprise architecture has aspects that can be applied to private industry as well.

Excerpts from the Chief Information Officer (CIO) Council guide[5] provide principles that help in the establishment of a enterprise architecture and, for our purposes, the establishment of an enterprise information security architecture:

- Architectures must be appropriately scoped, planned, and defined based on the intended use of the architecture.
- Architectures must be compliant with the law.
- Architectures facilitate change.
- Architectures must reflect the organization's strategic plan.
- Architectures continuously change and require transition toward the target architecture.
- Target architectures should project no more than three to five years into the future.
- Architectures provide standard business processes and common operating environments.
- The quality of the associated architecture documentation is dependent upon the information obtained from subject matter experts and business owners.
- Architectures minimize the burden of data collection, streamline data storage, and enhance data access.
- Target architectures should be used to control the growth of technical diversity.[6]

Although the CIO architecture model mentions security as a concept[7] that "overlies" the enterprise life cycle, and the Interoperability Clearinghouse, a nonprofit organization that develops architectures,[8] includes security as a domain architecture, the impact that security should have in the establishment of the architecture is not fully presented. The implementation of an enterprise information security architecture requires the establishment of strong, far-reaching business practices that ensure system compliance with the security architecture and needs continuous assessment to enforce compliance (with the full support of senior management). Otherwise, there is no way to assure that the enterprise information security architecture meets the established business needs and functions at an acceptable level of risk.

General Enterprise Information Security Architecture Principles

Objectives of an enterprise information security architecture, in support of the business mission, must include the following:

- Not impede the flow of authorized information or adversely affect user productivity
- Protect information at the point of entry into the enterprise
- Protect the information throughout its useful life
- Enforce common processes and practices throughout the enterprise
- Be modular to allow new technologies to replace existing ones with as little impact as possible
- Be virtually transparent to the user
- Accommodate the existing infrastructure[9]

Inputs to the Security Architecture

Exhibit 124.2 depicts the inputs to the initial process in formulating an enterprise information security architecture. The process should, at a minimum, consider the following inputs:

- Business-related inputs:
  - Business goals and objectives for protecting the organization's business interests, assets, personnel, and the public; and the future direction of the business and supporting information systems
  - Business operational considerations of how the business will operate day to day (e.g., centralized or decentralized approach to security administration)
  - Current business directions and initiatives for the installed information systems and those under development
  - Business information system requirements (e.g., access requirements, availability requirements, business partner connectivity)
  - Business policies and processes defining what is acceptable and what is not acceptable business behavior
  - Business assets to be protected by the architecture
  - Existing infrastructure including a characterization of the current technical environment and what may help or negatively affect information security

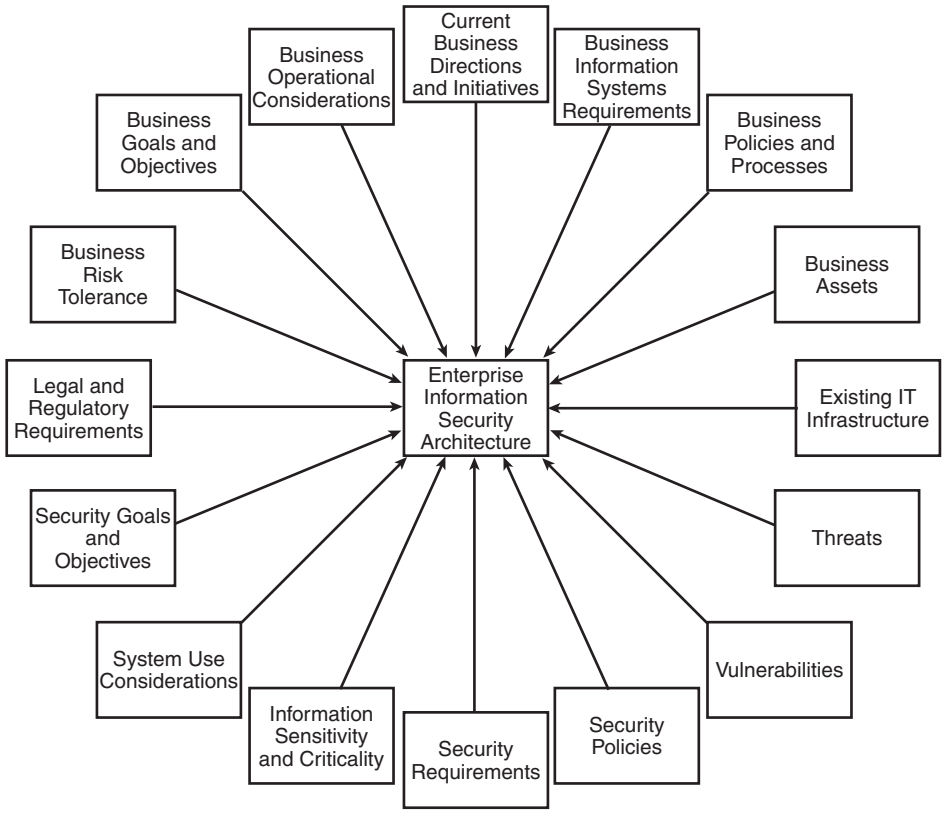

EXHIBIT 124.2 Considerations for formulating an enterprise information security architecture.

  - Business risk tolerance for information disclosure, unauthorized modification and loss, unavailability, downtime due to hackers and viruses, and defaced Web pages
  - Legal and regulatory requirements including laws and regulations such as privacy, basic due care and due diligence, and sentencing guidelines
  - Threats to the existing infrastructure or business operations
  - Vulnerabilities associated with the existing infrastructure or computing operations
- Security-related inputs:
  - Security goals and objectives (e.g., safeguard information assets from unauthorized and inappropriate use, loss, or destruction; protect sensitive information from unauthorized disclosure and manipulation; and protect the availability of critical information)
  - System use considerations including who will use the information systems (employees, contractors), what level of background screening, when (time of day, days of the week), where (office, home, travel), why (inquiries, file updating, research), etc.
  - Sensitivity and criticality of the information to be protected, including the impact due to unavailability or loss
  - Security requirements to protect information, applications, platforms, and networks based on the sensitivity and criticality of the information (e.g., label sensitive media, back up information, store backups off site, encrypt information stored in nonsecure locations or transmitted over untrusted networks)
- Security policies on what is and what is not acceptable security behavior

Moving from Design to Deployment

Building a Secure Computing Environment

As depicted in Exhibit 124.3, a well-defined enterprise information security architecture provides the foundation for a secure infrastructure and a secure computing environment. The building blocks of a secure computing environment include:

- Well-defined enterprise information security architecture, with accountability, deployment strategies, technology, and security services
- Effective information security processes, procedures, and standards, derived from policies, but dealing with specific components and technologies and providing detailed specifications that can be audited
- Effective information security training, including new-hire training; job-related operational training for executives, managers, supervisors, privileged users, and general users; and periodic awareness training
- Effective information security administration and management, including configuration management, information resources management (IRM), hardened platforms with the latest security patches and virus signature files, virus scanning, vulnerability scans, intrusion detection, penetration testing, logging, alarms, and reviews of common vulnerabilities and exposures (CVEs)
- Aggressive information security assurance, including certification, accreditation, self-assessments, inspections, audits, and independent verification and validation (IV&V)
- Secure infrastructure, including DMZ, routers, filters, firewalls, gateways, air gaps, protected distribution systems (PDSs), virtual private networks (VPNs), secure enclaves, and separate test environments
- Secure applications, including well-designed, structured, and documented modules; software quality assurance; code review; file integrity checking or change detection software, including products such as Tripwire and Advanced Intrusion Detection Environment (AIDE); and access based on the principles of clearance, need-to-know, and least privilege
- Secure information, including encryption, backups, and integrity checking software

Information Security Life Cycle

Exhibit 124.4 indicates how the information security life cycle interacts with the foundation and core components of an information security program. As the outer ring illustrates, organizations should continuously perform the following functions during the information security life cycle:

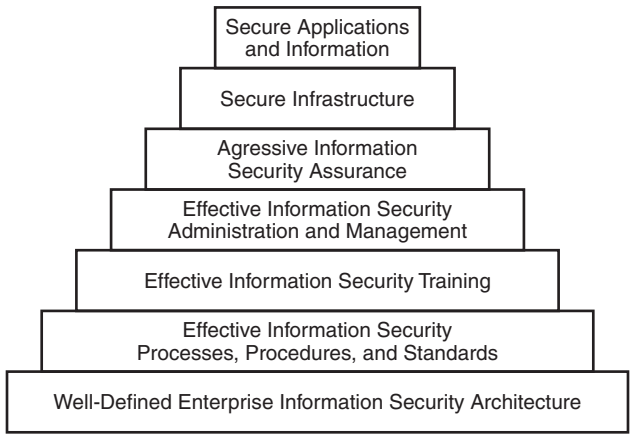

EXHIBIT 124.3 Building blocks of a secure computing environment.

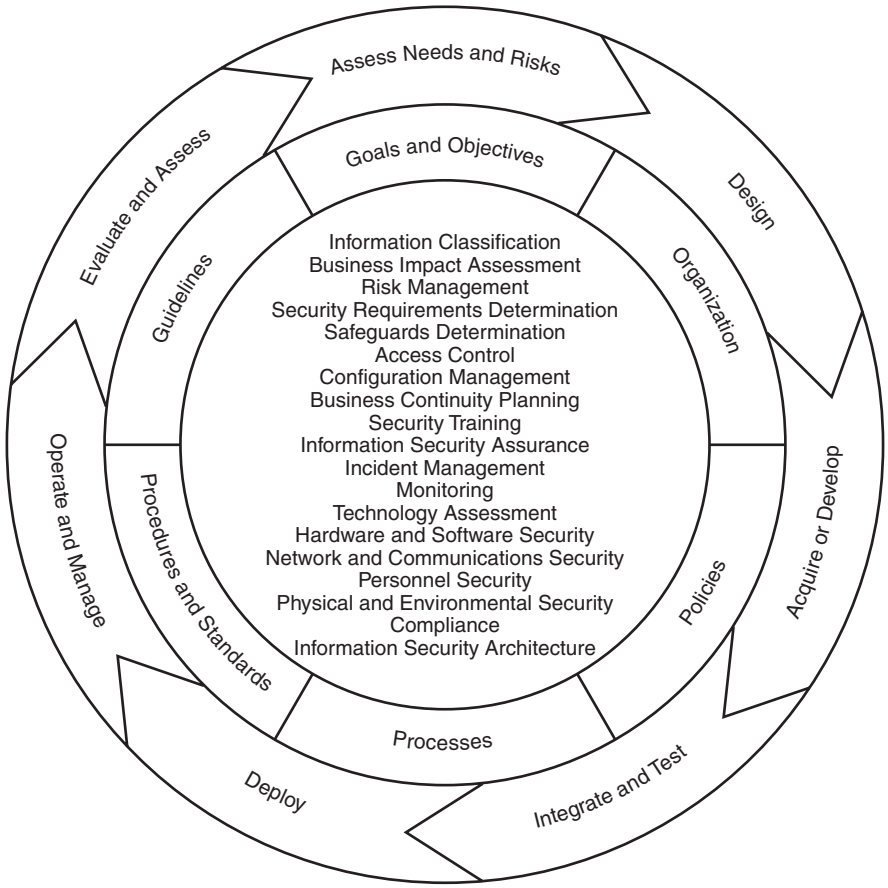

EXHIBIT 124.4 Information security lifecycle and the information security program.

- Assess business security needs and the risks to the organization
- Design security solutions to appropriately address the assessed risks
- Acquire or develop security solutions
- Integrate and test security solutions
- Deploy security solutions
- Operate and manage security solutions
- Evaluate and assess security solutions to assure their effectiveness

The organization can perform these functions directly or outsource them, and ensure they are implemented effectively. These functions should be performed continuously because security is an ongoing process, not a one-time destination. Business, technology, risk, and organization structure are not static.

The inner ring illustrates the foundation or essential ingredients of an information security program:

- *Goals and objectives:* Confidentiality and possession, integrity and authenticity, availability and utility, accountability, non-repudiation, and assurance
- *Organization:* Full-time and *ad hoc* personnel identified to implement the information security programs
- *Policies:* High-level management instructions that support an enterprisewide information security program that incorporates prudent practices from industry and government
- *Processes:* Methodologies that support the information security policies and cost effectively implement information security in the enterprise

- *Procedures and standards:* Detail components, technologies, and step-by-step actions that support the policies and processes
- *Guidelines:* Recommended activities to provide a more secure environment

The inner elements are the functional core components of an information security program:

- *Information classification:* The process and consulting support by which the sensitivity of each application is determined.
- *Business impact assessment:* The process and consulting support by which the criticality of each application is determined.
- *Risk management:* The process and consulting support for the identification and assessment of assets, threats, vulnerabilities, and the resulting risks and their successful mitigation, transfer, or acceptance.
- *Security requirements determination:* The process and consulting support for identifying the information security requirements given the sensitivity, criticality, and risks.
- *Safeguards determination:* The process and consulting support for identifying information security safeguards or controls that will satisfy the security requirements.
- *Access control:* The process of identification and authentication of users, maintaining audit records of their access, and enforcing individual accountability that prevents unauthorized access to information systems.
- *Configuration management:* The rigorous management of the change process that provides hardware and software integrity, and change and version control.
- *Business continuity planning:* The process and consulting support that implements effective planning for continued business operations under all conditions and situations.
- *Security training:* The operational and awareness guidance that ensures all employees are trained in the security aspects of their jobs and their associated security responsibilities, and the secure, appropriate use of information systems and data.
- *Information security assurance (also known as certification and accreditation):* The formal security evaluation and management approval process that ensures the information system is protected at a level appropriate to its sensitivity and criticality classifications; identifies the controls that satisfy the security requirements, and are documented in a security plan. Determines the residual risk before the information system is put into production as it is, and periodically reviewed over the life of the information system. Periodically tests and evaluates the effectiveness of protection mechanisms, based on current threats and vulnerabilities.
- *Incident management:* The process and consulting support that ensures appropriate actions for detecting, reporting, and responding to information security incidents. Receives and tracks information security incident reports through resolution, escalates serious incidents, and incorporates "lessons learned" into ongoing security awareness and operational training programs.
- *Monitoring:* The monitoring of logs and activities to verify the security stance, ensure appropriate resource use, and defend resources from attack.
- *Technology assessment:* The review, evaluation, and recommendation of advanced security technologies. Evaluates infrastructure and commercial-off-the-shelf (COTS) products for common vulnerabilities and exposures (CVEs).
- *Hardware and software security:* The procurement, configuration, installation, operation, and maintenance of hardware and software in a manner that ensures information security. Includes platform hardening and software integrity checking.
- *Network and communications security:* Perimeter protection, intrusion detection, vulnerability scans, penetration testing, remote access management, and control of modems. Determines the criteria for the evaluation of firewalls, recommends encryption solutions, determines when secure enclaves are required, and provides consulting support for the review of network connectivity requests.
- *Personnel security:* Identifies sensitive positions and ensures individuals assigned to those positions have an appropriate clearance. Includes information security in job descriptions, and through performance appraisals holds individuals accountable for carrying out their information security responsibilities and for their actions.
- *Physical and environmental security:* Protects hardware, software, and information through physical and environmental controls.

- *Compliance:* Administrative inspections, reviews, evaluations, audits, and investigations for the purpose of maintaining effective information security. Consulting support on best practices from industry and government on remedial action to address any significant deficiencies. Confiscation and removal of unauthorized hardware and software, and hardware, software, and data required for use as evidence of wrongdoing.
- *Information security architecture*: The framework for information security and the road map for implementation to ensure the confidentiality, integrity, and availability of applications and information.

Defense-in-Depth for a Secure Computing Environment

Exhibit 124.5 depicts the requirements for a secure computing environment. The lack of security in any one of these components is going to negatively impact the security of the computing environment. If there is no policy, there can be no uniform management direction on how to protect the business, its operations, its people, and its information. If there are no processes and procedures with associated standards, implementation of policy will be based on an individual's interpretation of policy — which is likely to vary from person to person. If there is no physical security, then logical and administrative controls can be easily circumvented without being discovered. The lack of environmental controls can bring down the enterprise and cause more destruction than a malicious agent. If there is inadequate personnel security, the likelihood of insider threat increases dramatically and the impact may not be detected for a significant period of time. The need for communications and network security is obvious; we live in a connected world. However, the unapproved use and unknown presence of a modem or wireless network access points will circumvent

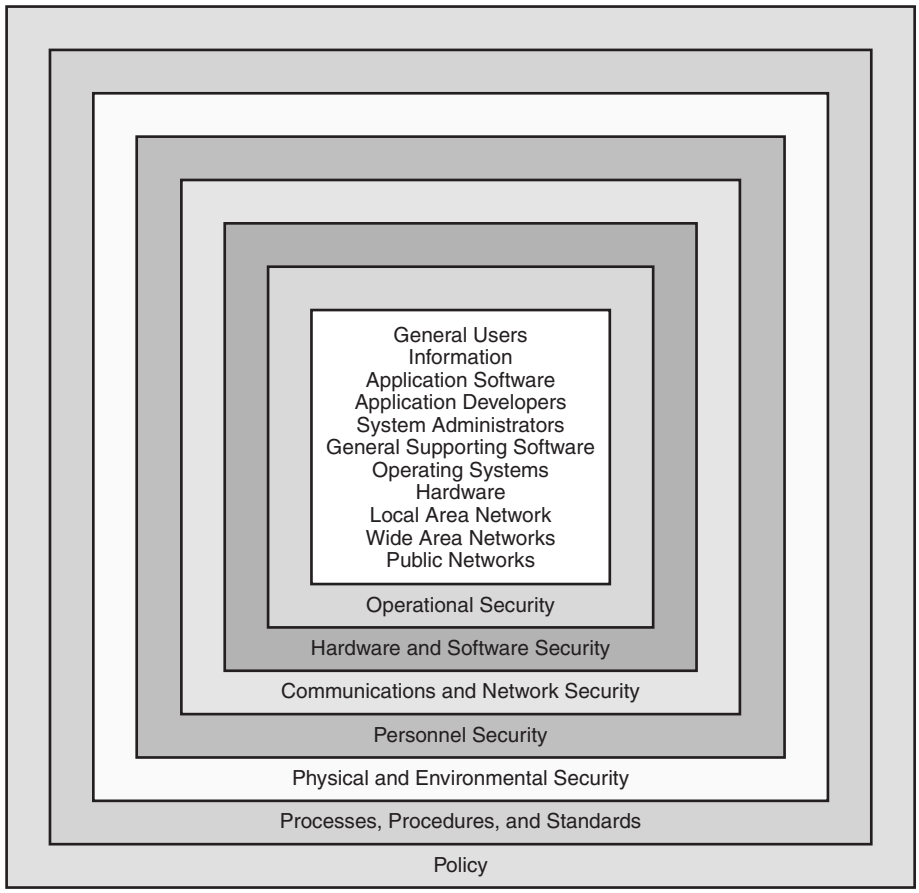

EXHIBIT 124.5 Defense-in-depth.

firewall protection. Hardware controls must be in line with the equipment functionality, e.g., servers must be hardened before deployment if it is going to be effective. Software and its associated controls must be up to date, including patches and updated virus signature files. Employees, contractors, vendors, and visitors must know what is expected of them to support enterprise information security. Public networks, although vital to many business operations, must be viewed as untrusted components of the enterprise architecture and handled appropriately. Wide area networks (WANs) and local area networks (LANs) have certain operational requirements that must be implemented to ensure information confidentiality, integrity, and availability. Hardware must be assessed on its ability to perform the required functions, and must be protected so it cannot be reconfigured to perform unauthorized functions. Software must be licensed, purchased from a trusted source, and assessed to ensure it does not contain malicious code even if it is shrink-wrapped. System administration and application developers must be trusted personnel with the appropriate clearances who have been trained to perform their job responsibilities accurately and effectively. Application software must be accurately designed, developed, and implemented to protect information and the business environment. Information is the lifeblood of the organization and must be protected from unauthorized disclosure, while being made available when required in an accurate, usable, and complete format. General users represent a significant threat to the secure computing environment, accidentally or with malicious intent. The actions of users must be controlled, and users must be trained in secure operations and use of information and computing and communications resources. The user is the weakest component of the secure computing environment, and carelessness or social engineering can result in established controls being circumvented. Therefore, defense-in-depth must also include checks and balances, with multiple security functions and associated components to address the security requirements. The standardization of security components is represented in this chapter as information security services.

Defining the Enterprise Information Security Architecture

Information Security Services

Information security services provide the enterprise information security architecture with standard methods to support the integration and implementation of information security across the organization infrastructure. These services must be standardized, shareable, and reusable. Information security services include people and technology services.

- *Accountability:* Associates each unique identifier (e. g., user account or log-on ID) with one and only one user or process to enable tracking of all actions of that user or process.
- *Assurance:* Provides a formal information security evaluation and management approval process to ensure information applications and the supporting infrastructure are protected at a level appropriate to their sensitivity and criticality.
- *Authentication:* Verifies the claimed identity of an individual, workstation, or process.
- *Authorization:* Determines whether and to what extent access should be granted to specific information, applications, and information systems.
- *Availability:* Ensures information, applications, and information systems will be accessible by authorized personnel or other information resources when required.
- *Confidentiality:* Ensures that information is not made available or disclosed to unauthorized individuals, entities, or processes.
- *Identification:* Associates a user with a unique identifier by which that user or process is held accountable for the actions and events initiated by that identifier.
- *Integrity:* Ensures the correct operation of applications and information systems, consistency of data structures, and accuracy of the stored information.

Information Security Functions

Each information security service consists of one or more security functions that further identify and define the security action or process needed to secure the information and information systems. Examples of such

information security functions include, but are not limited to, authorization, identification, authentication, accountability, risk assessment, confidentiality, encryption, physical access control, logical access control, digital signatures, integrity, intrusion protection, virus protection, non-repudiation, availability, security administration, audit logging and reviews, information security assurance, incident handling, monitoring, and compliance.

Enterprise Information Security Services Matrix

Exhibit 124.6 summarizes information security services and their related security functions. The exhibit is organized as follows:

- *Information Security Service.* Names the information security service that addresses one or more specific security needs or requirements identified to secure information and information systems and comply with applicable laws, statutes, regulations, policies, and best industry practices. Securing information and information systems may require the use of one or more information security services.
- *Security Function.* Lists the security functions that comprise an information security service.
- *Security Function Description.* Provides a brief description of the security function.
- *Vehicle.* Enumerates the mechanisms, processes, controls, and technologies that support, contribute, and implement the named information security service. Each information security service may be implemented through multiple processes and technologies.

Assessing the Enterprise Information Security Architecture

Controlling the Growth of Technical Diversity

The priorities established for the enterprise architecture will have to address all enterprise information security considerations. On the flip side, security projects, like business projects, will have to be reviewed in light of several considerations:

- *Business alignment:* Does the project support established strategic plans, goals, and objectives?
- *Business case solution:* What is the impact on the organization's information technology and business environments?
- *Sequencing plan:* Is the proposed investment consistent with the sequence (plan) and priorities established to reach the target architecture?
- *Technical plan compliance:* Does the proposed project comply with the enterprise standards and the architecture levels?

Ensuring Continued Support by Addressing Design Principles

The establishment of an enterprise security architecture is a significant undertaking. The perceived (or actual) complexity of the product could entice the viewer to assume that the architecture can successfully support the design, development, operation, and retirement of an information system. Periodically throughout the implementation of the architecture, it is good to look at the model in light of a system that supports a business function and see if it complies with security principles that support the system throughout its life cycle: initiation, development or acquisition, implementation, operation and maintenance, and disposal. Have the following design principles been addressed?

- Establish a sound security policy as the "foundation" for design.
- Treat security as an integral part of the overall system design.
- Clearly delineate the physical and logical security boundaries governed by associated security policies.
- Reduce risk to an acceptable level.
- Assume that external systems are insecure.
- Identify potential trade-offs between reducing risks and increased costs and decreases in other aspects of operational effectiveness.
- Implement layered security (ensure no single point of vulnerability).

EXHIBIT 124.6 Enterprise Information Security Services

Information Security Service	Security Function	Security Function Description	Vehicle
Accountability	Non-repudiation	Assures the sender cannot deny he sent the message and recipient cannot claim that he received a different message	Digital signature and certificates
	User deterrence	Places restraint on deviant activities by increasing the likelihood of identification and prosecution of personnel conducting such activities	Security awareness training Operational security training Policy, processes, and procedures
Assurance	Data designation	Determines the sensitivity and criticality of information and information systems	Data element assessment
	Monitoring	Provides surveillance of the activity being performed within the information systems as well as at its boundaries; the surveillance service is carried out on networks and on servers/hosts: network monitoring and host/server-based monitoring	Intrusion detection systems (IDS) Host-based IDS
	Intrusion detection	Detects attempts at system break-ins, behavior patterns, and anomalies with respect to activities at the boundaries of the information system (e.g., network, mainframe, or other device)	IDS
	Malicious code protection	Security code review provides assurance that the information system does and will only execute authorized operations that ensure, preserve, and maintain the integrity of the system and all the information systems accessed	Security code review
		Virus protection monitors, analyzes, and protects the information resource from possible virus attacks	Virus scanning Pattern distribution
	Security administration	Implements management constraints, operational procedures, and supplemental controls established to provide adequate protection of an information system	Configuration management Information resource life cycle Database administration
	Acceptable use monitoring	Ensures information resources will be used in an approved, ethical, and lawful manner to avoid loss or damage to operations, image, or financial interests	Audit logging Monitoring Content filtering
	Compliance	Reviews and examines the records, procedures, and activities to assess the information system security posture and ensure adherence with established criteria	Audit logging Monitoring Content filtering Inspection Independent assessment Penetration testing
	Audit	Provides the information systems with reviews as well as examination of records and activities to test for adequacy of the security controls, compliance with established policies, and operational procedures, and possibly recommends changes to policies and procedures	Audit logging Inspection Independent assessment

EXHIBIT 124.6 Enterprise Information Security Services (continued)

Information Security Service	Security Function	Security Function Description	Vehicle
	Assessment of business impact	Determines the level of sensitivity, criticality, recovery time objective (RTO); the potential consequences due to information and information system unavailability or loss; and the identification of security requirements	Business impact assessment
	Assessment of risk	Identifies vulnerabilities, threats, likelihood of occurrence, potential loss or impact, expected effectiveness of security measures, and residual risk for an information resource	Risk assessment COTS vulnerability assessment
	Security testing and evaluation	Provides support for testing to determine if all the required security controls and countermeasures described in the security plan are in place and functioning correctly	Security test and evaluation plan
	Certification	Establishes the extent to which the information system meets a specified set of security requirements	C&A process
	Accreditation	Provides support to management in their formal acceptance of the residual risk for operating the information system and approval to deploy	C&A process
	Enclaving	Allows for configuration of special network areas that provide additional protections and access controls to secure information resources	Enclaving process Firewalls IDS Vulnerability scans
	Network connectivity	Protects network and communications infrastructure by managing network connectivity	Network connectivity process
	Penetration testing and vulnerability scans	Checks the robustness and effectiveness of the boundary countermeasures implemented for a given information resource	Vulnerabilities test plan
	Physical security	Identifies specific physical weaknesses, vulnerabilities, and threats for a facility, network, enclave, and information system and implements countermeasures	Site security review System security plan Locks, mantraps, locking turnstiles Guards Fences Lighting CCTV Motion detectors
	Environmental security	Identifies specific environmental weaknesses, vulnerabilities, and threats to a facility, network, enclave, and information system and implements countermeasures	Redundant power UPS Backup diesel generators Redundant telecommunications Backup HVAC
	Personnel security	Identifies sensitive positions and provides the structure to ensure personnel are cleared and their information security responsibilities are defined and included in their performance evaluation	Personnel clearances Job descriptions Performance appraisals Sanctions Conditions of continued employment

EXHIBIT 124.6 Enterprise Information Security Services (continued)

Information Security Service	Security Function	Security Function Description	Vehicle
			Job rotation
	Incident management	Provides security incident handling and analysis	Incident reporting process
Authentication	Authentication	Verifies the claimed identity of an individual, workstation, or originator	Passwords and PINs Biometrics Smart cards Tokens Digital certificates
Authorization	Authorization	Determines whether and to what extent personnel should have access to specific information and information systems	User registration and authorization management
Availability	Fault isolation	Hardware: Allows the detection of hardware malfunction and the identification of the component that caused it	System alerts Network management systems/ protocols
		Software: Allows the detection of software malfunction and the identification of the component that caused it	Audit logging Network management systems/ protocols
	Contingency planning	Provides contingency planning for information and information systems, personnel, and the facilities that house them	Emergency plan Contingency plan Facility recovery plan Personnel evacuation plan
Confidentiality	Confidentiality	Ensures information is not disclosed to unauthorized individuals, entities, or processes; confidentiality applies to hardcopy and electronic media in storage, during processing, and while in transit	Eradicate media Encryption Secure storage Key management Information classification Screen savers Physical access controls Physical access controls Public key infrastructure Logical access controls Separation of duties
Identification	Trusted identification	Associates a user with a unique identifier (e.g., user account or log-on ID) by which that user is held accountable for the actions and events initiated by that identifier	Unique user identifier
Integrity	Data integrity	Ensures the consistency of data structures and accuracy of transmitted or stored information	Hashing Checksum Digital signature
	Information system integrity	Ensures the correct operation of information system	System development methodology Independent security testing and evaluation Configuration management Session management Screen savers Test environment restrictions Server hardening

- Implement tailored system security measures to meet organizational security goals.
- Strive for simplicity.
- Design and operate an information technology system to limit vulnerability and to be resilient in response.
- Minimize the system elements to be trusted.
- Implement security through a combination of measures distributed physically and logically.
- Provide assurance that the system is, and continues to be, resilient in the face of expected threats.
- Limit or contain vulnerabilities.
- Formulate security measures to address multiple overlapping information domains.
- Isolate public access systems from mission-critical resources (e.g., data, processes).
- Use boundary mechanisms to separate computing systems and network infrastructures.
- Where possible, base security on open standards for portability and interoperability.
- Use common language in developing security requirements.
- Design and implement audit mechanisms to detect unauthorized users and to support incident investigations.
- Design security to allow for regular adoption of new technology, including a secure and logical technology upgrade process.
- Authenticate users and processes to ensure appropriate access control decisions both within and across domains.
- Use unique identities to ensure accountability.
- Implement least privilege.
- Do not implement unnecessary security mechanisms.
- Protect information while it is being processed, in transit, and in storage.
- Strive for operational ease of use.
- Develop and exercise contingency or disaster recovery procedures to ensure appropriate availability.
- Consider custom products to achieve adequate security.
- Ensure proper security in the shutdown or disposal of a system.
- Protect against all likely classes of "attacks."
- Identify and prevent common errors and vulnerabilities.
- Ensure that developers are trained in how to develop secure software.[10]

Conclusion

Benefits of Architectures

The profit margin for most businesses is small, and the reduction of costs is vital to the success of the business. The enterprise security architecture can "reduce the response time for impact assessment, trade-off analysis, strategic plan redirection, and tactical action" with regard to security.

Some additional benefits are:

- Support for capital planning and investment management.
- Capturing a "snapshot in time" of business and technology assets.
- Provision of a strategy for systems and business migration.
- Help to mitigate risk factors in enterprise modernization.
- Identification of possible sites for innovative technology deployment.
- Support for key management decision making throughout the organization.[11]

Some direct cost-saving benefits include:

- Discounts on new products through bulk purchasing.

- Capital planning assistance from department CIO offices to ease the paperwork burden on division CIOs.
- Better career opportunities for information technology and security workers because their skill sets can be used on any of the standard systems that will be deployed throughout the department (enterprise).
- Increased ability to provide standardized training with a higher return on investment, because the number of people being trained by the same curriculum is greater for all levels of training, including users, technical support, and administrators.
- Ability to allocate human resources to areas other than their usual assignments to address key security concerns or incidents.

Helpful Hints from a Security Architecture Practitioner

The security architect is becoming a key function in many organizations, and functions as "the 'corporate clutch,' providing an interface between the security policy-makers and those tasked with providing information systems solutions to businesses." Concepts supporting a successful deployment and utilization of an enterprise security architecture include:

- Available architectural frameworks will have to be modified to adequately address security at the enterprise level.
- Avoid product focus (and resulting product wars) in the establishment of the security architecture.
- Deviations from initial security requirements must be managed to ensure compensating controls are used to minimize risk.
- Architectural documentation must be current and complete, or decisions will be made on obsolete information and ultimately require reworking.
- Documentation is a key deliverable of the architecture team; the lack of it can be costly — more so than the personnel costs associated with creating and maintaining the documentation.
- Project management supports the timely completion of tasking and deliverables.
- Publish all the information that can be provided to all members of the architectural team to facilitate their understanding of the security target architecture.
- Risk assessments are a valuable tool for any security architecture initiative and help to support a responsive architecture that avoids obsolescence and addresses business needs.
- Use business cases as a forum to assign costs to risks, focus the team on providing cost-effective solutions, and to contrast the costs of alternative (less desirable) solutions.
- Make presentation of architectural concepts and associated requests to senior management.
- Architecture supports policy and serves as a policy advocate, working to shape security requirements into practical solutions.[11]

The Bottom Line

The enterprise information security architecture is a complex model that incorporates business functions, technology, security policy, physical security, configuration management, risk management, contingency planning, users, and business partners and vendors. Generally speaking, all of these concepts will have to be applied to every business function or application, and the justification for the associated resources will have to be presented to senior management. Business functions have to be linked to security functions, and then added value has to be presented in a way that makes sense to senior management and positively affects the business bottom line.

Security Architecture and Models

Foster J. Henderson, CISSP, MCSE and
Kellina M. Craig-Henderson, Ph.D.

> He is like a man who built a house, and digged deep, and laid the foundation on a rock: and when the flood arose, the stream beat vehemently upon that house, and could not shake it; for it was founded upon a rock. But he that heareth, and doeth not is like a man that without a foundation built a house upon the earth; against which the stream did beat vehemently, and immediately it fell and the ruin of that house was great.
>
> **— Luke 6:48–49, The Bible, King James Version**

As this passage illustrates, a strong foundation has been akin to protection from adversity since the beginning of time. It should not be surprising then that information security professionals must have a good foundation to implement successful security architecture. Following are the areas designated as the cement for our "virtual foundation." A commitment to successful security architecture requires a clear understanding of issues involving:

- Technology
- Environment
- Software

What follows is initially a brief description of the components to this "tripartite" conceptualization of the virtual foundation. This in turn is followed by a more detailed discussion of exactly what the information security professional must know about each component, as well as the interactive effects of each.

Sounds easy; so why are more people *not* implementing successful security architecture? There are probably a number of reasons, but when one considers that architecture involves "the manner in which the components of a computer or computer system are organized and integrated,"[1] the answer should be fairly obvious. Security involves a very fine synergy that represents the interaction between software, technology, and the environment.

No IT system can be secured unless you unplug it and have "Fort Knox" security protecting it. Security is not only anti-virus software (insert your favorite vendor name) and a firewall. Importantly, people and policy must be factored in as well. And, with respect to the latter, a policy that is too strict, or that does not integrate seamlessly, or is not transparent to its user, is one that will be circumvented, ignored, or not supported.

Technology is multifaceted, and can be thought of as Intel, AMD, Motorola, and RISC chip architectures, wireless standards, Voice-over-IP, biometrics, smart card, IPv4, IPv6, etc. Each one has it advantages, disadvantages, and unique limitations. For example, a few years ago it was common knowledge among IT professionals that if your business operations required performing graphic-intensive work (such as computer-aided design), then you chose the Motorola chip (found in Apple computers) over the Intel chips (found in IBM-compatible personal computers [PCs]).

Environment is the second bullet in our initial outline. However, it is arguably the hardest one to tackle. Here, "environment" refers to the people, business operations, and risks, as well as the threats to your security

architecture or model. We incorporate policy to change our business environment. If the policy is properly implemented, we can expect that the people in the environment will be influenced and guided by it. For example, think of the way in which the air conditioner (AC) modifies the environment of the office, the home, or the car. Here, the AC represents a "policy" to the extent that it changes the environment. The best way to ensure that the environment is up to par is to perform an information security (InfoSec) risk assessment. By not performing one, you cannot or will not understand the environment in which a business operates. You will also be able to identify what environmental threats are lurking out there, such as insiders (i.e., disgruntled employees), hackers, and social engineers. Performing a business impact analysis will enable you to identify the critical practices and tasks essential to a business' survival.

Information Assurance

Information assurance is a term you now see a lot in publications, or job postings on the Internet or in newspapers — or you may even have heard it tossed around at professional meetings. So, what is information assurance? Information assurance consists of the following five areas:

1. *Integrity:* This refers to the quality or condition of being complete or unaltered, i.e., protecting information from unauthorized alterations or destruction.
2. *Confidentiality:* This has to do with having the assurance that the information is not disclosed to unauthorized persons, processes, or devices.
3. *Availability:* Information resources must be available and accessible to its user(s) in a timely manner.
4. *Authentication:* This entails validation and verification of the user and involves determining whether the user should be granted access.
5. *Non-repudiation:* This occurs when the sender is provided with proof of delivery, and the recipient is provided with proof of the sender's identity. It assures that neither party can deny possession of the data at a later time.

Not surprisingly, information assurance should be considered a requirement for all systems used to enter, process, store, display, or transmit national security information.[2] What is perhaps the easiest way to think about information assurance is to think of it as the process that ensures that the correct, unaltered information always gets delivered to its intended and authorized recipient(s) at the correct place and time. The U.S. government, it could be argued, is more concerned with confidentiality, integrity, and availability than is the commercial sector, whose primary focus is availability and integrity. An understanding of the information assurance concept will enable you to determine which solution is best for your environment.

Software Applications

Software refers to the set of instructions that cause the hardware to carry out specific physical tasks. Within this context, "software applications" refers not only to the obvious, but it also refers to "anti-virus," "mobile code," "malicious logic," as well as the various popular operation systems and more. Hopefully, you get the picture.

If you are thinking that what we have just outlined to discuss in this section is daunting, you are correct. But do not despair. At the end of this section you should have a firm grasp of the requisite concepts and ideas to successfully implement security architecture. We will discuss concepts, security practices, preventive, detective, and corrective controls (i.e., the environment), equipment, platforms, networks (i.e., technology), and applications (i.e., software) necessary to ensure information assurance. At various points you will note that the discussion will necessarily reflect the interactive nature of technology, environment, and software. For example, although we begin by discussing aspects of technology, this invariably entails a discussion of software.

Technology

Address Space

Address space refers to the set of all legal addresses in memory for a given application. The address space represents the amount of memory available to a program.[3] By using a technique called *virtual memory* or *virtual storage,* address space can be made larger than primary storage (i.e., RAM; primary storage is the main

memory assessed by the CPU).[4] Think of it this way: FJH is a National Football League fan who plans to see his favorite team, the Dallas Cowboys, at Texas Stadium, which has 65,846 seats.[5] Think of each seat as representing an address in memory. In his fantasy, FJH purchases an entire row of seats in section 28A, directly behind the Cowboys' bench. Think of the actual purchase of the row of seats as a program running in physical memory, which is the stadium. Imagine that, after a sensational season (yes, we said "imagine"), the Cowboys host the NFC Championship game at Texas Stadium, and tickets are sold out. So FJH goes to the local sports bar to watch the televised game on the big screen. The sports bar has a seating capacity of 200. Taking this metaphor a step further, this is represented by the hard drive. To tie all of this together, think of the combination of seating at Texas Stadium (i.e., the physical memory) and that of the sports bar (i.e., the hard drive) as making up virtual storage.

To understand when this process is used, its helpful to describe some related terms. To begin with, keep in mind that an operating system accesses virtual memory when it detects that physical RAM is close to being depleted. Once that limit has been reached, swapping — the process whereby information is transferred from RAM to secondary storage — begins. In contrast, paging is the process of moving information from the input/output device to primary storage. The operating system (OS) has to keep track of all of this movement. A good metaphor for an OS is the conductor of a symphony orchestra. Just as the conductor must account for and direct the movements of each musician, so too must the operating system keep track of all movement between primary, secondary, and virtual storage. Consequently, address space, which can consist of virtual storage, "includes the range of addresses that a processor or process[6] can access, or at which a device can be accessed."[7] Each process will have its own address space, which may be all or a part of the processor's address space. For example, to better understand address space, below is a list of common devices that should look familiar to you to demonstrate address space. It is a list of the most common interrupt request lines (IRQs [i.e.]) and includes the items listed in Exhibit 125.1.

Types of Addressing

The Texas Stadium example of address space pertains to physical addressing. It is an actual location. Relative addressing involves an expressed location from a known point. For example, imagine that you have ordered something from Amazon.com that will be shipped via United Parcel Service (UPS) to your address at 1 Main Street. You know that you will not be home for the delivery, so you leave a message for the driver to deliver the package to your next-door neighbor (3 Main Street). So the address to which the package is actually delivered is 3 Main Street.

Logical addressing is a little more complicated. It is the opposite of physical addressing; its location involves the translation of the physical address. Keep in mind that addressing does not apply to memory only, as is the case in programming, but it can also refer to mass storage as well. Examples include the file allocation table (FAT), the new technology file system (NTFS), or the compact disc file system (CDFS).

EXHIBIT 125.1 Interrupt Request Lines (IRQ)

IRQ 0	System timer
IRQ 1	Keyboard
IRQ 2	Cascade interrupt for IRQ 8–15
IRQ 3	COM 2: 2nd serial port
IRQ 4	COM 1: 1st serial port
IRQ 5	Sound card
IRQ 6	Floppy disk controller
IRQ 7	1st parallel port
IRQ 8	Real-time clock
IRQ 9	Open interrupt
IRQ 10	Open interrupt
IRQ 11	Open interrupt
IRQ 12	Mouse
IRQ 13	Coprocessor
IRQ 14	Primary IDE channel
IRQ 15	Secondary IDE channel[a]

[a] See broadbandreports.com

As you probably know, a central processing unit (CPU) is the heart of the computer. Although CPUs are made by various manufacturers, a few commonly known ones include Intel's Pentium 4, AMD's Athlon, and the PowerPC G4 chips.[8] Both the CPU and bus (the internal components of the CPU that are wired to the primary storage) are physical assets. Consequently, we say that physical addressing is used.[9] Because software is virtual or logical, relative and logical addressing is used. For example, think of using Excel to run a large spreadsheet. The phone rings; after the call has terminated, you return to your spreadsheet and ask yourself, "Which cell am I currently working in?"

Memory

RAM was discussed briefly in the section on address space, and it refers to volatile memory. The term "volatile" is an apt one given that once the power is turned off, all information held in RAM is lost. Nonvolatile memory is the opposite — when power is turned off, the information contained in the memory space is still there. A good example of nonvolatile memory is read-only memory (ROM), which is used in laser printers (the fonts are actually stored in ROM), in calculators, and in portions of the PC that boots the computer.[10] In addition, there is programmable read-only memory (PROM), erasable–programmable read-only memory (EPROM), as well as electrically erasable–programmable read-only memory (EEPROM).

What is the difference between the different types of memory? PROM is blank memory where a set of instructions that have been recorded cannot be used again; EPROM is like PROM, but with instructions that are erased by ultraviolet light. In contrast, EEPROM is PROM with an electric charge that is used to erase the set of instructions.

By the way, have you ever performed an update for a basic input/output system (i.e., BIOS) from a vendor with the latest update, or upgraded your modem with the latest vendor software? Or, have you changed the personal identification number (i.e., PIN) on a smart card? If you have answered "yes" to any of these questions, then you have most certainly had some experience with flash memory. And, guess what? Another name for EEPROM is flash memory. When programs are stored in them, this family of ROM products is also called *firmware,* which refers to the combination of hardware and software.

While we are still discussing the many aspects of memory, it is worth mentioning cache. Cache refers to the reserved section of main memory for high-speed reading and writing of instructions. When data is found, it is called a "hit" and a "miss," depending on whether the information is maintained in cache.

Why are we spending so much time discussing memory and addressing? The easy answer is that some viruses propagate in memory. The more complex answer has to do with the fact that buffer overflow attacks involve sending a set or block of instructions that overflows the set address space of the memory. A few blocks of a malicious code slip in at the tail end of a program being executed, for example, in a privileged state. Buffer overflows occur when programs do not adequately check for the appropriate length in value, and consequently, the malicious code gets executed. Because there is more input than expected, it spills into another program waiting to be executed by the CPU.[11]

For example, Sun Microsystems' Java Virtual Machines executes in memory or in temporary files in various operating systems. Java will run on just about anything that has storage space and a powerful enough CPU. Java applets are on some smart cards and cell phones, so the CPU required is not as large or as powerful as you may have thought. It is when those applets (i.e., Java programs) execute outside the sandbox (i.e., address space limitations) within your browser, or in temp folders on the hard drive, or in allocated memory space, that the trouble usually begins. A note of advice: Be aware of the environment!

We have discussed memory and the various kinds of memory, whether it is physical or symbolic. Now we will consider the importance of machine types.

Machine Types

We have briefly discussed one machine type — the virtual machine, which is the case when a program is being executed in memory (for example, Java Virtual Machine [VM], anti-virus heuristics technology). Symantec's white papers explain the basic principle behind heuristic technology. In a nutshell, Symantec's program, in addition to emulating the program in a virtual machine, is also monitoring requests being made to the operating system (OS).[12] The conceptual opposite of a virtual machine is the common three-dimensional, physical PC, which is "real." There are at least three other types of machines that we will discuss here: (1) the multistate, (2) the multitasking, and (3) the multiprogramming machines.

A multistate machine actually processes different classification levels at the same time. Think of it as a system enabling users with different authorized classifications to access information from the same workstation rather than using two workstations. For example, with classified documents a user would turn a switch on a box representing nonclassified information on the display screen. Think of it as maintaining confidential, public, and proprietary information.[13] In contrast, a multitasking machine exists when the OS slices out CPU time to different programs to execute specific tasks, or when each program can control the CPU as long as it needs to. For example, Windows 95, Windows NT, and UNIX workstations switch back and forth to give the appearance of executing tasks at the same time. An example of a multitasking machine is best demonstrated by the Windows 3.1 OS. By the way, this explains why 3.1 "locked" more than NT: it did not incorporate memory protection.[14]

The multiprogramming machine is similar to the multitasking machine. However, rather than switch between tasks, it involves execution of two or more programs by one processor. This should not be confused with the multiprocessor, which refers to the number of CPUs used to execute tasks or programs. With a multiprocessor, more than one CPU is being used; Novell's and Microsoft's various server application products support multiprocessors.

Operating Modes

Following a recent house move, we unpacked and I was happy to find a Netware 4.1 reference book. Do not laugh! The principles are still the same today. UNIX, Windows NT, and Novell Netware all use memory protection.

Consider the following example. Imagine a dartboard. Do you have the image in your mind? The smallest circle is a red area or "bull's eye." This circle is ring "0" (or ground zero for you military folks). There are four rings (0 to 3), and each circle gradually radiates outward, getting larger. Now, think of ring 0 as the area where operating systems such as UNIX, NT, and Novell operate. Netware 4.1 servers use this area as a default, although the system administrator could of course change the default setting. Whereas ring 0 is for the OS kernel and provides the least restriction to the CPU, ring 3 (i.e., the outermost ring for Netware 4.1) provides the most restrictions to the CPU. Ironically, although ring 0 is the smallest ring, it offers the fastest performance. As you move from the center outwards (that is, from ring 0 to ring 3), you take a hit in performance. As for the other rings, ring 1 is for the operating system (not the security portion), ring 2 is for the various drivers, and ring 3 is where the programs are executed.

Personally, I have always preferred Novell's security approach over the other OSs. The reason I developed this preference has to do with a little bit of history. Back then, Netware 4.1 would place things in ring 3 as a test or trial area. The process might run a little slower, but at least it did not crash the server! How is that possible? Because Netware 4.1 is operating in ring 0 memory address space, as noted earlier. For example, if the OS receives a request from a process or program to use the memory space in ring 0, the request is blocked; this process is called memory protection.[15] Data may be accessed on the same ring or from a less privileged ring by a program. Resources may be requested in the opposite manner; at the same ring level or from a higher-privileged ring. Processes operating in the inner ring are called "supervisor" or "privileged" state, and those working on the outer rings are called "user" state.[16]

CPU States

CPUs exist in two types of states. Supervisory state exists when a program can access an entire system (i.e., meaning the OS on the mainframe). It is in the supervisory state where both privileged and nonprivileged instructions can be executed. In contrast, a problem state is where nonprivileged instructions and application instructions are executed. For example, telecommunications, ports, and protocols were discussed in Domain 2. The more well-known ports — 1024 and below — operate in a privileged state.[17] As it happens, Microsoft defines eight process states for NT. However, we have cut down the first and last states to come up with a series that looks a lot like the four more commonly known states. This results in a total of six states and includes those listed in Exhibit 125.2.

To summarize, in this section on resource management we have discussed addressing, as well as swapping, paging, caching, storage types, and memory protection.

EXHIBIT 125.2 Process States

1	Ready	Ready to run on the next available processor
2	Running	Program currently being executed
3	Standby	Assigned a queue and about to run
4	Terminated	Finished executing the program
5	Waiting	Not ready for the processor
6	Transition	Ready, waiting on resources other than the CPU (e.g., input from the user, completing a print job, etc.)[a]

[a] See http://support.microsoft.com/support/ntserver/serviceware/nts40y60.asp

Environment

Now that we have discussed memory, CPUs, buses, logical and physical organizations, the basic technology concepts, and a little sprinkling on software, we will address the environment and software applications. In Domain 1, Access Control Systems and Methodology, control types were discussed. As a reminder, the control categories mentioned were "PAT." This is, of course, the easiest way to remember the following:

- Physical: Refers to locks, guards, alarms, badge systems, lights, etc.
- Administrative: Refers to policies and procedures, security awareness, auditing, etc.
- Technical: Refers to anti-virus, firewalls, intrusion detection systems (IDS), etc.

As stated before, it is important to know your environment. Consider the fact that Internet stock fraud is estimated at $10 billion per year, or $1 million per hour,[18] or as the FBI's Deputy Assistant Director recently stated, "Cyber crime continues to grow at an alarming rate, and security vulnerabilities contribute to the problem."[19] As evidence of this, results of the Seventh Annual 2002 Computer Crime and Security Survey revealed that:

- 94 percent detected security intrusions within the last year.
- 80 percent acknowledge financial loss.
- Financial losses caused by theft of proprietary information cited as the most severe cases again.
- 74 percent indicated their Internet connection as the most frequent point of attack.
- 78 percent detected employee abuse.
- 85 percent detected computer viruses.

As a result of findings like these and others, it should be clear that protection mechanisms are required now more than ever. Keep in mind that no system can be totally secured. Sooner or later an incident will occur. However, it is those actions and responses used to mitigate damage combined with corrective actions to ensure the same incident does not reoccur that distinguishes the superior (i.e., more secure) system from the others.

Layering

Layering is a concept that is important to understand when designing a security architecture. Remember the earlier discussion of memory protection as it was associated with Netware 4.1? That was actually layering in that the kernel is located in the center with programs located on the outer edge; drivers (for secondary storage) are located in between. Layering refers to the organization of separate functions that interact in a hierarchal sequence or order.[20] A good example for layering is the OSI model: there are seven component layers stacked upon each other. Whether you start from the bottom layer and work up, or the reverse order, there is an interaction among those layers.

Abstraction

Abstraction is something system administrators and programmers should be familiar with in their normal duties. Object-oriented programming uses abstraction. Abstraction (as the definition implies) involves the removal of characteristics from an entity in order to easily represent its essential properties. For example, it is easier for a system administrator to grant group rights to a group of 25 people called "Human Resources" than

to grant 25 individual rights to each HR member. Windows 2000 Professional provides six built-in local groups straight from the "jewel box," including:

- Administrators
- Backup operators
- Power users
- Users
- Guest
- Replicator

Each local group has a set of predefined rights for the user group. If you are "security smart," you have disabled the guest account and renamed the administrator group!

Data Hiding

This also has to do with object-oriented programming. Graphical user interfaces (GUIs) use object-oriented programming. For example, I am using the 2000 Professional OS. The printer icon, which is an object, contains information related to a specific printer. The information on this specific object is predefined. The object only needs to know certain information to complete its task. Think of the items recently learned in this section. Which IRQ, port, and protocol should be used to execute this task? What is the memory space address? Does the user have sufficient rights to print? In other words, anything not specifically needed to carry out the print task is hidden from the printer object.

Principle of Least Privilege

This brings us to the principle of least privilege that applies to programs as well as people. Programs and people should only be given access to those resources necessary to complete a specific task, execute a program, or accomplish their job. Once a process has been accomplished, depending on the circumstances, access to privileged resources should be removed. For example, your organization's work hours are from 7 A.M. to 6 P.M. You have decided to restrict outgoing fax calls between 6:30 P.M. and 7 A.M., preventing the cleaning crew or security guard from abusing the system. Data hiding, abstraction, and hardware segmentation each fall under the principle of least privilege. This principle is critical to understand to properly secure Novell Directory Services (NDS), Microsoft's Active Directory, Lightweight Directory Access Protocol (LDAP), and file, fax, server, and printer access within an organization. Failure to implement the correct assignation of administrative properties to objects, users, and resources, or to properly understand how inheriting rights are transferred, will lead to a security incident each and every time.

Now, as Emeril Lagasse says, "Let's take it up a few notches…." Bam! Remember the PAT acronym? We will begin focusing on a few additional concepts to tie it all together.

Security Practices

Remember that no system is totally secured unless you unplug it. Consequently, a secure system needs preventive, detective, and corrective controls in place in order to take proper action when incidents occur.

Preventive Controls

Preventive controls are measures carried out to block anticipated aggression from hostile forces. Locks, fences, alarms, guards, lighting, access control lists (ACL), IDS, anti-virus software, firewalls, logical access controls (smart cards, biometrics, PINs), demilitarized zones, and policies and procedures are all used to do the job so that those "hostile forces" are less likely to impact the operations. Just how can policy and procedures help? Consider that when an employee is terminated, resigns, or transfers positions, the user's profile must be removed from the network. This means that the third or at least the fourth person who should be notified within the organization is the senior IT security professional, who should remove that person's log-in account.

Exhibit 125.3 shows a list of preventive control tips, though not inclusive of all possible ones, which should provide you with an understanding of what is being discussed.

EXHIBIT 125.3 Preventive Control Tips

- Audit active employee names against user accounts or profiles currently assigned network file access privileges
  - — Remove/disable those accounts where there are discrepancies
- Use incremental and full backups and test backups
- Prepare contingency plans and test regularly
- System administrators should not access personal e-mail while logged into networks with system administration privileges (create a regular user profile to perform this task)
- Harden an operating system prior to placing it online
- Use standard integrated desktops for users
- Use log-in restrictions when it is feasible
- Develop educational and awareness programs for users and system administrators
- Clearly mark and label files (both soft and hard copies, and secondary storage devices)
  - — Sanitize electronic media (reminiscence security) and properly dispose of classified documents whether you are in the private or government sector[a]
- Apply critical patches (software bug fixes) to affected systems (automated tools are available)
- Use a test LAN (certification and accreditation process)[b]
- Use external connectivity controls
- Practice configuration management control
  - — Configure firewalls to allow only those services required for users to accomplish their tasks; restrict all other services or protocols
  - — Change default user passwords, disable guest, and rename administrator group accounts
  - — Set servers to retrieve anti-virus updates at least weekly[c]
    - Use a mobile code software tool to complement anti-virus software (layering technique)
  - — Use a trusted computing base (TCB) model (sorry, Millennium 9x or earlier does not qualify)
  - — Discourage placing Web server software running on top of e-mail server (double ouch!)

[a] This entails proper disposal of classified documents, whether private or federal. Keep in mind it also means proper sanitization of electronic media/equipment before turning it over to schools, charities, etc.

[b] We strongly encourage you to develop a test LAN that is representative of your local network (enclave) environment. Why? Would you want to install something on your main system network and then have to wait for the software interactions and trouble in having it impact the operational network? Instead, would you rather prefer the alternative of having problems on the test LAN segment and being able to work through the problems without impacting the operational network? A certification and accreditation process will minimize the potential for these sorts of problems. If your resources are scarce, do not throw away those old computers, routers, etc. Instead, place them in your test LAN.

[c] Anti-virus alone is not good enough to protect servers/clients, nor does it stop all malicious code. Anti-virus should be used in conjunction with mobile code software, because anti-virus is only as good as the installed definitions.

Detective Controls

Sooner or later someone will try to breach your security. As network professionals, we need to be vigilant about employing effective methods to catch cyber crooks. Below is a listing of a few detective controls:

- Enable logging for system changes, unsuccessful log-ins, system policy changes, access to files.
- Review those logs, outsource logging tasks, or automate the process (few good automated tools available).
- Conduct incident investigations.
- Use an IDS.
- Use anti-virus software. (*Note:* Can also be called preventive.)
- Make sure to have supervision oversight, job rotations, mandatory vacations.[21]

Corrective Controls

Zero-day incidents are here to stay and will probably increase in the near future. Zero-day incidents are attacks that are exploited in the wild before they are reported to the rest of the security community by groups such as the National Infrastructure Protection Center (NIPC), the Computer Emergency Response Team (CERT), or the Common Vulnerability Exposures (CVE) list. Not surprisingly, hackers exploit those exposed vulnerabilities. What can a network security professional do? Our recommendation: Develop work-arounds and apply the patches as they become available. Addressing audit deficiencies (company or government auditors) and incident investigations will allow the update of security policies and updating IDS databases.

Trusted Computing Base (TCB)

At this point, it is useful to restate that security involves a very fine synergy that represents the interaction between software, technology, and the environment. It should be clear to you that security is not only of the utmost importance, but it is multifaceted. Consider the following point from the National Information Systems Security Glossary on TCB:

> The totality of protection mechanisms within a computer system, including hardware, firmware, and software, the combination of which is responsible for enforcing a security policy. The ability of a trusted computing base to enforce correctly a unified security policy depends on the correctness of the mechanisms within the trusted computing base, the protection of those mechanisms to ensure their correctness, and the correct input of parameters related to the security policy.[22]

The tips we have suggested for preventive and detective controls fall under trusted computing base (TCB). Think of the TCB as a baseline model to obtain a level of trust. Newton's third law of motion states, "For every reaction there is an equal and opposite reaction."[23] Although Newton was discussing physics, the same case can be made for the various configuration and security policy settings a person can make to the hardware, software, and firmware of a system. We now turn to yet another aspect of security related issues.

Social Engineering

> People are the weakest link. You can have the best technology, firewalls, intrusion detection systems, biometric devices — and somebody can call an unsuspecting employee. That's all she wrote, baby. They got everything.
>
> **— Kevin Mitnick[24]**

Today, almost everyone who has at least a passing familiarity with the Internet and Internet-linked systems knows that the integrity of any good system lies in its ability to protect itself from intruders or would-be attackers. As a way of responding to the threat that computer hackers pose, organizations with public and private networks have implemented a variety of strategies ranging from static authentication — whereby a would-be intruder can gain access only by guessing at a legitimate user's authentication data, to more sophisticated intrusion detection systems that effectively discover unauthorized activity and in some cases identify intruders.[25] Although each of the different strategies varies in complexity and component parts, they are similar in that they each represent a deliberate attempt to discourage or at least minimize the threat of potential intruders.

Yet, there is an additional threat to which even the most secure systems are vulnerable. This additional threat, as illustrated by the above quote, has a decidedly human aspect to it, and occurs when would-be attackers try to access a system by manipulating and deceiving company employees or other legitimate system users. In its most egregious form, "social engineering" practices permit intruders to gain unrestricted access to closed systems by talking and interacting with company employees. In a slightly more benign form, it involves intruders gaining unauthorized information about employees or company business practices. In short, hackers[26] and would-be intruders use their "social skills" (e.g., persuasion, coercion, deception) to feign legitimacy in order to obtain compliance from unsuspecting employees. When this occurs, employees find themselves on the receiving end of an earnest request for information from what is ostensibly a legitimate user or company employee. Oftentimes the intruder poses as a senior executive of the company whose power and prestige make compliance with the intruder's request (however unusual) especially likely.

Consider the scenario in which a would-be intruder poses as a company executive and asks a help-desk employee to provide an access code he or she claims to have accidentally left in the office. Alternatively, imagine the hacker who telephones the CEO's executive secretary with an elaborate ruse that concludes with a request for the CEO's password. Although neither employee can be certain of the legitimacy of the request, they will feel a personal sense of obligation to comply with the actual request. Here, compliance occurs when the employee does what he or she is asked to do (by providing the unknown person with privileged information) even though he or she might prefer not to do so. In cases like these, successful computer hackers and intruders are able to influence company employees in a way that brings about compliance.

Social engineering represents a form of persuasive manipulation. Use of social engineering techniques involves the exploitation of common and basic human attributes — namely, that of helpfulness and trustworthiness. Although the term "social engineering" is specific to the computing industry, the techniques involved

are common to a host of situations and industries. Across all settings in which people are dependent on the compliance of others, social engineering techniques are at work. For example, the parent who wishes to influence a child to brush its teeth, the husband who seeks to convince his wife of the necessity of an expensive purchase, and the panhandler who requests money from passers-by each use social engineering skills to bring about compliance.

There are a number of well-known cases in the computer industry in which intruders have succeeded at social engineering. To be sure, the actual mediums through which these manipulative techniques are transmitted are varied, and include the telephone, e-mail, trash pilferage, in-person site visits, and, of course, snail mail. Regardless of the medium employed, would-be intruders intent on accessing a system hone their social skills to gain information, manipulate policies, and acquire resources, all with the unwitting assistance and compliance of company employees.

Students of human behavior know well the tendency for people to be compliant with requests emanating from people who they believe to be legitimate authority figures. Researchers in social psychology,[27] for example, have conducted numerous empirical studies investigating the conditions under which compliance is most likely, as well as those circumstances or factors that may limit its occurrence. Research findings pertaining to the latter would seem to be most relevant for computer professionals who are committed to ensuring the security of their network systems.

What does the research tell us about the effectiveness of efforts to resist social pressure? In other words, how can network administrators inoculate employees against the social engineering efforts of would-be intruders? Can anything be done to combat the would-be intruder and keep systems users and data safe and secure? The answer is "yes."

Fortunately, research on best business practices has revealed that there are important limitations to social engineering techniques. Knowledge of the limitations to social engineering schemes can significantly enhance a network administrator's ability to ensure the integrity of a system. Although network administrators cannot eliminate the problem of computer hackers, they can take specific steps to reduce the effectiveness of their influence schemes. What follows is a brief discussion of at least three prescriptions for network systems administrators who are vulnerable to social engineering schemes.

Risk Awareness Training

First and foremost, employees must be made aware of the potential problems posed by computer hackers. Only when employees and other system users know about the existence and pervasiveness of social engineering schemes can they act against them. According to some writers in this area,[28] when it comes to user suspicion, "paranoia is good!" Whether this occurs in the context of new employee orientation training or specific security awareness training for users, individuals must be informed about the potential risk for social engineering schemes. Far too often, individuals assume that their systems are invincible, and that requests for information come from legitimate users.

System users and employees must realize the role that they personally play in the security of a company's information. Any information awareness session should be focused on getting people to appreciate the fact that there are people out there who are trying to access companies' networks, and that their role as employees or legitimate users of the system is to be both proactive and reactive in making it as hard as possible for would-be intruders to succeed. Proactively, this means that users must be cautious about whose requests they comply with, and reactively, when users encounter unusual or outrageous requests for information either in-person or online they should immediately alert their network administrator.

The theory of psychological reactance may be particularly useful for those most apt to encounter hackers employing social engineering schemes. This theory is most relevant in situations where employees are sensitized to the potential risk of social engineering schemes, and would-be intruders employ high-pressure tactics. According to the theory, too much pressure to comply with a request can actually have the opposite intended effect.[29] The idea that forms the basis of the theory is that people are motivated to maintain their sense of personal freedom and when they suspect that they are being pressured or feel that their freedom is being threatened, they will act so as to protect their freedom by refusing to comply. Hence, they react against the pressure to comply by doing the exact opposite of what they are being asked to do. Employees who are aware of the risk of social engineering schemes and who confront would-be intruders using high-pressure tactics are especially likely to experience the phenomenon of reactance. Consequently, in these situations, by being less willing to comply, they are more apt to thwart the would-be intruder's efforts. Network administrators should

work to ensure that the risk of social engineering schemes remains salient for employees and other legitimate users with access to company information.

Formulate a Written Policy for Procedures

Sometimes employees who are approached with a request for information may suspect that something is amiss, but because they are unsure about what to do about their suspicions, they wind up complying with the would-be intruder's request. Even the most conscientious employees who are usually vigilant about information distribution may encounter a situation in which they are faced with a novel request. They may simply be at a loss to know the appropriate procedure. Although written policy cannot possibly speak to every potential request that a world-be intruder can come up with, existing policy should inform employees that "when in doubt, be conservative, do not comply."

The policy that is ultimately formulated with the help of users should be comprehensive and clear. Employees and others who are approached for information should clearly be able to distinguish a legitimate request for information from an illegitimate one, whether the person requesting the information is a legitimate user or not. What is more, employees must be able to feel that they can ask questions about the request in an environment in which they do not appear silly or ignorant. In some cases, network operators have initially failed to take users' requests for information seriously enough and in the end are burned. One way of ensuring that this does not happen is to create a policy that permits, indeed encourages, employees who are uncertain about information requests to verify the legitimacy of the request with a network operator. This may take more time up front, but in the long run it may prove to be extremely beneficial.

Eliminating Paper Trails and Staying Connected

The final set of prescriptions aimed at securing network systems from would-be intruders employing social engineering schemes has to do with the elimination of company documents and materials, and maintaining contact with organizations specializing in security. With respect to the former, although there has been considerable discussion about trash pilferage in the popular press, with the exception of a few highly secure federal agencies, people in general are lax about discarding their trash. Organizations must provide employees with convenient ways of discarding sensitive documents and material. Finally, companies should keep in touch with those organizations and agencies that can be trusted to provide up-to-date, dependable information about security issues.

Certification and Accreditation (C&A)

Remember the admonition to know your environment? Understanding which laws, policies, and service-level agreement contracts are in place is critical to effective implementation and testing of a security policy or architecture. Although there is no law that formally requires companies to perform a C&A, shareholders enforce policies within the private sector. Conversely, within the federal arena, Congress ultimately regulates such practices. But the question remains as to why C&A is important, and perhaps more importantly, what are its implications and impact for the network administrator?

The National Institute of Standards and Technology (NIST) defines certification as

> the comprehensive evaluation of the technical and nontechnical security controls of an IT system to support the accreditation process that establishes the extent to which a particular design and implementation meets a set of specified security requirements.[30]

What are the implications of this for private industry and the federal government? What motivates each to comply? For the private sector it may be argued that the primary motive is an economic one; in other words, "the wallet." When companies fail to do so, the consequences can be grave. Consider the following statement made by one attorney:

> We have seen several recent incidents where our clients have threatened legal action against trading partners who have been the cause of a security breach or virus infection. All of these cases have been settled out of court, primarily because of the unwanted publicity connected with court cases.[31]

Thus, having a C&A package that has demonstrated effective implementation is one manner of showing the courts due diligence.

As for the federal government, it is mandated by laws such as the Health Insurance Portability and Accountability Act of 1996 (HIPAA), Clinger–Cohen, and the Federal Information Security Management Act of 2002 (FISMA), to name a few. Although it depends on which part of the federal government you are referring to, the major policies are DoDD 8500.1, DoDD 5200.40, and NIST's Special Publication 800-37.

Accreditation

Accreditation refers to

> the authorization of an IT system to process, store, or transmit information, granted by a management official. Accreditation, which is required under OMB Circular A-130, is based on an assessment of the management, operational, and technical controls associated with an IT system.[32]

Simply stated, this amounts to management's formal approval of the certification process that essentially says that it can live with the risks to the IT system and the mitigation of those risks. It also means that there is help to assist someone through the process. Admittedly, this is a complicated process, but there are automated tools available from appropriate vendors. Just ensure that the information entered is valid and not "pencil-whipped."

Security Models

Taking the principle of trust further, we will discuss the more commonly used security models, including:

- Bell–LaPadula
- Biba
- Clark–Wilson

The Bell-LaPadula Model

In 1973, Drs. Bell and LaPadula from the MITRE Corporation developed a security model for the Department of Defense. (As you may recall, mainframes were common during this period.) The Bell–LaPadula model controls information flow. For example, Novell's and Microsoft's training literature discuss access rights to objects and resources. Those various access privileges (read, write, delete, modify, etc.) form a "woven lattice." One concept of the model states that a user cannot read an object of a higher classification than granted.

For example, if you have a government security clearance of Secret, you are allowed to read Secret and below classification level documents; accordingly, you have no access to Top Secret information. The Bell–LaPadula model incorporates the "* property," i.e., it states that a user cannot write from a higher classification level to a lower one. Using the previous example, Secret e-mail messages or documents cannot be sent to recipients who do not have a Secret or higher clearance or written or stored to file servers designated for Unclassified information. It is for this reason that the Bell–LaPadula model is considered a confidentiality model.

Biba Model

This model, developed in the late 1970s, uses a process similar to the Bell–LaPadula model (i.e., the subject cannot write to a higher integrity source). However, the Biba model is an integrity model. Whereas the Bell–LaPadula model was concerned with protecting the release of information to unauthorized users, the Biba model was developed strictly for the developing computer systems of that period. With this model, unauthorized objects are blocked from making modifications. The "* property" is used to block subjects from writing to objects of higher integrity, the "read property" keeps subjects from corruption by objects of lower integrity, and subjects cannot request services from objects maintaining a higher integrity model.[33]

For example, imagine that you work for the CIA as a low-level analyst with a Secret clearance. You do the leg work for a report to gather raw intelligence from various sources addressing sonar technology. You take your proposal to your supervisor for review; your supervisor makes further input to the report and hands it off to ex-Naval officers and an expert who has published extensively on bats' acute hearing techniques. They further refine the report to a finished product that lands on the Secretary of the Navy's desk. Although the Secretary would never read your report in its raw state, he would read the finished CIA product. Although you may wish to update the report in its finished form, you are actually blocked from write access to it because you are now at a lower level of integrity than the report. However, you would be allowed to read the report in accordance with Biba. The same principle could be used for a database recognized as the authoritative source such as that produced by the Bureau of the Census.

Clark–Wilson Model

This is another model developed to address integrity and uses a broader approach than the Biba model, which addressed only subjects and objects. Clark–Wilson addresses a special type of program called a "well-formed transaction." In this case, changes to a process or to data can be made only through this trusted program because the subject can access the object through the trusted program only. This concept binds the subject to the program and the program to the object, creating a "triple" instead of the subject–object "tuple" used in Biba. The trusted program is constructed to only make authorized changes. Think of it as incorporating a program to complete transactions, and one that incorporates the policy of separation of duties as well. Separation of duty involves breaking a task or operations into parts where no one person can complete a process. For example, this would prevent someone in Acquisition from cutting a check to purchase office furniture for use in a private home. Access control prevents unauthorized personnel from making alterations or changes to data. Separation of duty helps prevent authorized personnel from making unauthorized modifications.

Software Applications

At this point, it is worth asking, "How does a person know how to distinguish between the good, the bad, and the ugly software in order to develop a valid C&A package? What is the TCP based on?" These are good questions that you may already have considered asking. The answers have to do with the efforts of the federal government, which has provided a number of valuable resources to IT professionals through the National Information Assurance Partnership (NIAP). NIAP is an initiative to increase information technology security by collaborating with industry in security testing, research, and the development of information assurance methodologies.[34] From NIAP came the Common Criteria Evaluation and Validations Scheme (CCEVS), which is jointly managed by the National Security Agency and NIST. The CCEVS established a national program for the evaluation of information technology products. This program is known as Common Criteria (CC) and it is identified as International Standards Organization (ISO) 15408. Under CC there are seven protection profiles. A firm understanding of the CC's protection profiles, which also include seven evaluation assurance levels (EAL), is important for various reasons. If you are working in the federal government sector, following CC is a requirement mandated by policy. For evidence of this, see the reference cited in Note 2.

Minimizing the Need for Applying Patches

Why make life difficult? By using an enterprisewide architecture, which employs a layered approach, you will minimize the need to apply patches. Keep this in mind as your organization begins to perceive a shortage of resources and starts looking to cut resources from somewhere. Rather than being on the short end of the stick, be progressive: pitch the use of an enterprise architecture. Incidentally, this has been the direction in which the federal government is moving.

For example, using the Command, Control, Communications, Computers, Intelligence, Surveillance, Reconnaissance (C4ISR) architecture model, which applies to the federal government and to some extent carries over to the private sector, you can minimize a lot of the work down the road through detailed planning (for patches). The enterprise architecture can list software by version (i.e., an interim technical reference) for approving software prior to placing it on the desktop or network. The approval can include supporting the software, training, life cycle, etc. For example, imagine instituting a standardized integrated desktop configuration that includes the minimum standard for clients and network connectivity. For the desktop (as an example), you would only support Windows NT 4.0 Service Pack 6a. This minimizes the need to support the previous service packs as well as the time required for installing patches. The architecture would detail setting retirement dates (for applications and operating system) and planning for new technology insertion dates, thus minimizing the "software zoo."[35] This in turn reduces legacy applications, vendors' support (for phased-out software, much like NT 4.0 now), the associated security vulnerabilities, and time mitigating those vulnerabilities (applying patches, policy, etc.).

Not surprisingly, there are at least two cost-saving benefits associated with this effort. First, minimized desktop support is achieved by narrowing various operating system platforms to a few (even within the Microsoft family there are various versions of Office for the same OS). Second, by narrowing the software applications supported, you reduce manpower needs and patches to be maintained or applied. In this way, organizations can arrange individuals into groups (power user, standard user, sys-admin/support, as an example

for software applications) and apply the manpower to group configurations rather than the individual desktop zoo.

We conclude by listing the benefits of using an enterprise architecture, which are numerous:

- Capturing facts on operations and functions in an understandable manner to drive better planning and decision-making
- Supporting analyses of alternatives, risks, and trade-offs for the investment-management process, which reduces the risk of:
  - — Building systems that do not meet operational needs
  - — Expending resources on developing unnecessary duplicative functionality
- Improving consistency, accuracy, and timeliness of information shared collaboratively across the enterprise[36]

Security Models for Object-Oriented Data Bases

James Cannady

Payoff

Object-oriented (OO) techniques are a significant development in the management of distributed data. Data base design is influenced to an ever-greater degree by OO principles. As more DBMS products incorporate aspects of the object-oriented paradigm, data base administrators must tackle the unique security considerations of these systems and understand the emerging security model.

Introduction

Object-oriented (OO) programming languages and OO analysis and design techniques influence data base systems design and development. The inevitable result is the object-oriented data base management system (OODBMS).

Many of the established data base vendors are incorporating object-oriented concepts into their products in an effort to facilitate data base design and development in the increasingly object-oriented world of distributed processing. In addition to improving the process of data base design and administration, the incorporation of object-oriented principles offers new tools for securing the information stored in the data base. This article explains the basics of data base security, the differences between securing relational and object-oriented systems, and some specific issues related to the security of next-generation OODBMSs.

Basics of Data Base Security

Data base security is primarily concerned with the secrecy of data. Secrecy means protecting a data base from unauthorized access by users and software applications.

Secrecy, in the context of data base security, includes a variety of threats incurred through unauthorized access. These threats range from the intentional theft or destruction of data to the acquisition of information through more subtle measures, such as inference. There are three generally accepted categories of secrecy-related problems in data base systems:

- **The improper release of information from reading data that was intentionally or accidentally accessed by unauthorized users.** Securing data bases from unauthorized access is more difficult than controlling access to files managed by operating systems. This problem arises from the finer granularity that is used by data bases when handling files, attributes, and values. This type of problem also includes the violations to secrecy that result from the problem of inference, which is the deduction of unauthorized information from the observation of authorized information. Inference is one of the most difficult factors to control in any attempts to secure data. Because the information in a data base is semantically related, it is possible to determine the value of an attribute without accessing it directly. Inference problems are most serious in statistical data

bases, where users can trace back information on individual entities from the statistical aggregated data.

- **The improper modification of data.** This threat includes violations of the security of data through mishandling and modifications by unauthorized users. These violations can result from errors, viruses, sabotage, or failures in the data that arise from access by unauthorized users.

- **Denial-of-service threats.** Actions that could prevent users from using system resources or accessing data are among the most serious. SYN flood attacks against network service providers are an example of denial-of-service threats in which a barrage of messages is sent to the server at a rate faster than the system can deal with them. Such attacks prevent authorized users from using system resources.

Discretionary Versus Mandatory Access Control Policies

Both traditional relational data base management system (RDBMS) security models and object-oriented data base models make use of two general types of access control policies to protect the information in multilevel systems. The first of these policies is the discretionary policy. In the discretionary access control (DAC) policy, access is restricted based on the authorizations granted to the user.

The mandatory access control (MAC) policy secures information by assigning sensitivity levels, or labels, to data entities or objects. MAC policies are generally more secure than DAC policies and they are used in systems in which security is critical, such as military applications. However, the price that is usually paid for this tightened security is reduced performance of the data base management system. Most MAC policies also incorporate DAC measures as well.

Securing an RDBMS Versus OODBMS: Know the Differences

The development of secure models for object-oriented DBMSs has obviously followed on the heels of the development of the data bases themselves. The theories that are currently being researched and implemented in the security of object-oriented data bases are also influenced heavily by the work that has been conducted on secure relational data base management systems.

Relational DBMS Security

In traditional RDBMSs, security is achieved principally through the appropriate use and manipulation of view and the SQL GRANT and REVOKE statements. These measures are reasonably effective because of their mathematical foundation in relational algebra and relational calculus.

View-based Access Control.

Views allow the data base to be conceptually divided into pieces in ways that allow sensitive data to be hidden from unauthorized users. In the relational model, views provide a powerful mechanism for specifying data-dependent authorizations for data retrieval.

Although the individual user who creates a view is the owner and is entitled to drop the view, he or she may not be authorized to execute all privileges on it. The authorizations that

the owner may exercise depend on the view semantics and on the authorizations that the owner is allowed to implement on the tables directly accessed by the view. For the owner to exercise a specific authorization on a view that he or she creates, the owner must possess the same authorization on all tables that the view uses. The privileges the owner possesses on the view are determined at the time of view definition. Each privilege the owner possesses on the tables is defined for the view. If, later on, the owner receives additional privileges on the tables used by the view, these additional privileges will not be passed onto the view. In order to use the new privileges within a view, the owner will need to create a new view.

The biggest problem with view-based mandatory access controls is that it is impractical to verify that the software performs the view interpretation and processing. If the correct authorizations are to be assured, the system must contain some type of mechanism to verify the classification of the sensitivity of the information in the data base. The classification must be done automatically, and the software that handles the classification must be trusted. However, any trusted software for the automatic classification process would be extremely complex. Furthermore, attempting to use a query language such as structured query language (SQL) to specify classifications quickly becomes convoluted and complex. Even when the complexity of the classification scheme is overcome, the view can do nothing more than limit what the user sees—it cannot restrict the operations that may be performed on the views.

GRANT and REVOKE Privileges.

Although view mechanisms are often regarded as security “freebies” because they are included within SQL and most other traditional relational data base managers, views are not the sole mechanism for relational data base security. GRANT and REVOKE statements allow users to selectively and dynamically grant privileges to other users and subsequently revoke them if necessary. These two statements are considered to be the principal user interfaces in the authorization subsystem.

There is, however, a security-related problem inherent in the use of the GRANT statement. If a user is granted rights without the GRANT option, he or she should not be able to pass GRANT authority on to other users. However, the system can be subverted by a user by simply making a complete copy of the relation. Because the user creating copy is now the owner, he or she can provide GRANT authority to other users. As a result, unauthorized users are able to access the same information that had been contained in the original relation. Although this copy is not updated with the original relation, the user making the copy could continue making similar copies of the relation, and continue to provide the same data to other users.

The REVOKE statement functions similarly to the GRANT statement, with the opposite result. One of the characteristics of the use of the REVOKE statement is that it has a cascading effect. When the rights previously granted to a user are subsequently revoked, all similar rights are revoked for all users who may have been provided access by the originator.

Other Relational Security Mechanisms.

Although views and GRANT/REVOKE statements are the most frequently used security measures in traditional RDBMSs, they are not the only mechanisms included in most security systems using the relational model. Another security method used with

traditional relational data base managers, which is similar to GRANT/REVOKE statements, is the use of query modification.

This method involves modifying a user's query before the information is retrieved, based on the authorities granted to the user. Although query modification is not incorporated within SQL, the concept is supported by the Codd-Date relational data base model.

Most relational data base management systems also rely on the security measures present in the operating system of the host computer. Traditional RDMBSs such as DB2 work closely with the operating system to ensure that the data base security system is not circumvented by permitting access to data through the operating system. However, many operating systems provide insufficient security. In addition, because of the portability of many newer data base packages, the security of the operating system should not be assumed to be adequate for the protection of the wealth of information in a data base.

Object-Oriented DBMS Characteristics

Unlike traditional RDBMSs, secure object-oriented DBMSs (or OODBMSs) have certain characteristics that make them unique. Furthermore, only a limited number of security models have been designed specifically for object-oriented data bases. The proposed security models make use of the object-oriented concepts of:

- Encapsulation.
- Inheritance.
- Information hiding.
- Methods (in the OO paradigm, an object contains data and methods; methods are the components that act on the data and provide user access to the data. It helps to think of methods as functions from the structured programming environment.).
- The ability to model real-world entities.

The object-oriented data base model also permits the classification of an object's sensitivity through the use of class (of entities) and instance. When an instance of a class is created, the object can automatically inherit the level of sensitivity of the superclass. Although the ability to pass classifications through inheritance is possible in object-oriented data bases, class instances are usually classified at a higher level within the object's class hierarchy. This prevents a flow control problem, where information passes from higher to lower classification levels.

Object-oriented DBMSs also use unique characteristics that allow these models to control the access to the data in the data base. They incorporate features such as flexible data structure, inheritance, and late binding. Access control models for OODBMSs must be consistent with such features. Users can define methods, some of which are open for other users as public methods. Moreover, the OODBMS may encapsulate a series of basic access commands into a method and make it public for users, while keeping basic commands themselves away from users.

Proposed OODBMS Security Models

Currently only a few models use discretionary access control measures in secure object-oriented data base management systems.

Explicit Authorizations.

The ORION authorization model is probably the best OODBMS discretional access control security model available today. ORION permits access to data on the basis of explicit authorizations provided to each group of users. These authorizations are classified as positive authorizations because they specifically allow a user access to an object. Similarly, a negative authorization is used to specifically deny a user access to an object.

The placement of an individual into one or more groups is based on the role that the individual plays in the organization. In addition to the positive authorizations that are provided to users within each group, there are a variety of implicit authorizations that may be granted based on the relationships between subjects and access modes.

Data-Hiding Model.

A similar discretionary access control secure model is the data-hiding model proposed by Dr. Elisa Bertino of the Universita' di Genova. This model distinguishes between public methods and private methods.

The data-hiding model is based on authorizations for users to execute methods on objects. The authorizations specify which methods the user is authorized to invoke. Authorizations can only be granted to users on public methods. However, the fact that a user can access a method does not automatically mean that the user can execute all actions associated with the method. As a result, several access controls may need to be performed during the execution, and all of the authorizations for the different accesses must exist if the user is to complete the processing.

Similar to the use of GRANT statements in traditional relational data base management systems, the creator of an object is able to grant authorizations to the object to different users. The “creator” is also able to revoke the authorizations from users in a manner similar to REVOKE statements. However, unlike traditional RDBMS GRANT statements, the data-hiding model includes the notion of protection mode. When authorizations are provided to users in the protection mode, the authorizations actually checked by the system are those of the creator and not the individual executing the method. As a result, the creator is able to grant a user access to a method without granting the user the authorizations for the methods called by the original method. In other words, the creator can provide a user access to specific data without being forced to give the user complete access to all related information in the object.

Other DAC Models for OODBMS Security.

Rafiul Ahad has proposed a similar model that is based on the control of function evaluations. Authorizations are provided to groups or individual users to execute specific methods. The focus in Ahad's model is to protect the system by restricting access to the methods in the data base, not the objects. The model uses proxy functions, specific functions, and guard functions to restrict the execution of certain methods by users and enforce content-dependent authorizations.

Another secure model that uses authorizations to execute methods has been presented by Joel Richardson. This model has some similarity to the data-hiding model's use of GRANT/REVOKE-type statements. The creator of an object can specify which users may execute the methods within the object.

A final authorization-dependent model emerging from OODBMS security research has been proposed by Dr. Eduardo B. Fernandez of Florida Atlantic University. In this model the authorizations are divided into positive and negative authorizations. The Fernandez model also permits the creation of new authorizations from those originally specified by the user through the use of the semantic relationships in the data.

Dr. Naftaly H. Minsky of Rutgers University has developed a model that limits unrestricted access to objects through the use of a view mechanism similar to that used in traditional relational systems data base management systems. Minsky's concept is to provide multiple interfaces to the objects within the data base. The model includes a list of laws, or rules, that govern the access constraints to the objects. The laws within the data base specify which actions must be taken by the system when a message is sent from one object to another. The system may allow the message to continue unaltered, block the sending of the message, send the message to another object, or send a different message to the intended object.

Although the discretionary access control models do provide varying levels of security for the information within the data base, none of the DAC models effectively addresses the problem of the authorizations provided to users. A higher level of protection within a secure object-oriented data base model is provided through the use of mandatory access control.

MAC Methods for OODBMS Security.

Dr. Bhavani Thuraisingham of MITRE Corp. proposed in 1989 a mandatory security policy called SORION. This model extends the ORION model to encompass mandatory access control. The model specifies subjects, objects, and access modes within the system, and it assigns security/sensitivity levels to each entity. Certain properties regulate the assignment of the sensitivity levels to each of the subjects, objects, and access modes. In order to gain access to the instance variables and methods in the objects, certain properties that are based on the various sensitivity levels must be satisfied.

A similar approach has been proposed in the Millen-Lunt model. This model, developed by Jonathan K. Millen of MITRE Corp. and Teresa Lunt of SRI/DARPA(Defense Advanced Research Projects Agency), also uses the assignment of sensitivity levels to the objects, subjects, and access modes within the data base. In the Millen-Lunt model, the properties that regulate the access to the information are specified as axioms within the model. This model further attempts to classify information according to three different cases:

- The data itself is classified.
- The existence of the data is classified.
- The reason for classifying the information is also classified.

These three classification broadly cover the specifics of the items to be secured within the data base; however, the classification method also greatly increases the complexity of the system.

The SODA Model.

Dr. Thomas F. Keefe of Penn State University proposes a model called Secure Object-Oriented Data Base (SODA). The SODA model was one of the first models to address the specific concepts in the object-oriented paradigm. It is often used as a standard example of secure object-oriented models from which other models are compared.

The SODA model complies with MAC properties and is executed in a multilevel security system. SODA assigns classification levels to the data through the use of inheritance. However, multiple inheritance is not supported in the SODA model.

Similar to other secure models, SODA assigns security levels to subjects in the system and sensitivity levels to objects. The security classifications of subjects are checked against the sensitivity level of the information before access is allowed.

Polyinstantiation

Unlike many current secure object-oriented models, SODA allows the use of polyinstantiation as a solution to the multiparty update conflict. This problem arises when users with different security levels attempt to use the same information. The variety of clearances and sensitivities in a secure data base system result in conflicts between the objects that can be accessed and modified by the users.

Through the use of polyinstantiation, information is located in more than one location, usually with different security levels. Obviously the more sensitive information is omitted from the instances with lower security levels.

Although polyinstantiation solves the multiparty update conflict problem, it raises a potentially greater problem in the form of ensuring the integrity of the data within the data base. Without some method of simultaneously updating all occurrences of the data in the data base, the integrity of the information quickly disappears. In essence, the system becomes a collection of several distinct data base systems, each with its own data.

Conclusion

The move to object-oriented DBMSs is likely to continue for the foreseeable future. Because of the increasing need for security in distributed environment, the expanded selection of tools available for securing information in this environment should be used fully to ensure that the data is as secure as possible. In addition, with the continuing dependence on distributed data the security of these systems must be fully integrated into existing and future network security policies and procedures.

The techniques that are ultimately used to secure commercial OODBMS implementations will depend in large part on the approaches promoted by the leading data base vendors. However, the applied research that has been conducted to date is also laying the groundwork for the security components that will in turn be incorporated in the commercial OODBMSs.

Common System Design Flaws and Security Issues

William Hugh Murray, CISSP

This chapter identifies and describes many of the common errors in application and system design and implementation. It explains the implications of these errors and makes recommendations for avoiding them. It treats unenforced restrictions, complexity, incomplete parameter checking and error handling, gratuitous functionality, escape mechanisms, and unsafe defaults, among others.

In his acceptance of the Turing Award, Ken Thompson reminded us that unless one writes a program oneself, one cannot completely trust it. Most people realize that although writing a program may be useful, even necessary, for trust, it is not sufficient. That is to say, even the most skilled and motivated programmers make errors. On the other hand, if one had to write every program that one uses, computers would not be very useful. It is important to learn both to write and recognize reliable code.

Historically, the computer security community has preferred to rely on controls that are external to the application. The community believed that such controls were more reliable, effective, and efficient. They are thought to be more reliable because fewer people have influence over them and those people are farther away from the application. They are thought to be more effective because they are more resistant to bypass. They are thought to be more efficient because they operate across and are shared by a number of applications.

Nonetheless, application controls have always been important. They are often more granular and specific than the environmental controls. It is usually more effective to say that those who can update the vendor name and address file cannot also approve invoices for payment than it is to say that Alice cannot see or modify Bob's data. Although it sometimes happens that the privilege to update names and addresses maps to one data object and the ability to approve invoices maps to another data object, this is not always true. Although it can always be true that the procedure to update names and addresses is in a different program from that to approve invoices, and although this may be coincidental, it usually requires intent and design.

However, in modern systems, the reliance on application controls goes up even more. Although the application builder may have some idea of the environment in which his program will run, his ability to specify it and control it may be very low. Indeed, it is increasingly common for applications to be written in cross-platform languages. These languages make it difficult for the author to know whether his program will run in a single-user system or a multi-user system, a single application system or a multi-application system. Historically, one relied on the environment to protect the application from outside interference or contamination; in modern systems one must rely on the application to protect itself from its traffic. In distributed systems, environmental controls are far less reliable than in traditional systems. It has become common, not to say routine, for systems to be contaminated by applications.

The fast growth of the industry suggests that people with limited experience are writing many programs. It is difficult enough for them to write code that operates well when the environment and the inputs conform to their expectation, much less when they do not.

The history of controls in applications has not been very good. Although programs built for the marketplace are pretty good, those built one-off specifically for an enterprise are often disastrous. What is worse, the same error types are manifesting themselves as seen 20 years ago. The fact that they get renamed, or even treated as novel, suggests that people are not taking advantage of the history. "Those who cannot remember the past are condemned to repeat it."[1]

This chapter identifies and discusses some of the more common errors and their remedies in the hope that there will be more reliable programs in the future. Although a number of illustrations are used to demonstrate how these errors are maliciously exploited, the reader is asked to keep in mind that most of the errors are problems *per se*.

Unenforced Restrictions

In the early days of computing, it was not unusual for program authors to respond to error reports from users by changing the documentation rather than changing the program. Instead of fixing the program such that a particular combination of otherwise legitimate input would not cause the program to fail, the programmers simply changed the documentation to say, "Do not enter this combination of inputs because it may cause unpredictable results." Usually, these results were so unpredictable that, while disruptive, they were not exploitable. Every now and then, the result was one that could be exploited for malicious purposes.

It is not unusual for the correct behavior of an application to depend on the input provided. It is sometimes the case that the program relies on the user to ensure the correct input. The program may tell the user to do A and not to do B. Having done so, the program then behaves as if the user will always do as he is told. For example, the programmer may know that putting alpha characters in a particular field intended to be numeric might cause the program to fail. The programmer might even place a caution on the screen or in the documentation that says, "Put only numeric characters in this field." What the programmer does not do is check the data or constrain the input such that the alpha data cannot cause an error.

Of course, in practice, it is rarely a single input that causes the application to fail. More often, it is a particular, even rare, combination of inputs that causes the failure. It often seems to the programmer as if such a rare combination will never occur and is not worth programming for.

Complexity

Complexity is not an error *per se.* However, it has always been one of the primary sources of error in computer programs. Complexity causes some errors and may be used to mask malice. Simplicity maximizes understanding and exposes malice.

Limiting the scope of a program is necessary but not sufficient for limiting its complexity and ensuring that its intent is obvious. The more one limits the scope of a program, the more obvious will be what it does. On the other hand, the more one limits the scope of all programs, the more programs one ends up with.

Human beings improve their understanding of complex things by subdividing them into smaller and simpler parts. The atomic unit of a computer program is an instruction. One way to think about programming is that it is the art of subdividing a program into its atomic instructions. If one were to reduce all programs to one instruction each, then all programs would be simple and easy to understand, but there would be many programs and the relationship between them would be complex and difficult to comprehend.

Large programs may not necessarily be more complex than short ones. However, as a rule, the bigger a program is, the more difficult it is to comprehend. There is an upper bound to the size or scope of a computer program that can be comprehended by a human being. As the size of the program goes up, the number of people that can understand it approaches zero and the length of time required for that understanding approaches infinity. Although one cannot say with confidence exactly where that transition is, neither is it necessary. Long before reaching that point, one can make program modules large enough to do useful work.

The issue is to strike a balance in which programs are large enough to do useful work and small enough to be easily understood. The comfort zone should be somewhere between and 10 and 50 verbs and between one complete function and a page.

Another measure of the complexity of a program is the total number of paths through it. A simple program has one path from its entry at the top to its exit at the bottom. Few programs look this way; most will have some iterative loops in them. However, the total number of paths may still be numbered in the low tens as

long as these loops merely follow one another in sequence or embrace but do not cross. When paths begin to cross, the total number of possible paths escalates rapidly. Not only does it become more difficult to understand what each path does, it becomes difficult simply to know if a path is used (i.e., is necessary) at all.

Incomplete Parameter Check and Enforcement

Failure to check input parameters has caused application failures almost since Day One. In modern systems, the failure to check length is a major vulnerability. Although modern databases are not terribly length sensitive, most systems are sensitive to input length to some degree or another.

A recent attack involved giving an e-mail attachment a name more than 64 kb in length. Rather than impose an arbitrary restriction, the designer had specified that the length be dynamically assigned. At lengths under 64 kb, the program worked fine; at lengths above that, the input overlaid program instructions. Neither the programmer, the compiler, nor the tester asked what would happen for such a length. At least two separate implementations of the function failed in this manner.

Yes, there really are people out there that are stressing programs in this way. One might well argue that one should not need to check for a file name greater than 64 kb in length. Most file systems would not even accept such a length. Why would anyone do that? The answer is to see if it would cause an exploitable failure; the answer is that it did.

Many compilers for UNIX permit the programmer to allocate the size of the buffer statically at execution time. This makes such an overrun more likely but improves performance. Dynamic allocation of the buffer is more likely to resist an accidental overrun but is not proof against attacks that deliberately use excessively long data fields.

These attacks are known generically as "buffer-overflow" attacks. More than a decade after this class of problem was identified, programs vulnerable to it continue to proliferate.

In addition to length, it is necessary to check code, data type, format, range, and for illegal characters. Many computers recognize more than one code type (e.g., numeric, alphabetic, ASCII, hexadecimal, or binary). Frequently, one of these may be encoded in another. For example, a binary number might be entered in either a numeric or alphanumeric field. The application program must ensure that the code values are legal in both code sets — the entry and display set and the storage set. Note that because modern database managers are very forgiving, the mere fact that the program continues to function may not mean that the data is correct. Data types (e.g., alpha, date, currency) must also be checked. The application itself and other programs that operate on the data may be very sensitive to the correctness of dates and currency formats. Data that is correct by code and data type may still not be valid. For example, a date of birth that is later than the date of death is not valid although it is a valid data type.

Incomplete Error Handling

Closely related to the problem of parameter checking is that of error handling. Numbers of employee frauds have their roots in innocent errors that were not properly handled. The employee makes an innocent error; nothing happens. The employee pushes the envelope; still nothing. It begins to dawn on the employee that she could make the error in the direction of her own benefit — and still nothing would happen.

In traditional applications and environments, such conditions were dangerous enough. However, they were most likely to be seen by employees. Some employees might report the condition. In the modern network, it is not unusual for such conditions to be visible to the whole world. The greater the population that can see a system or application, the more attacks it is likely to experience. The more targets an attacker can see, the more likely he is to be successful, particularly if he is able to automate his attack.

It is not unusual for systems or applications to fail in unusual ways when errors are piled on errors. Programmers may fail to program or test to ensure that the program correctly handles even the first error, much less for successive ones. Attackers, on the other hand, are trying to create exploitable conditions; they will try all kinds of erroneous entries and then pile more errors on top of those. Although this kind of attack may not do any damage at all, it can sometimes cause an error and occasionally cause an exploitable condition. As above, attackers may value their own time cheaply, may automate their attacks, and may be very patient.

Time of Check to Time of Use (TOCTU)

Recently, a user of a Web mail service application noticed that he could "bookmark" his Inbox and return to it directly in the future, even after shutting down and restarting his system, without going through log-on again.

On a Friday afternoon, the user pointed this out to some friends. By Saturday, another user had recognized that one of the things that made this work was that his user identifier (UID), encoded in hexadecimal, was included in the universal record locator (URL) for his Inbox page. That user wondered what would happen if someone else's UID was encoded in the same way and put into the URL. The reader should not be surprised to learn that it worked. By Sunday, someone had written a page to take an arbitrary UID encoded in ASCII, convert it to hexadecimal, and go directly to the Inbox of any user. Monday morning, the application was taken down.

The programmer had relied on the fact that the user was invited to logon before being told the URL of the Inbox. That is, the programmer relied on the relationship between the time of the check and the time of use. The programmer assumes that a condition that is checked continues to be true. In this particular case, the result of the decision was stored in the URL, where it was vulnerable to both replay and interference. Like many of the problems discussed here, this one was first documented almost 30 years ago.

Now the story begins to illustrate another old problem.

Ineffective Binding

Here, the problem can be described as ineffective binding. The programmer, having authenticated the user on the server, stores the result on the client. Said another way, the programmer stores privileged state in a place where he cannot rely on it and where he is vulnerable to replay.

Client/server systems seem to invite this error. In the formal client/server paradigm, servers are stateless. That is to say, a request from a client to a server is atomic; the client makes a request, the server answers and then forgets that it has done so.

To the extent that servers remember state, they become vulnerable to denial-of-service attacks. One such attack is called the Syn Flood Attack. The attacker requests a TCP session. The victim acknowledges the request and waits for the attacker to complete and use the session. Instead, the attacker requests yet another session. The victim system keeps allocating resources to the new sessions until it runs out.

Because the server cannot anticipate the number of clients, it cannot safely allocate resource to more than one client at a time. Therefore, all application states must be stored on the clients. The difficulty with this is that it is then vulnerable to interference or contamination on the part of the user or other applications on the same system. The server becomes vulnerable to the saving, replicating, and replay of that state.

Therefore, at least to the extent that the state is privileged, it is essential that it be saved in such way as to protect the privilege and the server. Because the client cannot be relied on to preserve the state, the protection must rely on secret codes.

Inadequate Granularity of Controls

Managers often find that they must give a user more authority than they wish or than the user needs because the controls or objects provided by the system or application are insufficiently granular. Stated another way, they are unable to enforce usual and normal separation of duties. For example, they might wish to assign duties in such a way that those who can set up accounts cannot process activity against those accounts, and vice versa. However, if the application design puts both capabilities into the same object (and provides no alternative control), then both individuals will have more discretion than management intends. It is not unusual to see applications in which all capabilities are bundled into a single object.

Gratuitous Functionality

A related but even worse design or implementation error is the inclusion in the application of functionality that is not native or necessary to the intended use or application. Because security may depend on the system doing only what is intended, this is a major error and source of problems. In the presence of such functionality,

not only will it be difficult to ensure that the user has only the appropriate application privileges but also that the user does not get something totally unrelated.

Recently, the implementer of an E-commerce Web server application did the unthinkable; he read the documentation. He found that the software included a script that could be used to display, copy, or edit any data object that was visible to the server. The script could be initiated from any browser connected to the server. He recognized that this script was not necessary for his use. Worse, its presence on his system put it at risk; anyone who knew the name of the script could exploit his system. He realized that all other users of the application knew the name of that script. It was decided to search servers already on the Net to see how many copies of this script could be found. It was reported that he stopped counting when he got to 100.

One form of this is to leave in the program hooks, scaffolding, or tools that were originally intended for testing purposes. Another is the inclusion of backdoors that enable the author of the program to bypass the controls. Yet another is the inclusion of utilities not related to the application. The more successful and sensitive the application, the greater the potential for these to be discovered and exploited by others. The more copies of the program in use, the bigger the problem and the more difficult the remedy.

One very serious form of gratuitous functionality is an escape mechanism.

Escape Mechanisms

One of the things that Ken Thompson pointed out is the difficulty maintaining the separation between data and procedure. One man's data is another man's program. For example, if one receives a file with a file name extension of .doc, one will understand that it is a document, that is, data to be operated on by a word processing program. Similarly, if one receives a file with .xls, one is expected to conclude that this is a spreadsheet, data to be operated on by a spreadsheet program. However, many of these word processing and spreadsheet application programs have mechanisms built into them that permit their data to escape the environment in which the application runs. These programs facilitate the embedding of instructions, operating system commands, or even programs, in their data and provide a mechanism by which such instructions or commands can escape from the application and get themselves executed on behalf of the attacker but with the identity and privileges of the user.

One afternoon, the manager of product security for several divisions of a large computer company received a call from a colleague at a famous security consulting company. The colleague said that a design flaw had been discovered in one of the manager's products and that it was going to bring about the end of the world. It seems that many terminals had built into them an escape mechanism that would permit user A to send a message to user B that would not display but would rather be returned to the shared system looking as if it had originated with user B. The message might be a command, program, or script that would then be interpreted as if it had originated with user B and had all of user B's privileges.

The manager pointed out to his colleague that most buyers looked at this "flaw" as a feature, were ready to pay extra for it, and might not consider a terminal that did not have it. The manager also pointed out that his product was only one of many on the market with the same feature and that his product enjoyed only a small share of the market. And, furthermore, there were already a million of these terminals in the market and that, no matter what was offered or done, they would likely be there five years hence. Needless to say, the sky did not fall and there are almost none of those terminals left in use today.

On another occasion, the manager received a call from another colleague in Austin, Texas. It seems that this colleague was working on a mainframe e-mail product. The e-mail product used a formatter produced by another of the manager's divisions. It seems that the formatter also contained an escape mechanism. When the exposure was described, the manager realized that the work required to write an exploit for this vulnerability was measured in minutes for some people and was only low tens of minutes for the manager.

The behavior of the formatter was changed so that the ability to use the escape mechanism could be controlled at program start time. This left the question of whether the control would default to "yes" so that all existing uses would continue to work, or to "no" so as to protect unsuspecting users. In fact, the default was set to the safe default. The result was that tens of thousands of uses of the formatter no longer worked, but the formatter itself was safe for the naïve user.

Often these mechanisms are legitimate, indeed even necessary. For example, MS Word for DOS, a single-user single-tasking system, required this mechanism to obtain information from the file system or to allow the

user access to other facilities while retaining its own state. In modern systems, these mechanisms are less necessary. In a multi-application system, the user may simply "open a new window;" that is, start a new process.

Nonetheless, although less necessary, these features continue to proliferate. Recent instances appear in MS Outlook. The intent of the mechanisms is to permit compound documents to display with fidelity even in the preview window. However, they are being used to get malicious programs executed. All such mechanisms can be used to dupe a user into executing code on behalf of an attacker. However, the automation of these features makes it difficult for the user to resist, or even to recognize, the execution of such malicious programs.

They may be aggravated when the data is processed in an exceptional manner. Take, for example, so-called "Web mail." This application turns two-tier client/server e-mail into three-tier. The mail agent, instead of running as a client on the recipient's system, runs as a server between the mail server and the user. Instead of accessing his mail server using an application on his system, the user accesses it via this middleware server using his (thin client) browser. If HTML tags are embedded in a message, the mail agent operating on the server, like any mail agent, will treat them as text. However, the browser, like any browser, will treat these tags as tags to be interpreted.

In a recent attack, HTML tags were included in a text message and passed through the mail agent to the browser. The attacker used the HTML to "pop a window" labeled "….Mail Logon." If the user were duped into responding to this window, his identifier and password would then be broadcast into the network for the benefit of the attacker.

Although experienced users would not be likely to respond to such an unexpected log on window, many other users would. Some of these attacks are so subtle that users cannot reasonably be expected to know about them or to resist their exploitation.

Excessive Privilege

Many multi-user, multi-application systems such as the IBM AS/400 and most implementations of UNIX contain a mechanism to permit a program to run with privileges and capabilities other than those assigned to the user. The concept seems to be that such a capability would be used to provide access control more granular and more restrictive than would be provided by full access to the data object. Although unable to access object A, the user would be able to access a program that was privileged to access object A but which would show the user a only a specified subset of object A.

However, in practice, it is often used to permit the application to operate with the privileges of the programmer or even those of the system manager. One difficulty of such use is manifest when the user manages to escape the application to the operating system, but retain the more privileged state. Another manifests itself when a started process, subsystem, or daemon runs with excessive privilege. For example, the mail service may be set up to run with the privileges of the system manager rather than with a profile created for the purpose. An attacker who gains control of this application, for example by a buffer overflow or escape mechanism, now controls the system, not simply with the privileges required by the application or those of the user, but with those of the system manager.

One might well argue that such a coincidence of a flawed program with excessive privilege is highly unlikely to occur. However, experience suggests that it is not only likely, but also common. One might further argue that the application programmer causes only part of this problem; the rest of it is the responsibility of the system programmer or system manager. However, in practice, it is common for the person installing the program to be fully privileged and to grant to the application program whatever privileges are requested.

Failure to a Privileged State

Application programs will fail, often for reasons completely outside of their control, that of their programmers, or of their users. As a rule, such failures are relatively benign. Occasionally, the failure exposes their data or their environment.

It is easiest to understand this by comparing the possible failure modes. From a security point of view, the safest state for an application to fail to is a system halt. Of course, this is also the state that leaves the fewest options for the user and for system and application management. They will have to reinitialize the system,

reload and restart the application. While this may be the safest state, it may not be the state with the lowest time to recovery. System operators often value short time to recovery more than long time to failure.

Alternatively, the application could fail to log on. For years, this was the failure mode of choice for the multi-user, multi-application systems of the time. The remedy for the user was to log on and start the application again. This was safe and fairly orderly.

In more modern systems like Windows and UNIX, the failure mode of choice is for the application to fail to the operating system. In single-user, multi-application systems, this is fairly safe and orderly. It permits the user to use the operating system to recover the application and data. However, although still common in multi-user, multi-application systems, this failure mode is more dangerous. Indeed, it is so unsafe that crashing applications has become a favored manner of attacking systems that are intended to be application-only systems. Crash the application and the attacker may find himself looking at the operating system (command processor or graphical user interface [GUI]) with the identity and privileges of the person who started the application. In the worst case, this person is the system manager.

Unsafe Defaults

Even applications with appropriate controls often default to the unsafe setting of those controls. That is to say, when the application is first installed and until the installing user changes things, the system may be unsafely configured. A widespread example is audit trails. Management may be given control over whether the application records what it has done and seen. However, out of the box, and before management intervenes, the journals default to "off." Similarly, management may be given control of the length of passwords. Again, out of the box, password length may default to zero.

There are all kinds of good excuses as to why a system should default to unsafe conditions. These often relate to ease of installation. The rationale is that if the system initializes to safe settings, any error in the procedure may result in a deadlock situation in which the only remedy is to abort the installation and start over. The difficulty is that once the system is installed and running, the installer is often reluctant to make any changes that might interfere with it.

In some instances, it is not possible for designers or programmers to know what the safe defaults are because they do not know the environment or application. On the other hand, users may not understand the controls. This can be aggravated if the controls are complex and interact in subtle ways. One system had a control to ensure that users changed their passwords at maximum life. It had a separate control to ensure that it could not be changed to itself. To make this control work, it had a third control to set the minimum life of the password. A great deal of special knowledge was required to understand the interaction of these controls and their effective use.

Exclusive Reliance on Application Controls

The application designer frequently has a choice of whether to rely on application program controls, file system controls, database manager controls, or some combination of these. Application programmers sometimes rely exclusively on controls in the application program. One advantage of this is that one may not need to enroll the user to the file system or database manager or to define the user's privileges and limitations to those systems. However, unless the application is tightly bound to these systems, either by a common operating system or by encryption, a vulnerability arises. It will be possible for the user or an attacker to access the file system or database manager directly. That is, it is possible to bypass the application controls. This problem often occurs when the application is developed in a single-system environment, where the application and file service or database manager run under a single operating system and are later distributed.

Note that the controls of the database manager are more reliable than those in the application. The control is more localized and it is protected from interference or bypass on the part of the user. On the other hand, it requires that the user is enrolled to the database manager and that the access control rules are administered.

This vulnerability to control bypass also arises in other contexts. For example, controls can be bypassed in single-user, multi-application systems with access control in the operating system rather than the file system. An attacker simply brings his own operating system in which he is fully privileged and uses that in lieu of the operating system in which he has no privileges.

Recommendations

The following recommendation should be considered when crafting and staging applications. By adhering to these recommendations, the programmer and the application manager can avoid many of the errors outlined in this chapter.

1. Enforce all restrictions that are relied on.
2. Check and restrict all parameters to the intended length and code type.
3. Prefer short and simple programs and program modules. Prefer programs with only one entry point at the top or beginning, and only one exit at the bottom or end.
4. Prefer reliance on well-tested common routines for both parameter checking and error correction. Consider the use of routines supplied with the database client. Parameter checking and error correcting code is difficult to design, write, and test. It is best assigned to master programmers.
5. Fail applications to the safest possible state. Prefer failing multi-user applications to a halt or to log-on to a new instance of the application. Prefer failing single-user applications to a single-user operating system.
6. Limit applications to the least possible privileges. Prefer the privileges of the user. Otherwise, use a limited profile created and used only for the purpose. Never grant an application systemwide privileges. (Because the programmer cannot anticipate the environment in which the application may run and the system manager may not understand the risks, exceptions to this rule are extremely dangerous.)
7. Bind applications end-to-end to resist control bypass. Prefer a trusted single-system environment. Otherwise, use a trusted path (e.g., dedicated local connection, end-to-end encryption, or a carefully crafted combination of the two).
8. Include in an application user's privileges only that functionality essential to the use of the application. Consider dividing the application into multiple objects requiring separate authorization so as to facilitate involving multiple users in sensitive duties.
9. Controls should default to safe settings. Where the controls are complex or interact in subtle ways, provide scripts ("wizards"), or profiles.
10. Prefer localized controls close to the data (e.g., file system to application, database manager to file system).
11. Use cryptographic techniques to verify the integrity of the code and to resist bypass of the controls.
12. Prefer applications and other programs from known and trusted sources in tamper-evident packaging.

Domain 7
Operations Security

Operations security is used to identify the controls over hardware, media, and the operators with access privileges to any of these resources. Operations security involves the administrative management of all types of information processing operations, the concepts of security of centralized as well as distributed operations, the various choices for operations controls, resource protection requirements, auditing operations, monitoring, and intrusion detection.

To obtain a complete understanding of "operations security," it is necessary to look at it from a historical perspective. In the 1960s and 1970s, the processing of information took place in one central location and was controlled by only a handful of people. The term "data center" referred to this central location, while "operations" referred to the day-to-day data processing that occurred within the data center. The "operators" included the experienced, knowledgeable staff who performed the day-to-day operation of the computers.

Although data center operations are still in existence today, the term "operations security" now refers to the central location of all IT processing areas, whether it is called a data center, server room, or computing center.

This domain focuses on the security needs for this type of information system operations — that is, the needs of the data centers, server rooms, computer rooms — the back-end locations where information system processing is accomplished, and the personnel who have privileged access to the resources in these areas.

Operations: The Center of Support and Control

Kevin Henry, CISA, CISSP

The operations security domain encompasses all of the other domains of information systems security. This domain is where theory and design meet the reality of daily operations. Ideas, once only a concept, become a critical part of an organization's infrastructure. The policies and procedures developed in a conference room or through a rigorous review and approval process are enacted for the benefit and protection of the organization, the employees, and the various other stakeholders.

Operations entails control, procedures, and monitoring. It involves support for users, communication with outside business partners, emergency actions and response, and in many cases 24-hour vigilance.

There are several areas of operations security that we will look at in this chapter: the importance and types of controls, the role of production support, the use of good supervision, and the protection and continuity of business operations through backups, maintenance, and incident response.

The operations group has evolved over the years from a console-based mainframe administration group to the widespread network administration techies that provide critical support for users halfway around the globe. However, regardless of the environment, whether mainframe, single office, or multinational and multiple platform organizations, the key elements are the same. The operators (for the most part I will include only network administrators in this group) have high-level access and the ability to make or break many companies by virtue of this level of access. Operators execute tasks that often require some of the highest levels of authority on the system. They can see, touch, and alter almost anything. They are required to make decisions in pressure situations that may affect the ability of the organization to continue normal or alternative business operations.

The importance of an understanding of security and best practices is crucial for operations personnel. Operators need to be aware of availability, and their critical role in keeping systems running. They need to understand the risks of disclosure and the need to enforce confidentiality, which includes the concepts of privacy, secrecy, and trust (or confidence). Organizations are under increasing pressure to maintain the privacy of individuals — whether they are customers or employees. Many organizations are either required to, or have chosen to, declare their privacy policy. This is a meaningful statement and the operations group needs to be aware of the risks and potential liabilities to the organization if these policies are violated or disregarded. An organization often depends on the confidence of its customers. A foolish or negligent act — or even a perceived breach of this confidence — may impair the business activity of the organization for years to come. The final part of the information security triad is integrity. Integrity in this instance includes proper, accurate, or reliable processing, change control, storage, and behaviors. Often an operations group may be bound by Service Level Agreements (SLAs) and a failure to provide the contracted level of service prescribed in the SLA can affect the respect, reputation, and even financial viability of an operations group.

Many organizations today outsource operations and network admin functions. This chapter does not deal extensively with outsourcing; however, the concepts and requirements are in many ways similar. Outsource suppliers need to respect and honor contractual obligations and provide the required level of service and support. Suppliers may need to provide more than basic functionality — they may need to provide advice, warnings, recommendations, expertise, and value-added services. They may be the source of hardware, soft-

ware, and applications support, but moreover they may be providing the expertise and technical skills an organization relies on. No doubt this is a responsible and challenging role.

The firm that has decided to choose an outsourcing solution is relying on the strength of another company to provide the support and service it requires. This decision may have been based on a need for expertise the firm did not have in-house; it may have been a financial decision; it may have been in response to an immediate need that could not be provided through other channels. Whatever the reason for choosing an outsource solution, the organization is under the same pressure it would be if it was an in-house support group — that is, ensuring that the promised services are delivered and that the services meet the cultural, operational, and security requirements of the organization.

Controls

We will take a look at types of controls and how they may be used in an operations setting. First of all, it is important that controls are seen as a tool to be used prudently and reasonably. A control is a restriction or restraint. Moreover, a control is required to be used as a response to a risk. Once a risk has been identified — that is, we have established what the threats are and the likelihood that these threats will become a reality (or exposure) — then we need to set up controls to respond to these risks. A control may try to prevent a risk or it may be a way to detect a problem.

Preventive Controls

An ounce of prevention is worth a pound of cure. A preventive control is designed to stop an event from happening. It is a type of proactive control that relies on the establishment of procedures and tools that, hopefully, will catch and stop an adverse event from affecting the organization. There are many types of preventive controls and they are continuously changing as the risk environment, threats, cultures, markets, and regulatory conditions change. For example, a programmer who includes an edit in the data entry fields of an online system has implemented a preventive control.

Detective Controls

A detective control recognizes that some untoward activity either has taken place or is taking place, and institutes mechanisms to report, mitigate, limit, or contain the damage. It may also include logging or tracking functionality to record the details of the activity for use in subsequent analysis or possible disciplinary action. Detective controls include reviews and comparisons, audits, account reconciliations, input edit checks, checksums, and message degests.

Corrective Controls

Corrective controls are used when an event has caused some damage and it is necessary to restore or reconstitute operations to a normal or alternative operational state. They may be procedures for network isolation, restriction of traffic, forced lockout of most users, etc.

Compensating Controls

Sometimes no other control is possible. For example, we would not usually grant a user root-level or high-level access to a system. This principle of least privilege — granting a user only the minimal amount of access, authority, or privilege required to do his or her job — is an effective control.[1] It often prevents misuse, accidental errors, and curiosity-based discoveries, and mitigates many risks created by poor access control. However, in the case of network administrators and operators this control is not possible. Such personnel require a high level of access to run the utilities, execute jobs, change configurations, etc., that are a part of their routine duties. Because of this, we require compensating controls, controls that compensate or address a weakness in the control infrastructure that cannot be eliminated using normal controls. Compensating controls often use greater levels of supervision, monitoring, review of activity logs and separation of duties to prevent or detect the types of errors that may come from a weaker control environment.

The following control types are methods of implementing the types of controls listed earlier. An administrative control, for example, may be preventive, deterrent, or detective, depending on whether it is designed to be proactive or reactive. It may also be corrective where it sets forth escalation procedures and incident response programs.

Administrative

Administrative controls, often called "soft controls," are procedures and policies to provide direction and declare intent to users and affected personnel. Examples of administrative controls include change control, user registration, visitor logs, hiring and termination practices, punishment for failure to comply, roles, responsibilities and job descriptions, and privacy statements.

Technical or Logical

These types of controls are "hard" or functional controls, often depending on the use of tools, software, or hardware to restrict access, limit capabilities, or prevent virus infections, for example. A preventive technical control may be a firewall, or a detective control may include an intrusion detection system.

Physical

Physical controls are extremely important in this domain. Operators have responsibility for the core computing platforms and equipment used by the organization. Unauthorized access to these areas may result in catastrophic loss for an organization. All steps must be taken to protect equipment from damage — environmental (lightning, dust, smoke, extreme humidity or temperature conditions), utility-based (gas, water, sewer, or electrical problems), disaster (fire, flood, or structural failure), and man-made (vandalism, accidental damage). Physical controls include locking doors and telephone equipment closets, installing fire detection and suppression equipment, having uninterruptible power supplies and surge protectors and proper installation locations. The principle of separation of duties also applies to segregating the operations staff from other staff (especially programmers) so that no one can usurp the normal workflow procedures and the checks and balances that were established.

Documentation

One of the most important resources an operations department has is knowledge. It is remarkable therefore how many organizations do not have adequate documentation. Documentation is a key to understanding, maintaining, and reacting to system activities. When we look at incident response later, one of the key factors in mitigating the damage from an incident is to recognize that something is happening. In far too many cases an untoward event is not noticed in a timely manner just because no one knew what "normal" was. They had no record of usual or unusual activity, or if they did, no one looked at it, with the result that an attack or error was allowed to continue much longer than it should have.

When auditing an operations center, one of the first items reviewed should be the documentation of the systems. Where is it kept? Is there a copy off-site? Can it be accessed easily in a disaster? Is it up to date? Does it describe the systems? Does it show the interaction and interdependencies between systems? Does it show normal processing flows and does it contain lists of error codes and proper responses to errors?

Some of the documentation that must be provided includes inventory of equipment, location and configuration of hardware, networks, communications, storage, and support equipment. One firm recently had a major shutdown that lasted for several hours because an electrical circuit-breaker tripped and no one was able to find the electrical distribution panel that supplied the equipment.

A past incident log is often an excellent resource for an organization. It lists system failures, the actions taken, and people involved to correct the failures. Because certain failures may happen only occasionally and the same people may not be involved the next time there is a failure, an available listing of previous incidents and corrective procedures may dramatically reduce the time needed to repair this later failure. This document is also a valuable tool for the production support group, as we will review later in this chapter.

Operations

The Operations staff is responsible for the day-to-day operation and maintenance of a system. Whether the system is mainframe, client/server, PC based, or stand-alone, there needs to be personnel who are knowledge-

able about the system to ensure it is functioning properly, to perform maintenance and backup routines, upload patches and new configuration files, and schedule jobs, maintenance, and upgrades. These tasks may be performed by one group or a series of groups, depending on the size of the organization, the skill level of the staff, the risk involved, and the complexity of the network. Ideally, there still needs to be an exact series of checks and balances to ensure that all work is being done, that backups are performed (it is surprising how many times I have found instances where the backups encountered an error and had not run for several days and no one noticed)

Roles and Responsibilities within the Operations Area

The Operator

The operator is the person whose finger is on the pulse of the system. He or she is responsible for daily operations of the systems and applications, performing the routine maintenance work, and monitoring the system for failures, exceptions, and often balancing completed job runs to ensure correct completion.

The Scheduler

The scheduler's role in many organizations is to set up and coordinate jobs in preparation for execution. The scheduler is the person usually responsible for exceptional job runs or running tasks out of the ordinary job flow. The separation of scheduling and operations tasks allows a double check of the duties of the scheduler and, quite often, the scheduler is also tasked with double-checking the work of the operations group. It is imperative that all exception processing is documented and reviewed. When a job is run as an "override" or exception, the job may also need to be removed from the normal job stream so that it does not continue to run. All exceptions need to be submitted for approval and have backout or recovery procedures. A person knowledgeable about the exception should also be on call to ensure that recovery procedures can be enacted in the event of a failure.

The Librarian

The librarian is responsible for maintaining the various media that are entering or leaving production. Tapes, microfiche, CDs, DVDs, and reports may be passed between departments, business partners, regulatory agencies, clients, or vendors. The librarian is responsible to ensure that discarded media do not contain sensitive information, keeping an inventory of the various media and protecting the organization from corrupt or contaminated media. Distributing backup tapes to offsite storage and recovering aged backups for reuse are important tasks of the librarian. Finally, the librarian is usually responsible for moving updated programs and accompanying documentation into production, as one of the final steps in the change control process.

The Help Desk

One of the most visible activities of an operations group is the help desk, which in many cases provides a first-level support for the users. Often it is backed up with a second tier of support by applications or systems experts who respond to problems encountered that are beyond the skill of the help desk personnel or would require more time. The help desk is often the front line between the users and the information technology department. The responsiveness, availability, and friendliness of the help desk staff will often affect the overall attitude of the users to the IT department. Whether the users like or dislike systems and applications may be influenced by their interaction with the help desk. For that reason, continuous supervision of help desk functions should be utilized to gauge the attitude of the users and whether they feel that the help desk personnel are knowledgeable, helpful, and responsive.

The help desk requires specific training in social engineering. This department has tremendous power and privilege, and is often a target of manipulation by internal and external customers. One of the easiest methods of gaining unauthorized access to systems or data can be through cultivating a "friendship" with the help desk personnel. Access also may be gained through intimidation or coercion of help desk personnel and "bullying" them into providing an exception to the normal rules or procedures. A help desk is sometimes staffed by fairly low-paid and inexperienced personnel; oftentimes they are supporting personnel that they will never meet and at odd hours when managers or other experts may not be readily available. Therefore, care must be taken to set up procedures and workflows to assist the help desk personnel in executing their duties in a secure manner. If a person requires or demands some form of exception to the rules, the manner of approving this must be

established so that the help desk personnel are not forced or persuaded into breaking policy and jeopardizing operations.

One of the most common calls to a help desk is for password resets. This is a critically problematic area. Who is on the other end of the line? And how do we know that the person requesting the password reset is actually the true owner of the ID? Especially if the password is for an ID with high-level access, some form of controls must be set up to ensure that only the rightful owner of that ID can gain a password reset.

The help desk is often one of the last to know about a change to an application or system. This causes them grief when they begin to receive calls about an application they know nothing about. Therefore, help desk managers should be a part of all change control workflow so that they can ensure their staff is notified and trained on the new system prior to implementation. During a major revision to a system, it is good to have some applications or systems experts on call or even working in the help desk area to assist with problems and other questions.

All calls to a help desk should be logged and the logs reviewed regularly. Review of these logs may indicate problem areas or the need for training users or revising procedures to reduce repeated calls. This can also be put into a knowledge-based system to assist in answering future calls or in setting a menu option on an Integrated Voice Response (IVR) system. A help desk should also have a good communications system through phone and e-mail, including answering queues in case of high-traffic loads, and the ability to take messages instead of users reaching a busy or extended on-hold waiting period.

Production Support

Often closely related to the help desk function is a production support group. This group may operate as a second tier to the help desk, handling the production failures, user problems, and emergency fixes to applications. This group needs to be knowledgeable in systems, applications, programming, networks, security, and business unit requirements. Production support is often one of the first groups to learn about problems with applications, user interfaces, and external threats. In the event of a failure, production support should always review the actions taken by the response team. Thorough analysis may lead to better responses in the future, changes to procedures, but most importantly as a double check to detect errors in the recovery process. There have been several documented cases where an error made in the recovery process after hours should have been caught the following morning by production support, and yet, because this crucial double check was missing, it led to the failure of the entire corporation.

Production support is closely linked with quality assurance. When a change to an application, change to configurations, or new network connections are about to take place, production support should be aware of the changes and possibly review the changes to ensure that they are effective, complete, and follow organizational standards.

Monitoring of system activity is an important role of a production support group. Whereas the operators review at a level of job completion, error codes, etc., the production support personnel need to review CPU, bandwidth, and memory usage. Closely monitoring these activities may allow better forecasting of future resource needs so that equipment can be installed before availability becomes a concern, and some applications that are on the verge of failure due to insufficient resources may be provided additional support prior to a full-scale production failure. This data also assists in the scheduling of jobs so that production and maintenance windows can be maximized for ideal efficiency.

Incident Response

In the event of a system, application, communication, or peripheral component failure, the operations staff is commonly the first group to know of the failure. As mentioned before, this requires careful monitoring of network activity so that an abnormal condition is noticed as rapidly and identified as accurately as possible. Once identified, a proper and effective response is often detailed in procedural documentation. This may require notification of other departments, capturing of event information (for future analysis or forensic investigation), the alerting of key personnel, or the containment of the event through shutdowns or isolation.

Many operations are migrating toward automated alarm reporting or lights-out operations. These remove the reliance on the operators to be present or vigilant to detect abnormalities. These automated alerts may indicate anything from environmental problems such as fire or temperature, to network or hardware failures. These alarms need to be tested on a regular basis to ensure that they are functioning correctly and that they will alert the proper people. Often the call pattern for the alarm does not get changed when the personnel responsible for answering the alarm changes jobs.

All incidents should be documented so that analysis of the event can be performed. This will also permit the organization to learn from the event and establish new policies, countermeasures, or training to prevent future incidents.

Although operations staff may be familiar with recovery procedures, all recovery should be performed under the direct, careful supervision of skilled staff. This is similar to a medical setting where each person knows his or her limitations and a nurse, despite knowing the correct response, does not perform the responsibilities of a doctor. This allows checks and balances to prevent errors or omissions, or in some cases perhaps even malicious activity on the part of operations personnel.

Escalation procedures and guidelines should also be established. These will provide direction for operations staff about when and how to notify higher management of incidents. In most cases, it is best to notify too early rather than too late!

If the event is a major failure that will require extended recovery procedures, the operations room may become extremely busy and stressful. It is good to have conference rooms and communications set up nearby to permit the coordination of the recovery procedures without having overcrowded and poorly communicated facilities.

The operations group should also be represented on the Business Continuity Planning team. This team is responsible for continuity of business operations or recovery of operations in the event of a major failure to normal operations. The operations group should be knowledgeable about BCP plans and their role in a disaster. They also need to know the corporate priorities for recovery operations in the event that more than one system, application, or department is affected.

Supervision

Supervision is one of the most important factors in preventing, detecting, and mitigating errors, malfeasance, or other types of violations of policy, procedure, and operations. Because operations personnel have elevated authority and access to a system, they need extra oversight as a compensating control for this vulnerability. Quite often, many administrator and operator positions are considered entry-level jobs and the people in those positions may not be familiar with corporate policy, culture, loyalty, and regulations. They need frequent review and training to assist them in addressing their tasks securely and effectively. Because much of the effort for an operations group takes place after hours and during times of reduced network usage, the manager must also be prepared to attend the workplace and be available during off hours. This includes performing tests and drills after hours as well — fire, emergency response, network attack, etc.

Summary

Operations can be described as the heartbeat of most organizations today. For this reason, it requires careful maintenance, oversight, training, and coordination. When all of these factors are addressed, this department can be relied on to provide support and impetus for the organization — resulting in reliable processing, secure data handling, and the confidence of business units, business partners, users, shareholders, and regulatory groups.

Note

1. The author also likes to incorporate the condition of timing into the concept of least privilege — that is, that the user is granted the minimum amount of rights necessary to do his or her tasks for the shortest possible time.

128

Why Today's Security Technologies Are So Inadequate: History, Implications, and New Approaches

Steven Hofmeyr, Ph.D.

They grab headlines as they cut a wide swath of destruction through corporate America: viruses, worms (such as Code Red and Nimda), and hackers. The unfortunate fact is that even in organizations with extensive deployment of firewall, encryption, and intrusion detection systems (IDS), attacks still occur with alarming frequency. According to a Computer Security Institute/FBI survey of Fortune 1000 organizations that have suffered attacks, 91 percent had deployed firewalls and 61 percent had installed intrusion detection systems.

So, it is evident that although they provide some initial layers of protection for corporate systems, today's security tools have a distressing tendency to be several steps behind the latest exploits. This chapter explains why security technologies have evolved the way they have and describes the ways in which security systems need to adapt and change to meet the new demands of corporate information protection in the post-September 11 world.

Historical Perspective

Security for the first isolated mainframes focused primarily on physical access and the authentication and control of users. Experts believed that a provably correct security system could be built, based on the notion of a security kernel; that is, core security code that was verifiably secure. Confidence in this formal methods approach was so strong that researchers declared in 1973 that, "It is our firm belief that by applying these principles we can have secure shared systems in the next few years."[1] In the government's 1983 Orange Book, the most secure system is one that uses formal methods to prove the integrity of a "trusted code base." But these efforts failed because it is not possible to build a nontrivial, provably correct security system, any more than it is possible to write bug-free code.

In addition to security kernels, security teams in those days relied on monitoring user behavior. Audit systems collected extensive logs of user actions that human experts scanned periodically for potential threats. The emphasis was on accountability rather than on timely detection: if a compromise was detected, it was, by definition, an insider job. In the military/government context in which most computing took place, knowing which insiders were involved was key because they represented an ongoing threat to the organization.

With the increasing use of private networking, as well as the advent of the Arpanet and its evolution into the Internet in the late 1980s, it became possible for outsiders to penetrate computer systems. In addition, the interconnectedness of networked computers created a viable environment for new automated threats such as

worms. The most famous of these early automated threats was the Morris worm, which took down 25 percent of the Internet in 1988.

Security responses to these new threats continued to rely heavily on human expertise but there was a growing shift toward the network or perimeter, and away from the host, with such technologies as firewalls, which restrict network traffic, and network intrusion detection systems (NIDs), which scan network traffic for signatures of known attacks. However, these technologies are severely limited: firewalls cannot protect vulnerable applications that are legitimately accessed through the firewall, and NIDs suffer from notoriously high rates of false alarms and can only detect attacks already known to the signature writers.

Finally, another major source of security problems emerged with the advent of the desktop computer, which proved a fertile environment for viruses. Security solutions for protection against viruses focused on the host computer itself, in the form of anti-virus (AV) software. AV software maintains a database of virus signatures and scans files to determine if any are infected with known viruses. This technology is similar in principle to NIDs that use signatures and consequently has similar limitations; for example, it cannot detect new types of viruses. However, it is still successful at increasing the security of the desktop — the adoption of AV technology on the desktop is almost universal.

The Ever-Changing IT Landscape

Of course, the number of computers connected to the Internet continues to grow at a tremendous rate, and with this growth comes a dramatic increase in the numbers and types of threats. In particular, automated threats such as worms and e-mail viruses are on the rise. The notorious ILOVEYOU virus in 2000 is estimated to have affected upward of 10 million users and, more recently, the Code Red worm in 2001 infected over 150,000 systems in a mere 14 hours, resulting in billions of dollars in damages. In addition, the large number of vulnerable desktops connected to the Internet has encouraged distributed denial-of-service (DDoS) attacks, in which a collection of individual machines targets a single victim, bombarding it with traffic.

Not only are the numbers of connected computers increasing, but the patterns of connectivity are also changing. As more business is transacted over the Web, the boundaries between the "trusted" internal network and external networks are dissolving, requiring increasing use of encryption to protect communications in potentially hostile environments. Consequently, network-based security systems are becoming obsolete because they are predicated on the notion of a perimeter and need to scan the contents of network packets, which is not possible if the packets are encrypted.

In addition, today's IT environments are becoming exponentially more complex, incorporating a wider range of applications, middleware, and integration software. There are simply not enough experts to manage such complex systems, and experts cannot react fast enough to deal with the problems seen today. Meanwhile, few businesses today are as concerned about accountability as government organizations have been in the past. With mission-critical corporate data residing in vulnerable enterprise systems, today's corporations place a premium on prevention of attacks, rather than on catching or prosecuting the perpetrators after the fact.

From Human Expertise to Machine Intelligence

In response to these trends, security solutions are moving away from the network and back onto the host. Securing each host computer individually does not depend on defining a perimeter, and all processing of information can be done after traffic is decrypted at the host. Although this move back to the host is promising, other "old" ideas hold less potential. For example, just as in the days of mainframe computing, the security community is gravitating once again to the idea of "trusted" or "secure" systems, this time with a focus on trusted operating systems. Such operating systems attempt to put all applications and users into specific compartments and then limit functionality based on those compartments. However, if trusted computing could not be made to work in the single-machine mainframe era, it can hardly be expected to succeed now, in today's world of highly complex, interconnected, and vulnerable systems. The task of designing and verifying a set of policies for every variation of every application and operating system for any conceivable user requirement is, quite simply, infeasible.

What, then, is the answer? The security community must embrace a fundamental change in the way security systems are designed and built. A new security paradigm is needed, one based on machine intelligence, not human expertise. Security systems need to be self-aware, adaptive, and autonomous. They also need to focus

on prevention rather than just detection and source identification. Key to achieving these goals is the use of anomaly detection methods. With these methods, the computer security system observes the normal behavior of the computer to be protected, learns the profile of that normal behavior, and subsequently detects deviations (anomalies) from the profile that are indicative of attacks. The use of anomaly detection methods is the only way of detecting entirely new attacks; knowledge-based approaches that require knowing what the attacks look like beforehand will always fall short.

To ensure accuracy and avoid high false-alarm rates with anomaly detection, the system must monitor the appropriate characteristics. These characteristics should lead to a compact and stable profile under normal conditions but result in clear deviations from the normal profile during attacks. A poor choice of characteristic is exemplified by early research into anomaly detection that focused on user behavior. Users are inherently variable and thus any anomaly detection system profiling their behavior will generate masses of false alarms. A much better characteristic is paths through program code. If the program being profiled is a server, then its behavior is likely to be very consistent because servers repeatedly perform a few tasks and those tasks have predictable, regular code paths. The behavior of the server program is still driven by user behavior but that behavior is aggregated across many individuals and restricted through the program to a constrained, well-defined set of options.

Every anomaly detection system must have a training phase, during which the anomaly detection system develops a profile of normal behavior. In general, each system to be protected will exist in a different environment, with different configuration requirements and different usage patterns. These differences mean that it is essential for the anomaly detection system to learn the normal profile within each specific local environment. Moreover, even within a single system, the environment will vary over time. New software is added, old software is patched, configurations are changed, machines are removed or added, etc. Every time the system changes it has an effect on the normal profile of the system. Therefore, a key requirement of any useful anomaly detection system is the ability to adapt autonomously to changes in the environment. For example, each time a profiled program is updated to a more recent version, the anomaly detection system should "relearn" the normal behavior. The more similar the program's new behavior is to the old behavior, the more rapid the relearning; that is, the anomaly detection system does not need to throw away all the information it has previously learned.

Of course, the danger in making a system self-aware and more intelligent is that it becomes more difficult to understand what the system is doing and why. This is why any good anomaly detection system should have a comprehensive set of secondary analytics — additional information gathered about the anomaly that is not essential to detecting the anomaly. For example, it may be that anomalies are detected by simply monitoring program code paths, but when an unusual code path is reported, the network connections occurring at the time are also reported, to give a human operator more understanding of the anomaly. Secondary analytics can also be enhanced by the use of signatures, which can help humans understand the attacks through categorization of anomalies. This is different from traditional signature-based systems because the signatures are not used for detection, but only for informing human operators. In this way, the limitations and pitfalls of the signature-based approach are avoided.

Learning from History

A study of the history of computer security yields some guidelines that should be adhered to by any designer of a security technology for today's open, distributed, and highly interconnected systems.

- *Do not hard-code knowledge.* When designing security systems, people are often tempted to hard-code in their specific expertise about the problem at hand. For example, the designer might fervently believe that an application should never carry out a particular kind of behavior, and so hard-code in a restriction on that behavior. Succumbing to such temptations is shortsighted, destroys flexibility and adaptability, and is subject to human error and bias. It is well known in programming that hard-coding solutions to specific instances of a problem is a bad idea; the same applies to security.
- *Avoid the central weak point.* Designers like to have a system in which all information is gathered centrally at one point so that a human operator can control and monitor a large number of nodes from one location. This in itself is not a bad idea. However, placing too much dependence on the central location is. There is a trend today toward centralized correlation and analysis. Data is taken in from various sensors around the network, then analyzed and correlated in one location. If that one location should be compromised, then the entire security system will fail. The sensors themselves should be able to

react autonomously and independently so that even if the central location is compromised, they can continue to protect the network. And if correlation from multiple sensors is required, then this is more robust if done in a distributed peer-to-peer fashion.

- *There is no such thing as a trusted code base.* The resurgence of trusted operating systems is predicated on the belief in a trusted code base. In reality, there is no such thing. Only the most trivial, useless bit of code will be provably secure. Designers should operate under the assumptions that any part of the system is insecure and could be compromised. For example, across a set of distributed sensors, it must be assumed that some of them could be compromised or be in error. However, it can reasonably be assumed that not all of them will be compromised immediately, and so solutions can be designed that rely on voting and other forms of Byzantine agreement to isolate compromised sensors.
- *Profile actions, not data.* A detection system should monitor actions that are a consequence of an application receiving data, and not the data itself. Data, such as network packets, can be forged to look anomalous and flood a data-monitoring detection system with spurious alarms. Actions, by contrast, cannot be forged; if an action is successful, it means the system is truly vulnerable. Furthermore, it is difficult for a detection system to interpret data in exactly the same way as the application it is protecting. Errors in data interpretation are exploited by attackers to evade a detection system; for example, an attack can be hidden in fragmented packets if an NIDs does not properly reconstruct entire packets. Monitoring actions after the data has been interpreted by an application avoids this problem.
- *Do not compromise functionality for security.* A common mistake made when designing security systems is to focus on security measures, without regard to how those measures impact the functionality of the system being protected. The consequence is overly restrictive security systems. The problem with such overly restrictive systems is that legitimate users, in addition to attackers, find ways around the system. A good example is the firewall that restricts all access to and from the Internet, allowing only http traffic. This is sufficiently restrictive that nonmalicious users design their applications to run on top of http so that they can pass through firewalls. Consequently, more and more traffic is now running on top of http and the firewall is progressively more useless. Security systems must be designed with a clear regard for how they compromise functionality.

Summary

Today's computing world will never replicate the simplicity and central control of early mainframe environments; for better or worse, enterprise networks today are highly complex, interconnected, and vulnerable to automated and human threats. In moving away from the focus on accountability and the over-dependence on human expertise of past approaches, it is essential to embrace an automated, flexible, and highly adaptive approach — one that applies the best lessons from the past to consistently and reliably protect computing assets in the future.

A cornerstone of this new approach is anomaly detection systems that run on the host computers. These systems must be able to operate autonomously, monitoring appropriate characteristics to accurately profile normal and detect attacks, and using automated responses to stop attacks before they do harm. They should be able to adapt to legitimate changes with minimum human intervention. In addition, these anomaly detection systems should have comprehensive secondary analytics, including signature-based interpretation of anomalies. Of course, such systems will not guarantee security but, if implemented correctly, will raise security to a new level, taking a step ahead in the constant arms race between defender and attacker.

Information Warfare and the Information Systems Security Professional

Jerry Kovacich

Although the Cold War has ended, it has been replaced by new wars. These wars involve the use of technology as a tool to assist in conducting information warfare. It encompasses electronic warfare, techno-terrorist activities, and economic espionage. The term "information warfare" is being referred to as the twenty-first century method of waging war. The U.S., among other countries, is in the process of developing cyberspace weapons.

These threats will challenge the information security professional. The threats from the teenage hacker, company employee, and phreakers are nothing compared with what may come in the future. The information warfare warriors, with Ph.D.s in computer science backed by millions of dollars from foreign governments, will be conducting sophisticated attacks against U.S. company and government systems.

THE CHANGING WORLD AND TECHNOLOGY

The world is rapidly changing and, as the twenty-first century approaches, the majority of the nations of the world are entering the information age as described by Alvin and Heidi Toffler. As they discussed in several of their publications, nations have gone or are going through three waves or periods:

- The agricultural period, which according to the Tofflers ran from the time of humans to about 1745.
- The industrial period, which ran from approximately 1745 to the mid-1900s.
- The information period, which began in 1955 (the first time that white-collar workers outnumbered blue collar workers) to the present.

Because of the proliferation of technologies, some nations, such as, Taiwan and Indonesia, appear to have gone from the agricultural period almost directly into the information period. The U.S., as the information technology leader of the world, it is the most information systems-dependent country in the world and, thus, the most vulnerable.

What is meant by technology? Technology is basically defined as computers and telecommunications systems. Most of today's telecommunications systems are computers. Thus, the words telecommunications, technology, and computers are sometimes synonymous.

Today, because of the microprocessor, its availability, power, and low cost, the world is building the Global Information Infrastructure (GII). GII is the massive international connections of world computers that will carry business and personal communications, as well as those of the social and government sectors of nations. Some contend that it could connect entire cultures, erase international borders, support cyber-economies, establish new markets, and change the entire concept of international relations.

The U.S. Army recently graduated its first class of information warfare hackers to prepare for this new type of war. The U.S. Air Force, Army, and Navy have established information warfare (IW) centers. Military information war games are now being conducted to prepare for such contingencies.

INFORMATION AGE WARFARE AND INFORMATION WARFARE

Information warfare (IW) is the term being used to define the concept of twenty-first century warfare, which will be electronic and information systems driven. Because it is still evolving, its definition and budgets are unclear and dynamic.

Government agencies and bureaus within the Department of Defense all seem to have somewhat different definitions of IW. Not surprisingly, these agencies define IW in terms of strictly military actions; however, that does not mean that the targets are strictly military targets.

Information warfare, as defined by the Defense Information Systems Agency (DISA) is "actions taken to achieve information superiority in support of national military strategy by affecting adversary information and information systems while leveraging and protecting our information and information systems." This definition seems to apply to all government agencies.

The government's definition of IW can be divided into three general categories: offensive, defensive, and exploitation. For example:

- Deny, corrupt, destroy, or exploit an adversary's information or influence the adversary's perception (i.e, offensive).
- Safeguard the nation and allies from similar actions (i.e., defensive), also known as IW hardening.

- Exploit available information in a timely fashion to enhance the nation's decision or action cycle and disrupt the adversary's cycle (i.e., exploitative).

In addition, the military looks at IW as including electronic warfare (e.g., jamming communications links); surveillance systems, precision strike (e.g., if a telecommunications switching system is bombed, it is IW); and advanced battlefield management (e.g., using information and information systems to provide information on which to base military decisions when prosecuting a war).

This may be confusing, but many, including those in the business sector, believe that the term *information warfare* goes far beyond the military-oriented definition. Some, such as Winn Schwartau, author and lecturer, have a broader definition of IW and that includes such things as hackers attacking business systems, governments attacking businesses, even hackers attacking other hackers. He divides IW into three categories, but from a different perspective. He believes that IW should be looked at by using these categories:

- *Level 1: Interpersonal Damage*. This is damage to individuals, which includes anything from harassment, privacy loss, and theft of personal information, for example.
- *Level 2: Intercorporate Damage*. This is attacks on businesses and government agencies, which includes such things as theft of computer services and theft of information for industrial espionage.
- *Level 3: International and Intertrading Block Damage*. This relates to the destabilization of societies and economies, which includes terrorist attacks and economic espionage.

There seems to be more of the traditional, business-oriented look at what many call computer or high-tech crimes. By using the traditional government view of information warfare, the case can be made for Level 2 and Level 3 coming closest to the government's (i.e., primarily the Department of Defense) view of information warfare.

Then, there are those who tend to either separate or combine the term information warfare and information age warfare. To differentiate between these two terms is not that difficult. By using the Tofflers' thoughts about the three waves as a guide, as previously discussed information age warfare can be defined as warfare fought in the information age, with information age computer-based weapons systems, primarily dominated by the use of electronic and information systems. It is not this author's intent to establish an all-encompassing definition of IW, but only to identify it as an issue to consider when discussing information and information age warfare. Further, those information systems security professionals within the

government, and particularly those in the Department of Defense, will probably use any definition as it relates to military actions.

Those information systems security professionals within the private business sector (assuming that they were interested in using the term information warfare) would probably align themselves closer to Mr. Schwartau's definition. Those information systems security professionals within the private sector who agree with the government's definition would probably continue to use the computer crime terminology in lieu of Mr. Schwartau's definition.

The question arises if information warfare is something that the nongovernment business-oriented information systems security professional should be concerned about. Each information systems security professional must be the judge of that based on his or her working environment and also on how he or she see things from a professional viewpoint. Regardless, information warfare will grow in importance as a factor to consider, much as viruses, hackers, and other current threats must be considered.

The discussion of information warfare can be divided into three primary topics:

- Military-oriented war.
- Economic espionage.
- Technology-oriented terrorism (i.e., techno-terrorism).

MILITARY-ORIENTED WAR

The military technology revolution is just beginning. In the U.S., the military no longer drives technology as it once did in the 1930s through the 1970s. The primary benefactor of early technology was the government, primarily the Department of Defense (DoD), which in those early days of technology (e.g., ENIAC) the DoD had funding and the biggest need for technology. This was the time of both hot wars and the Cold War. The secondary benefactor was NASA (e.g., space exploration).

Between these government agencies, and to a lesser extent others, hardware and software products were developed with a derivative benefit to the private, commercial, and business sector. After all, these were expensive developments and only the government could afford to fund such research and development efforts. Today, the government has taken a back seat to the private sector. As hardware and software became cheaper, it became more cost effective for private ventures into technology research, development, and production. Now, technology is being business driven. Computers, microprocessors, telecommunications, satellites, faxes, video, software, networks, the Internet, and multimedia are just some of the technologies that are driving the information period. In the U.S., more than 95% of military communications are conducted over commercial systems.

In the next century, an increased use of technology will be used to fight wars. Stealth, surveillance, distance, and precision strike will be key concepts. As information age nations rely more and more on technology and information, these systems will obviously become the targets during information warfare.

The information warfare techniques are necessary due, in part, to economics. Every economics student learns about the "guns or butter" theory. It is believed that society cannot afford to adequately fund those programs that support society, while at the same time provide for a strong military structure. As the world continues to increase competitively the resources, for example, funding for expensive weapons systems, are competing with the resources needed to support society and the economic competition, which can also be considered as a type of warfare. Thus, commercial off-the-shelf (COTS), cheap, and secure weapons are being demanded.

Another important factor forcing the use of information warfare as a type of warfare is that the majority of civilized nations, because of world communications systems, can witness the death and destruction associated with warfare. They demand an end to such death and destruction. Casualties are not politically acceptable. Furthermore, as in the case of the U.S., why should a country continue to be destroyed and, then after peace is restored, spend billions of dollars to rebuild what had been destroyed? In information warfare, the death and destruction will be minimized, with information and information systems primarily being the target for destruction.

This new environment will cause these changes:

- Large armies will convert to smaller armies.
- More firepower will be employed from greater distances.
- Ground forces will only be used to identify targets and assess damages.
- A blurring of air, sea, and land warfare will occur.
- E-mail and other long-range smart information systems weapons will be available.
- Smaller and stealthier ships will be deployed.
- Pilotless drones will replace piloted aircraft.
- Less logistical support will be required.
- More targeting intelligence will be available.
- Information will be relayed direct from sensor to shooter.
- Satellite transmissions will be direct to soldier, pilot, or weapon.
- Military middle-management staff will be eliminated.
- Field commanders will access information directly from drones, satellites, or headquarters on the other side of the world.
- Friend or foe will be immediately recognized.

Technology, Menu-Driven Warfare

Technology is available that can build a menu-driven system, with data bases to allow the IW commanders and warriors to "point and click" to attack the enemy. For example, an information weapons system could provide these menu-driven computerized responses:

- Select a nation.
- Identify objectives.
- Identify technology targets.
- Identify communications systems.
- Identify weapons.
- Implement.

The weapons can be categorized as attack, protect, exploit, and support systems. For example:

- *IW-Network Analyses (Exploit).* Defined as the ability to covertly analyze networks of the adversaries to prepare for their penetration to steal their information and shut them down.
- *Crypto (Exploit and Protect).* Defined as the encrypting of U.S. and allies' information so that it is not readable by those who do not have a need to know; the decrypting of the information of adversaries is to be exploited for the prosecution of information warfare.
- *Sensor Signal Parasite (Attack).* Defined as the ability to attach malicious code (e.g., virus, worms) and transmit that signal to the adversary to damage, destroy, exploit, or deceive the adversary.
- *Internet-Based Hunter Killers (Attack).* Defined as a software product that will search the Internet, identify adversaries' nodes, deny them the use of those nodes, inject disinformation, worms, viruses, or other malicious codes.
- *IW Support Services (Services).* Defined as those services to support the preceding or to provide for any other applicable services, including consultations with customers to support their information warfare needs. These services may include modeling, simulations, training, testing, and evaluations.

Some techniques that can be considered in prosecuting information warfare include:

- Initiate virus attacks on enemy systems.
- Intercept telecommunications transmissions and implant code to dump enemy data bases.
- Attach a worm to enemies' radar signal to destroy the computer network.
- Intercept television and radio signals and modify their content.
- Misdirect radar and content.

- Provide disinformation, such as bushes that look like tanks and trees that look like soldiers.
- Information overload enemy computers.
- Penetrate enemies' GII nodes to steal or manipulate information.
- Modify maintenance systems information.
- Modify logistics systems information.

ECONOMIC ESPIONAGE: A FORM OF INFORMATION WARFARE

In looking at rapid technology-oriented growth, there are nations of haves and have-nots. There are also corporations that conduct business internationally and those that want to. The international economic competition and trade wars are increasing. Corporations are finding increased competition and looking for the competitive edge or advantage.

One way to gain the advantage or edge is through industrial and economic espionage. Both forms of espionage have been around since there has been competition. However, in this information age the competitiveness is more time-dependent, more crucial to success, and has increased dramatically, largely due to technology. Thus, there is an increased use of technology to steal that competitive advantage and, ironically, these same technology tools are also what is being stolen. In addition, more sensitive information is consolidated in large data bases on internationally networked systems whose security is questionable.

Definitions of Industrial and Economic Espionage

Industrial espionage is defined as an individual or private business entity sponsorship or coordination of intelligence activity conducted for the purpose of enhancing a competitor's advantage in the marketplace. According to the FBI, economic espionage is defined as: "Government-directed, sponsored, or coordinated intelligence activity, which may or may not constitute violations of law, conducted for the purpose of enhancing that country's or another country's economic competitiveness."

Economics, World Trade, and Technologies

What has allowed this proliferation of technologies to occur? Much of it was due to international business relationships among nations and companies. Some of it was due to industrial and economic espionage.

The information age has brought with it more international businesses, more international competitors, and more international businesses working joint projects against international competitors. This has resulted in more opportunities to steal from partners. Moreover, one may be a business partner on one contract while competing on another; thus, providing the opportunity to steal vital economic information. Furthermore, the

world power of a country, today, is largely determined by its economic power. Thus, in reality, worldwide business competition is viewed by many as the economic war. This world competition, coupled with international networks and telecommunications links, has provided more opportunities for more people such as hackers, phreakers, and crackers to steal information through these networks. The end of the Cold War has also made many out-of-work spies available to continue to practice their craft, but in a capitalistic environment.

Proprietary Economic Information

This new world environment makes a corporation's proprietary information more valuable than previously. Proprietary economic information according to the FBI is "…all forms and types of financial, scientific, technical, economic, or engineering information including but not limited to data, plans, tools, mechanisms, compounds, formulas, designs, prototypes, processes, procedures, programs, codes, or commercial strategies, whether tangible, or intangible… and whether stored, compiled, or memorialized physically, electronically, graphically, photographically, or in writing…". This statement assumes that the owner takes reasonable measures to protect it, and that it is not available to the general public.

A security association's survey taken among 32 corporations disclosed that proprietary information had been stolen from their corporations. These thefts included research, proposals, plans, manufacturing information, pricing, and product information. The costs to these corporations were substantially in terms of legal costs, product loss, administrative costs, lost market share, security cost increases, research and development costs, and loss of corporate image in the eyes of the public.

Economic Espionage Vulnerabilities

The increase in economic espionage is also largely due to corporate vulnerabilities to such threats. Corporations do not adequately identify and protect their information, nor do they adequately protect their computer and telecommunications systems. They do not have adequate security policies and procedures; employees are not aware of their responsibilities to protect their corporation's proprietary information. Many of the employees and also the management of these corporations do not believe that they have any information worth stealing or believe that it could happen to them.

Economic Espionage Risks

When corporations fail to adequately protect their information they are taking risks that will in all probability cause them to lose market share, profits, business, and also help in weakening the economic power of their country.

These are some actual cases of economic espionage:

- A foreign government intelligence service compiled secret dossiers of proprietary proposals of two companies from two other countries. Then, they gave that information to one of their country's companies, also bidding on the same contract. Their country's company won a billion dollar contract.
- A company contracted with a foreign government for a product. After disagreements, the government gave the proprietary information to one of their own companies.
- Foreign businessmen were arrested in a government agent sting operation for stealing proprietary information from their competitor.
- An employee of a U.S. microprocessor corporation admitted selling technology information from two companies where he had been employed. The information was alleged to have been sold to China, Iran, and Cuba.
- A foreign company, which could be a foreign government-fronted company, buys into a contract at a bid below its costs. They used the opportunity to steal technology information to be used by their country.

How Safe Are We? According to the International Trade Commission, the loss to U.S. industries due to economic espionage in 1987 was $23.8 billion and in 1989 was $40 billion. Today, these losses are projected to be over $70 billion. During the same time, the American Society for Industrial Security found that U.S. companies only spent an average of $15,000 per year to protect their proprietary information.

It was determined by one survey that only 21% of the attempted or actual thefts of proprietary information occurred in overseas locations, indicating that major threats are U.S. based. A CIA survey found that 80% of one country's intelligence assets are directed towards gathering information on the U.S. and to a lesser degree towards Europe. The FBI indicates that of 173 nations, 57 were actively running operations targeting U.S. companies and over 100 countries spent some portion of their funds targeting U.S. technologies. It was determined that current and former employees, suppliers, and customers are said to be responsible for over 70% of proprietary information losses. No one knows how much of those losses are due to foreign government-sponsored attacks.

Economic Espionage Threats

Economic espionage — that espionage supported by a government to further a business — is becoming more prevalent, more sophisticated, and easier to conduct due to technology. Business and government share a responsibility to protect information in this information age of international business competition.

Businesses must identify what needs protection; determine the risks to their information, processes, and products; and develop, implement, and maintain a cost-effective security program. Government agencies must understand that what national and international businesses do affects their country. They must define and understand their responsibilities to defend against such threats, and they must formulate and implement plans that will assist their nation in the protection of its economy. Both business and government must work together, because only through understanding, communicating, and cooperating will they be able to assist their country in the world economic competition.

It is quite obvious from the preceding discussion that when it comes to economic espionage, a new form of information warfare, the information systems security professional must play an active role in the economic information protection efforts. These efforts will help protect U.S. companies or government agencies and will enhance the U.S.'s ability to compete in the world economy.

TERRORISTS AND TECHNOLOGY (TECHNO-TERRORISTS): A FORM OF INFORMATION WARFARE

The twenty-first century will bring an increased use of technology by terrorists. Terrorism is basically the use of terror or violence, or the use of violent and terrifying actions for political purposes by a government to intimidate the population or by an insurgent group to oppose the government in power. The FBI defines terrorism as: "…the unlawful use of force or violence against persons or property to intimidate or coerce a government, the civilian population, or any segment thereof, in furtherance of political or social objectives."

The CIA defines international terrorism as: "…terrorism conducted with the support of foreign governments or organizations and/or directed against foreign nations, institutions, or governments." The Departments of State and Defense define terrorism as: "…premeditated, politically motivated violence perpetrated against a non-combatant target by sub-national groups or clandestine state agents, usually intended to influence an audience. International terrorism is terrorism involving the citizens or territory of more than one country." Therefore, a terrorist is anyone who causes intense fear and who controls, dominates, or coerces through the use of terror.

Why Are Terrorist Methods Used?

Terrorists generally use terrorism when those in power do not listen, when there is no redress of grievances, or when individuals or groups oppose current policy. Terrorists find that there is usually no other recourse available. A government may want to use terrorism to expand its territory or influence another country's government.

What Is a Terrorist Act?

In general, it is what the government in power says it is. Some of the questions that arise when discussing terrorism are

- What is the difference between a terrorist and a freedom fighter?
- Does "moral rightness" excuse violent acts?
- Does the cause justify the means?

The Results of Terrorist Actions

Acts of terrorism tend to increase security efforts. It may cause the government to decrease the freedom of its citizens to protect them. This, in turn, may cause more citizens to turn against the government, thus supporting the terrorists. It also causes citizens to become aware of the terrorists and their demands.

The beginning of this trend can be seen in the U.S. Americans are willing to give up some of their freedom and privacy to have more security and personal protection. Examples include increased airport security searches and questioning of passengers.

Terrorists cause death, damage, and destruction as a means to an end. Sometimes, it may cause a government to listen, and it may also cause social and political changes. Current terrorist targets have included transportation systems, citizens, buildings, and government officials.

Terrorists' Technology Threats

Today's terrorists are using technology to communicate and to commit crimes to fund their activities. They are also beginning to look at the potential for using technology in the form of information warfare against their enemies. It is estimated that this use will increase in the future.

Because today's technology-oriented countries rely on vulnerable computers and telecommunications systems to support their commercial and government operations, it is becoming a concern to businesses and government agencies throughout the world. The advantage to the terrorist of attacking these systems is that the techno-terrorist acts can be done with little expense by a few people and yet cause a great deal of damage to the economy of a country. They can conduct such activities with little risk to themselves, because these systems can be attacked and destroyed from a base in a country that is friendly to them. In addition, they can do so with no loss of life; thus not causing the extreme backlash against them as would occur had they destroyed buildings, causing much loss of life.

These are some actual and potential techno-terrorist actions:

- Terrorists, using a computer, penetrate a control tower computer system and send false signals to aircraft, causing them to crash in mid-air or fall to the ground.
- Terrorists use fraudulent credit cards to finance their operations.
- Terrorists penetrate a financial computer system and divert millions of dollars to finance their activities.
- Terrorists bleach $1 bills and, by using a color copier, reproduce them as $100 bills and flood the market with them to destabilize the dollar.
- Terrorists use cloned cellular phones and computers over the Internet to communicate, using encryption to protect their transmissions.
- Terrorists use virus and worm programs to shut down vital government computer systems.
- Terrorists change hospital records, causing patients to die because of an overdose of medicine or the wrong medicine. They may also change computerized tests and alter the results.
- Terrorists penetrate a government computer and causes it to issue checks to all its citizens.
- Terrorists destroy critical government computer systems processing tax returns.
- Terrorists penetrate computerized train routing systems, causing passenger trains to collide.
- Terrorists take over telecommunications links or shut them down.
- Terrorists take over satellite links to broadcast their messages over televisions and radios.

Some may wonder if techno-terrorist activities can actually be considered as information warfare. Most IW professionals believe that techno-terrorism is part of IW, assuming that the attacks are government sponsored and that the attacks are done in support of a foreign government's objectives.

DEFENDING AGAINST INFORMATION WARFARE ATTACKS

To defend against information warfare attacks, the information systems security professional must be aggressive and proactive. Now, as in the past, the basic triad of information security processes are usually installed:

- Individual accountability.
- Access control.
- Audit trail systems.

This passive defense kept the honest user honest, but did not do much to stop the more computer-literate user such as the hacker, cracker, or phreaker. Management support was not always available unless something went wrong. Then, management became concerned with information systems security — albeit only until the crisis was over. This passive

approach, supported by short-lived proactive efforts, was and continues to be "how information security is done."

With the advent and concerns associated with information warfare, government agencies, businesses, and the U.S. in general can no longer afford to take such a passive approach. As a profession, the possibility of an information systems Pearl Harbor is discussed. Most of the time, this is dismissed as rhetoric, and that security people are trying to justify their budgets. This approach will no longer work, and security professionals would be remiss in their responsibilities if they did not start looking at how to "information warfare-harden" (IW-H) computerized systems. IW-H means to provide a defensive shield — an early warning countermeasures system to protect government and business information infrastructures in the event of IW attacks.

Attacking a Commercial Target May Be a Prelude to War

In a time of war, would government systems be the primary target? A new age in warfare, commonly known as the Revolution in Military Affairs (RMA), is being entered. As previously discussed, there is a worldwide economic war being waged, where balance of trade statistics determine the winners and losers, along with the unemployment trends and the trends indicating the number of businesses moving overseas. In the information systems business, that trend also continues and may be increasing. Microprocessors are made in Malaysia and Singapore, software is written in India, and systems are integrated and shipped from Indonesia, for example. No one checks to determine if malicious code is embedded in the firmware or software, waiting for the right sequence of events to be activated to release that new, devastating virus or to reroute information covertly to adversaries.

Consideration must also be given to networking with other information systems security professionals to establish an IW early warning network, as well as to share IW defensive and IW countermeasures information. This can be equated somewhat with the early warning radar sites that the Department of Defense has scattered throughout the U.S.'s sphere of influence. These systems warn against impending attacks. If such a system was in place on the Internet when the Morris Worm was initiated, the damage could have been minimized and the recovery completed much quicker. If the U.S. is the object of all-out IW attacks, the Morris Worm type of problem would be nothing compared with the work of government-trained IW attack warriors.

SUMMARY

When a government agency or business computer system is attacked, the response to such an attack will be based on the type of attacker. Will the attacker be a hacker, phreaker, cracker, or just someone breaking in for

fun? Will the attacker be an employee of a business competitor, or in the case of an attack on a business system will it be a terrorist or a government agency-sponsored attack for economic reasons? Will the attacker be a foreign soldier attacking the system as a prelude to war?

These questions require serious consideration when information systems are being attacked, because it dictates the response. Would one country attack another because of what a terrorist or economic spy did to a business or government system? To complicate the matter, what if the terrorist was in a third country but only made it look like as though he or she was coming from a potential adversary? The key to the future is in information systems security for defense and information warfare weapons. As with nuclear weapons used as a form of deterrent, in the future, information weapons systems will be the basis of the information warfare deterrent.

Steps for Providing Microcomputer Security

Douglas B. Hoyt

Payoff

Microcomputers are most often associated with end-user computing, which traditionally have not been the systems development manager's responsibility. Nevertheless, senior management often holds the systems development manager responsible for an organization's entire computing resources, which include microcomputer systems. In addition, the rapid-proliferation of microcomputers throughout most organizations makes it important for the systems development manager to take an interest in microcomputer security issues. This article examines how the systems development manager can provide security for microcomputers and examines issues particular to microcomputer security.

Problems Addressed

Microcomputers have brought many benefits to business, but these benefits can be undermined if these desktop machines are not properly secured. sensitive information stored in a microcomputer is vulnerable to theft or to being copied by unauthorized individuals. Lost data can be difficult, costly, or impossible to reconstruct, especially if its source is no longer available. Microcomputer systems are also vulnerable to hardware malfunctions, fluctuations in source power, operator errors, software bugs, and viruses. In addition, the quality of information produced by microcomputer systems can be questionable, because microcomputer systems are seldom subjected to the controls that apply to mainframe or minicomputer systems.

Ensuring the security of microcomputers is a complicated issue for systems development managers, who are typically responsible for the development of information systems and the supervision of centralized computer operations. Systems development managers may have less than full— or no—control over microcomputer systems (including LANs). Because senior management generally relies on systems development managers to ensure the integrity of an organization's overall computer systems, however, systems development managers not only must be able to ensure proper controls for computer-based operations under their direct control but must manage, or influence, the proper use of microcomputers or networks by end users not directly under their control. Their indirect influence over microcomputer security can be strengthened if systems development managers educate senior management about the importance of such security.

This article can help systems development managers educate senior management as well as themselves about microcomputer security. It examines the security vulnerabilities particular to microcomputer systems and ways of protecting these susceptible areas. Guidelines and a checklist for establishing and implementing microcomputer security practices are also provided.

Steps for Securing Microcomputers

Assessing Vulnerabilities and Needs

Potential vulnerabilities in microcomputer systems should be reviewed periodically and systematically. One possible method of review is to establish a schedule that lists all the organization's microcomputer systems, the potential areas of vulnerability for those systems (rated as a percentage or as high, medium, or low risk), the value of what could be

lost as a result of failure of the system, and steps for preventing such a loss. Updating this list every one or two years can ensure that major areas of vulnerability are not allowed to exist unprotected or undetected. This type of review requires appropriate fact gathering and analysis.

Such a structured analysis of microcomputer vulnerabilities can be used to organize a presentation to senior management to help gain its support for security measures. It could also help justify expenditures for security products that the analysis indicates are worthwhile. It is essential that senior management be made aware of microcomputer security vulnerabilities and needs, and it is often the systems development manager's responsibility to see that that is accomplished.

Ensuring Information and Software Backup

Most systems development managers have established methods and schedules for backing up software programs, data bases, and other transaction data so that the information can be available to resume interrupted operations. However, additional safeguards are needed to restart operations promptly after a major disaster. It is preferable to have two backups, each at a different location, so that recovery of operations does not depend on one backup alone. In addition, extra backups reflecting current transactions should be kept off site.

The systems development managers should first determine which microcomputer files, programs, and data bases are critical to operations. Then, each item should be analyzed and an appropriate backup method and locations selected. The off-site location may be another place within the organization, or it even could be furnished by a service that warehouses backup copies in electronic, microfilm, and paper form. These services usually provide carefully controlled storage environments, pickups and deliveries, and records of deliveries to and from their facilities.

Although most microcomputer and network users are aware of the value of backing up data and software, many do not do it properly. It is human nature to procrastinate with matters that do not seem urgent. To correct this tendency, a firm schedule must be set and followed. Even organizations that do keep backups often store them near the original; they must correct this situation by maintaining duplicate backup copies at another location.

There are three basic ways to back up Disk Operating System systems copies: the COPY command, the XCOPY command, or a backup and restore utility. The COPY command is limited to the capacity of a diskette. The XCOPY command can be used to copy a subdirectory with many files on it. A backup and restore utility dumps all data onto as many diskettes as are needed.

Protecting Hardware and Guaranteeing Availability

Common security measures for microcomputer hardware include locks and guards for the areas in which equipment is located. Microcomputer equipment can be protected from thieves by means of cables, locks, adhesives, bolts, and even alarms that sound when a turned-off microcomputer is moved. These are effective in deterring thefts, but there is no way of completely preventing the theft of such equipment.

Most microcomputer equipment can be readily replaced. In addition to the purchase costs, the time and cost of replacing the software and data sometimes can be comparable to the equipment loss itself, even if the software and data have been properly backed up.

One possible aid to recovering stolen equipment is keeping records of serial numbers and other such identification numbers that help police identify and retrieve microcomputer equipment. Another aid to identifying stolen equipment is the branding of disks with the owner's identification; branding is done by imprinting the owner's name or tax identification number on unused disk space. Some organizations have a large inventory of

microcomputers and maintain spare computers, parts, and peripherals to replace items that may be stolen or have become inoperable; such inventories are helpful in minimizing replacement time.

Implementing Access Controls

Access controls are needed to safeguard against such dangers as stealing data, wiping out or altering critical data, spying, and other malicious actions. Such dangers are all real and can justify the considerable time and cost involved in implementing protective measures. However, most damage from intrusions is inadvertently caused by employees who are not properly trained or who accidentally access a wrong program or data because of weak controls. The variety of risks from unauthorized access makes it necessary for systems development managers to study the possible dangers, weigh their consequences, systematically analyze employee functions, and install controls to ensure that access procedures to view and modify programs and data are logically designed. Easy access, especially in networks, can increase risk as well as efficiency.

For many systems, sufficient access control can be provided by requiring users to enter their individual IDs and passwords. Those passwords and IDs should allow users access to only those programs and data bases that they need to fulfill their individual responsibilities. The passwords must not be names or words that others might guess and should be changed regularly. An added control can be the documentation of who accesses what system and data base and when; this audit trail can verify conformity to authorize activities and may gave clues to any improper use.

When access to a microcomputer or network is over telephone lines, there is the danger that someone who has surreptitiously learned a password and ID could access the system. Several vendors have developed callback security products that prevent unauthorized access over the telephone. With these products, a caller enters a password, an ID, or both; the system then terminates the connection and places a call to the telephone number known to be the authorized source for the particular password or ID. The authorized caller is allowed to complete the transaction. A list of callback security products is given in Exhibit 1.

Callback Security Products

Networks increase the complexity of the access control problem. When microcomputers and workstations are connected to one or more servers and maybe to a minicomputer or mainframe, the users at each station must be prevented from having access to network data and programs that they do not need for their individual responsibilities. Their password and ID authorizations must be defined accordingly.

The network security problem is further complicated when networks are connected to networks. Without restriction, users can move from network to network through gateways, bridges, and routers. Several special security systems have been developed to address this multiple network problem. One such system, for example, is Intrusion Detection Expert System (IDES) designed by Stanford Research Institute International. IDES analyzes users' normal behavior patterns and alerts administrators to deviations that are symptoms of violations to be investigated.

Absolute computer security is impossible to achieve because any access obstacle can be overcome by a clever and determined technician. The more obstacles that are established, however, the less likely it will be that they will be surmounted. For example, invisible characters can be embedded in file or directory names; only authorized users know the key invisible characters, which prevent easy access to unauthorized persons. File names in the directories of DOS systems can be hidden from unauthorized persons using such utility programs as the Norton Utilities from Symantec Corp. or alarm, lockup, and encryption

features available with DOS systems. Data encryption can provide another layer of protection for extra-sensitive data. This is especially effective for data that is to be transmitted between locations.

Providing Power Protection and Backup

Another area that needs to be protected is the microcomputer system's power supply. Too much or too little power can do great harm if proper protective measures are not taken. Blackouts, brownouts, and sags can cause loss of data and disrupt computer operations. Strong surges such as those caused by lightning can seriously damage hardware. The two main preventives for power problems are surge protectors and uninterruptable power supplies (UPSs).

Surge protectors are used frequently because they are relatively inexpensive and prevent damage to data from minor power fluctuations that commonly occur. They cost from $25 to $30 and are installed simply by being inserted between the electrical outlet and the microcomputer.

There are two types of UPSs—online and offline. They both can safeguard against damage from lightning as well as ensure 15 minutes or more of power if the regular source is stopped. This gives time to save data and shut down the computers in an orderly fashion. Online UPSs, which can cost several thousand dollars, run continuously, providing even current from batteries. Offline UPSs also furnish even current from batteries, but their batteries provide power only when the regular source ceases or fluctuates. Because online UPSs are relatively expensive, their use is justified only for larger networks or for highly important operations. Offline UPSs, on the other hand, are available for less than $100.

Performing Maintenance and Housekeeping

Maintenance and housekeeping can reduce the likelihood of sudden microcomputer system failures. These failures are rare but should be avoided.

Hardware with moving parts is most prone to breakdown. Following are some procedures that can help avoid failure problems:

- Carefully following the manufacturer's recommendations for caring for equipment.
- Keeping the microcomputer vicinity free from dust and undue moisture, allowing air to flow freely around microcomputer equipment, and forbidding eating, drinking, and smoking in the area.
- Avoiding excessive moves of equipment.
- Minimizing static buildup by using grounded antistatic mats or antistatic carpet spray as well as by using a humidifier if the heating system dries the air.
- Using electrical outlets that are not connected to such devices as motors, heating appliances, for fluorescent lights.
- Keeping wires neatly bundled and away from where they could be hit by passersby.
- Cleaning disk drives and tape drives periodically with specially designed cleaning disks and tapes.
- Keeping copies of backup data off site to protect against theft or other disasters.

· Establishing plans for regular maintenance.

Providing Written Policies and Instructions

The auditors of a manufacturing company recently reviewed the company's applications on microcomputers and found many of them to contain such vital information as strategic plans, pricing, and invoices. Much of this key information was not backed up, and the auditors were concerned about the vulnerability of such important operations.

To correct this security weakness, the auditors initiated programs to establish manuals of standards and policies and a training program to instruct all concerned in proper safeguarding principles. In fact, manuals for microcomputer users are more essential than those for the mainframe operations. Mainframe operations are usually managed by a centralized organization, but microcomputer users do not have centralized authority to guide them and therefore need the guidance of manuals much more.

Whether an organization has two microcomputers or two thousand, the policies, procedures, and standards for safeguarding microcomputers and their information must be documented. Those drafting the manual should review the guidelines and adapt them in a form that would be clear and meaningful to the microcomputer users of the organization. One important part of all such manuals should be a summary of the responsibilities of all concerned—the users, their managers, the systems staff, auditors, and security administration. For example, Tompkins County Trust Co., Ithaca NY, developed a microcomputer security manual for reasons similar to those cited in the previous example and has made the manual available for sale.

Training Personnel.

The manufacturing company previously mentioned developed a videotape on microcomputer security and used it in a series of seminars to explain and reinforce the principles in the manuals they had distributed. Their approach was to encourage rather than mandate compliance, and allowed for variations in security procedures. Whatever the approach used, it is worthwhile to conduct some form of regular training for microcomputer users to foster understanding of security needs and practices and to help motivate them to carry out the proper procedures on a continuing basis.

Performing Security Audits

Auditors at the manufacturing company included a review of microcomputer security practices as a routine part of their EDP audit programs. They checked compliance with the principles and standards in the company's manuals and reported deviations and suggested improvements to the management of the areas that used microcomputers. Although flexibility and independence were allowed and encouraged, significant deficiencies were detected and corrected. In situations in which the auditors do not review microcomputer security compliance, systems managers should regularly verify conformity to security principles and practices and initiate corrective action where necessary.

Guarding Against Viruses

Viruses have become of great concern because of their increasing prevalence and capability to do harm. New viruses continually appear and nullify security assurance gained from previous protection measures. Practices to minimize the possibility of virus infections include:[78]

---

[78] National Computer Security Association, *NCSA News 5*(March/April 1992), p. 3.

- Backing up the system regularly. Care should be taken because a recent backup may contain infected files.
- Using software from a known, trusted source. Pirated software should never be used. If shareware is used, it should be obtained from a source as close to the author as possible.
- Using a reliable virus scanner. Many such scanners are available as shareware.
- Scanning all new software before running it.
- Consulting an expert. Vendors of antivirus products generally offer assistance and advice.

The International Computer Security Association (ICSA), Washington DC, offers an interactive virus tutorial, ViruSchool, which explains virus protection techniques. Several other organizations have been formed with the common purpose of conducting research and disseminating information on virus controls. These organizations as well as the ICSA are listed in Exhibit 2.

Antivirus Organizations *ISPNews*, July/August 1992, p. 17.

Studies have indicated that virus detection and prevention software products do not always cover the viruses listed in their advertising. It has been suggested to use two or more such products to help ensure proper coverage and to gain the benefit of differing features of different software. It is essential that new or upgraded antivirus products be acquired and applied frequently to protect against new and modified viruses. Virus protection software should be checked against all existing programs as well as any new programs. Running a virus detection program before making backups ensures that the backups are free of viruses.

Technology Issues Affecting Security

LANs and WANs

Local area networks (LANs) and Wide Area Network (WANs) have an increased vulnerability and consequently an increased need for protective measures. For example, a worker at one network station can access data of another to which that worker is not entitled. A system moved from a mainframe to a network is no longer in a centralized environment. A virus implanted in one microcomputer in a network can infect programs in the other network's stations. (Of the microcomputers with viruses, 71% are said to be in networks.) The benefits of these networks—flexibility and lower costs—can be impaired if suitable security steps are not taken.

Where networks are not under the direct control of the systems manager, the manager should use every means available to influence and coordinate the application of proper security standards and procedures. These means include keeping current records on the networks' hardware, software, and applications; setting standards for and influencing the use of access control procedures and antivirus software; establishing training programs and standards manuals; and gaining the support of auditors to help monitor the established security policies and standards. Of course, the systems manager's coordination of security standards should apply as well as standalone microcomputers that are not connected to networks.

Disk mirroring is a technique for providing a high level of network security. This technique makes use of two disk drive servers and fault-tolerant computing. If one server commits an error, the other takes over, and users do not detect the change in service. The faulty drive is corrected and resumes parallel operation with the other server.

Diskless Workstations

Some organizations have found that diskless workstations connected to networks can provide added security features as well as other benefits. Viruses cannot be introduced directly into diskless workstations nor can unauthorized programs or games. The diskless workstation prevents theft of critical data by eliminating the capability of copying data onto diskettes.

In addition to the security benefits, diskless workstations cost less, are more reliable because they have fewer moving parts, and take up less space on the desk. Applications for which diskless workstations are well suited include airline reservations and operations in such large offices as a state tax department, where several hundred diskless stations can be effective and economical. One disadvantage is that diskless workstations are dependent on the network so that if the network fails, the diskless workstations cannot operate.

Laptop Issues

Laptop computers present additional vulnerabilities. The main danger is the ease with which laptops can be stolen. The hardware and software of each lost laptop can cost a few thousand dollars, but a more serious loss is usually the data. Lost data can require many hours or days to reconstruct. Sometimes the data cannot be reconstructed because the source information no longer exists.

The most effective security measure for laptops is to keep them close by and keep an eye on them. Any important data should be copied onto a disk that is kept at a place separate from the laptop. If there is concern that data might fall into the wrong hands, an encryption program should be used to scramble the information.

Biometric Devices

Several mechanisms have been developed that can give greater assurance that only authorized persons can access a network. These devices include equipment that can record a person's eye features, signature, handwriting, hand- or fingerprints, or speech patterns. They can overcome the major weakness in most access control systems: people often give their IDs and passwords to other people. These biometric systems have not yet become widespread because of their cost, the inconvenience of putting them into practice, and user resistance.

Recommended Course of Action

Most systems development managers have implemented some microcomputer security measures. This article can help these managers determine what further security measures should be instituted to provide proper protection against existing vulnerabilities. It is recommended that these systems development managers:

- Review the steps for securing microcomputers and their information.

- Compare each item under those headings with the existing practices to evaluate what security areas need improvement.

- Plan and revise protective measures to accomplish the required improvements.
- Implement the new and revised protective measures.
- Ensure that security practices are kept up to date.
- Ensure that security policies and practices are audited and monitored to verify that they are properly carried out.

To aid in reviewing existing practices to evaluate the effectiveness of microcomputer security, a systems development manager should ask the following questions:

- Has an inventory been made of the existing microcomputer hardware, software, and applications?
- Has a systematic security evaluation been made of the microcomputer items on that inventory?
- Has senior management been educated about the microcomputer security vulnerabilities and needs of the organization?
- Are updated backup copies of software and data kept for all microcomputer systems?
- Are backup copies maintained off site for important data files?
- Are sufficient measures taken to deter the theft of hardware?
- Are users required to use both passwords and IDs?
- How frequently are passwords revised? Are checks made to see that they are not names or words? That they are not written in viewable places?
- Are callback controls applied for access by phone?
- Is each user restricted to applications and data on a strict need-to-know basis?
- Is encryption used when sensitive data is transmitted over wires?
- Are surge protectors provided for all microcomputers and uninterrupted power for vital microcomputer and network operations?
- Are housekeeping rules enforced regarding food, drink, smoking, dust, and related matters?
- Are written security policies and standards in the hands of all microcomputer and network users? Are they current?
- Is there a training program that covers microcomputer security practices?
- Do auditors review conformity to security policies and rules as a regular part of their audit program?
- Is virus detection and therapy software applied to each microcomputer and network?

- Is new software checked against the virus detection program before it is put into use?
- Are users of networks prevented from applications and data to which they are not entitled?
- Is owner's identification etched on equipment covers?
- Are logs maintained of who uses which application and when?
- Are sensitive files kept from appearing on screen directories?

Protecting the Portable Computing Environment

Phillip Q. Maier

Today's portable computing environment can take on a variety of forms: from remote connectivity to the home office to remote computing on a standalone microcomputer with desktop capabilities and storage. Both of these portable computing methods have environment-specific threats as well as common threats that require specific protective measures. Remote connectivity can be as simple as standard dial-up access to a host mainframe or as sophisticated as remote node connectivity in which the remote user has all the functions of a workstation locally connected to the organization's local area network (LAN). Remote computing in a standalone mode also presents very specific security concerns, often not realized by most remote computing users.

PORTABLE COMPUTING THREATS

Portable computing is inherently risky. Just the fact that company data or remote access is being used outside the normal physical protections of the office introduces the risk of exposure, loss, theft, or data destruction more readily than if the data or access methods were always used in the office environment.

Data Disclosure

Such simple techniques as observing a user's remote access to the home office (referred to as shoulder surfing) can disclose a company's dial-up access phone number, user account, password, or log-on procedures; this can create a significant threat to any organization that allows remote dial-up access to its networks or systems from off-site. Even if this data or access method isn't disclosed through shoulder surfing, there is still the intermediate threat of data disclosure over the vast amount of remote-site

to central-site communication lines or methods (e.g., the public phone network). Dial-up access is becoming more vulnerable to data disclosure because remote users can now use cellular communications to perform dial-up access from laptop computers.

Also emerging in the remote access arena is a growing number of private metropolitan wireless networks, which present a similar, if not greater, threat of data disclosure. Most private wireless networks don't use any method of encryption during the free-space transmission of a user's remote access to the host computer or transmission of company data. Wireless networks can range in size from a single office space serving a few users to multiple clusters of wireless user groups with wireless transmissions linking them to different buildings. The concern in a wireless data communication link is the threat of unauthorized data interception, especially if the wireless connection is the user's sole method of communication to the organization's computing resources.

All of these remote connectivity methods introduce the threat of data exposure. An even greater concern is the threat of exposing a company's host access controls (i.e., a user's log-on account and static password), which when compromised may go undetected as the unauthorized user accesses a system under a valid user account and password.

Data Loss and Destruction

Security controls must also provide protection against the loss and destruction of data. Such loss can result from user error (e.g., laptop computers may be forgotten in a cab or restaurant) or other cause (e.g., lost baggage). This type of data loss can be devastating, given today's heavy reliance on the portable computer and the large amount of data a portable computer can contain. For this reason alone some security practitioners would prohibit use of portable computers, though increased popularity of portable computing makes this a losing proposition in most organizations.

Other forms of data loss include outright theft of disks, copying of hard disk data, or loss of the entire unit. In today's competitive business world, it is not uncommon to hear of rival businesses or governments using intelligence-gathering techniques to gain an edge over their rivals. More surreptitious methods of theft can take the form of copying a user's diskette from a computer left in a hotel room or at a conference booth during a break. This method is less likely to be noticed, so the data owner or company would probably not take any measures to recover from the theft.

Threats to Data Integrity

Data integrity in a portable computing environment can be affected by direct or indirect threats, such as virus attacks. Direct attacks can occur from an unauthorized user changing data while outside the main facility on

a portable user's system or disk. Data corruption or destruction due to a virus is far more likely in a portable environment because the user is operating outside the physical protection of the office. Any security-conscious organization should already have some form of virus control for on-site computing; however, less control is usually exercised on user-owned computers and laptops. While at a vendor site, the mobile user may use his or her data disk on a customer's computer, which exposes it to the level of virus control implemented by this customer's security measures and which may not be consistent with the user's company's policy.

Other Forms of Data Disclosure

The sharing of computers introduces not only threats of contracting viruses from unprotected computers, but also the distinct possibility of unintended data disclosure. The first instance of shared computer threats is the sharing of a single company-owned portable computer. Most firms don't enjoy the financial luxury of purchasing a portable computer for every employee who needs one. In order to enable widespread use of minimal resources, many companies purchase a limited number of portable computers that can be checked out for use during prolonged stays outside the company. In these cases, users most likely store their data on the hard disk while working on the portable and copy it to a diskette at the end of their use period. But they may not remove it from the hard disk, in which case the portable computer's hard disk becomes a potential source of proprietary information to the next user of the portable computer. And if this computer is lost or misplaced, such information may become public. Methods for protecting against this threat are not difficult to implement; they are discussed in more detail later in this chapter.

Shared company portables can be managed, but an employee's sharing of computers external to the company's control can lead to unauthorized data disclosure. Just as employees may share a single portable computer, an employee may personally own a portable that is also used by family members or it may be lent or even rented to other users. At a minimum, the organization should address these issues as a matter of policy by providing a best practices guideline to employees.

DECIDING TO SUPPORT PORTABLES

As is the case in all security decisions, a risk analysis needs to be performed when making the decision to support portable computers. The primary consideration in the decision to allow portable computing is to determine the type of data to be used by the mobile computing user. A decision matrix can help in this evaluation, as shown in Exhibit 1. The vertical axis of the decision matrix could contain three data types the company uses: confidential, sensitive, and public. Confidential data is competition-sensitive

	CONTROL STRATEGY			
DATA CLASSIFICATION	PORTABLE COMPUTING NOT PERMITTED	PORTABLE COMPUTING WITH STRINGENT SAFEGUARDS	PORTABLE COMPUTING WITH MINIMAL SAFEGUARDS	PORTABLE COMPUTING WITH FEW SAFEGUARDS
Company Confidential	Recommended Action	Not Permitted	Not Permitted	Not Permitted
Company Sensitive	Recommended Action	Recommended Action	Not Permitted	—
Public Data			Recommended Action	Recommended Action

Exhibit 1. Decision Matrix for Supporting Portable Computers

data which cannot be safely disclosed outside the company boundaries. Sensitive data is private, but of less concern if it were disclosed. Public data can be freely disclosed.

The horizontal axis of the matrix could be used to represent decisions regarding whether the data can be used for portable computer use and the level of computing control mechanisms that should be put in place for the type of data involved. (The data classifications in Exhibit 1 are very broad; a given company's may be more granular.) The matrix can be used by users to describe their needs for portable computing, and it can be used to communicate to them what data categories are allowed in a portable computing environment.

This type of decision matrix would indicate at least one data type that should never be allowed for use in a mobile computing environment (i.e., confidential data). This is done because it should be assumed that data used in a portable computing environment will eventually be compromised even with the most stringent controls. With respect to sensitive data, steps should be taken to guard against the potential loss of the data by implementing varying levels of protection mechanisms. There is little concern over use of public data. As noted, the matrix for a specific company may be more complex, specifying more data types unique to the company or possibly more levels of controls or decisions on which data types can and cannot be used.

PROTECTION STRATEGIES

After the decision has been made to allow portable computing with certain use restrictions, the challenge is to establish sound policies and protection strategies against the known threats of this computing environment. The policy and protection strategy may include all the ideas

	DATA DISCLOSURE		DATA LOSS/DESTRUCTION		DATA INTEGRITY	
THREATS	Authentication Disclosure	Transmission Disclosure	Direct Theft	Indirect Theft	Virus	Malicious Tampering
PROTECTIONS	One-Time Passwords	Encryption	Software Controls	Physical Controls	Antivirus Software	Software Access Controls
		Hardware Control	Encryption	Color-Coded Disks	Physical Control Procedures	
			Encryption			

Exhibit 2. Portable Computing Threats and Protection Measures

discussed in this chapter or only a subset, depending on the data type, budget, or resource capabilities.

The basic implementation tool for all security strategies is user education. Implementing a portable computing security strategy is no different; the strategy should call for a sound user education and awareness program for all portable computing users. This program should highlight the threats and vulnerabilities of portable computing and the protection strategies that must be implemented. Exhibit 2 depicts the threats and the potential protection strategies that can be employed to combat them.

User Validation Protection

The protection strategy should reflect the types of portable computing to be supported. If remote access to the company's host computers and networks is part of the portable computing capabilities, then strict attention should be paid to implementing a high-level remote access validation architecture. This may include use of random password generation devices, challenge/response authentication techniques, time-synchronized password generation, and biometric user identification methods. Challenge/response authentication relies on the user carrying some form of token that contains a simple encryption algorithm; the user would be required to enter a personal ID to activate it. Remote access users are registered with a specific device; when accessing the system, they are sent a random challenge number. Users must decrypt this challenge using the token's algorithm and

provide the proper response back to the host system to prove their identity. In this manner, each challenge is different and thus each response is unique. Although this type of validation is keystroke-intensive for users, it is generally more secure than one-time password methods; the PIN is entered only into the remote users' device, and it is not transmitted across the remote link.

Another one-time password method is the time-synchronized password. Remote users are given a token device resembling a calculator that displays an eight-digit numeric password. This device is programmed with an algorithm that changes the password every 60 seconds, with a similar algorithm running at the host computer. Whenever remote users access the central host, they merely provide the current password followed by their personal ID and access is granted. This method minimizes the number of keystrokes that must be entered, but the personal ID is transmitted across the remote link to the host computer, which can create a security exposure.

A third type of high-level validation is biometric identification, such as thumb print scanning on a hardware device at the remote user site, voice verification, and keyboard dynamics, in which the keystroke timing is figured into the algorithm for unique identification. The portable computer user validation from off-site should operate in conjunction with the network security firewall implementation. (A firewall is the logical separation between the company-owned and managed computers and public systems.) Remote users accessing central computing systems are required to cross the firewall after authenticating themselves in the approved manner. Most first-generation firewalls use router-based access control lists (ACLs) as a protection mechanism, but new versions of firewalls may use gateway hosts to provide detailed packet filtering and even authentication.

Data Disclosure Protection

If standalone computers are used in a portable or mobile mode outside of the company facility, consideration should be given to requiring some form of password user identification on the individual unit itself. Various software products can be used to provide workstation-level security.

The minimum requirements should include unique user ID and one-way password encryption so that no cleartext passwords are stored on the unit itself. On company-owned portables, there should be an administrative ID on all systems for central administration as necessary when the units return on-site. This can help ensure that only authorized personnel are using the portable system. Although workstation-based user authentication isn't as strong as host-based user authentication, it does provide a reasonable level of security. At the least, use of a commercial ID and password software products on all portables requires that all users register for access to the portable and the data contained on it.

Other techniques for controlling access to portables include physical security devices on portable computers. Though somewhat cumbersome, these can be quite effective. Physical security locks for portables are a common option. One workstation security software product includes a physical disk lock that inserts into the diskette drive and locks to prevent disk boot-ups that might attempt to override hard-disk-resident software protections.

In addition to user validation issues (either to the host site or the portable system itself), the threat of unauthorized data disclosure must also be addressed. In the remote access arena, the threats are greater because of the various transmission methods used: dial-up over the public switched telephone network, remote network access over such media as the Internet, or even microwave transmission. In all of these cases, the potential for unauthorized interception of transmitted data is real. Documented cases of data capture on the Internet are becoming more common. In the dial-up world, there haven't been as many reported cases of unauthorized data capture, though the threat still exists (e.g., with the use of free-space transmission of data signals over long-haul links).

In nearly all cases, the most comprehensive security mechanism to protect against data disclosure in these environments is full-session transmission encryption or file-level encryption. Simple Data Encryption Standard (DES) encryption programs are available in software applications or as standalone software. Other public domain encryption software such as Pretty Good Privacy (PGP) is available, as are stronger encryption methods using proprietary algorithms. The decision to use encryption depends on the amount of risk of data disclosure the company is willing to accept based on the data types allowed to be processed by portable computer users.

Implementing an encryption strategy doesn't need to be too costly or restrictive. If the primary objective is protection of data during remote transmission, then a strategy mandating encryption of the file before it is transmitted should be put in place. If the objective is to protect the file at all times when it is in a remote environment, file encryption may be considered, though its use may be seen as a burden by users, both because of the processing overhead and the potentially extra manual effort of performing the encryption and decryption for each access. (With some encryption schemes, users may have to decrypt the file before using it and encrypt it again before storing it on the portable computer. More sophisticated applications provide automatic file encryption and decryption, making this step nearly transparent to the user.) Portable computer hardware is also available that can provide complete encryption of all data and processes on a portable computer. The encryption technology is built into the system itself, though this adds to the expense of each unit.

A final point needs to be made on implementing encryption for portable users, and that is the issue of key management. Key management is the coordination of the encryption keys used by users. A site key management scheme must be established and followed to control the distribution and use of the encryption keys.

VIRUS PROTECTION IN A PORTABLE ENVIRONMENT

All portable or off-site computers targeted to process company data must have some consistent form of virus protection. This is a very important consideration when negotiating a site license for virus software. What should be negotiated is not a site license per se, but rather a use license for company's users, wherever they may process company data. The license should include employees' home computers and as well as company-owned portables. If this concept isn't acceptable to a virus software vendor, then procedures must be established in which all data that have left the company and may have been processed on a nonvirus-protected computer must be scanned before it can reenter the company's internal computing environment. This can be facilitated by issuing special color-coded diskettes for storing data that are used on portables or users' home computers. By providing the portable computer users with these disks for storage and transfer of their data and mandating the scanning of these disks and data on a regular basis on-site, the threat of externally contracted computer viruses can be greatly reduced.

CONTROLLING DATA DISSEMINATION

Accumulation of data on portable computers creates the potential for its disclosure. This is easily addressed by implementing a variety of procedures intended to provide checks against this accumulation of data on shared portable computers. A user procedure should be mandated to remove and delete all data files from the hard disk of the portable computer before returning it to the company loan pool. The hardware loaning organization should also be required to check disk contents for user files before reissuing the system.

THEFT PROTECTION

The threat of surreptitious theft can be in the form of illicit copying of files from a user's computer when unattended, such as checked baggage or when left in a hotel room. The simplest method is to never store data on the hard disk and to secure the data on physically secured diskettes. In the case of hotel room storage, it is common for hotels to provide in-room

safes, which can easily secure a supply of diskettes (though take care they aren't forgotten when checking out).

Another method is to never leave the portable in an operational mode when unattended. The batteries and power supply can be removed and locked up separately so that the system itself is not functional and thus information stored on the hard disk is protected from theft. (The battery or power cord could also easily fit in the room safe.) These measures can help protect against the loss of data, which might go unnoticed. (In the event of outright physical theft, the owner can at least institute recovery procedures.) To protect against physical theft, something as simple as a cable ski lock on the unit can be an effective protection mechanism.

USER EDUCATION

The selection of portable computing protection strategies must be clearly communicated to portable computer users by means of a thorough user education process. Education should be mandatory and recurring to assure the most current procedures, tools, and information are provided to portable users. In the area of remote access to on-site company resources, such contact should be initiated when remote users register in the remote access authentication system.

For the use of shared company portable computers, this should be incorporated with the computer check-out process; portable computer use procedures can be distributed when systems are checked out and agreed to by prospective users. With respect to the use of noncompany computers in a portable mode, the best method of accountability is a general user notice that security guidelines apply to this mode of computing. This notification could be referenced in an employee nondisclosure agreement, in which employees are notified of their responsibility to protect company data, on-site or off-site. In addition to registering all portable users, there should be a process to revalidate users in order to maintain their authorized use of portable computing resources on a regular basis. The registration process and procedures should be part of overall user education on the risks of portable computing, protection mechanisms, and user responsibilities for supporting these procedures.

Exhibit 3 provides a sample checklist that should be distributed to all registered users of portables. It should be attached to all of the company's portable computers as a reminder to users of their responsibilities. This sample policy statement includes nearly all the protection mechanisms addressed here, though the company's specific policy may not be as comprehensive depending on the nature of the data or access method used.

- Remove all data from hard disk of company-owned portables before returning them to the loan pool office.
- Leave virus-scanning software enabled on portable computers.
- If it is necessary to use company data on home computers, install and use virus-scanning software.
- Use company-supplied color-coded ("red") disks to store all data used outside the company.
- If no virus-scanning software is available on external computers, virus scan all red disks before using them on company internal computers.
- Physically protect all company computing resources and red disks outside of the facility. (Remember that the value of lost data could exceed that of lost hardware.)
- Be aware of persons watching your work or eavesdropping when you work at off-site locations.
- Report any suspicious activity involving data used in an off-site location. (These might involve data discrepancies, disappearances, or unauthorized modifications.)
- Remote Access (Dial-Up) Guidelines
- If dial-up facilities are to be used, register with the information security office and obtain a random password token to be used for obtaining dial-up access.
- Encrypt all company-sensitive data files before transferring them over dial-up connections in or out of the central facility.
- Report when you no longer require dial-up access and return your password-generating token to the security office.

Exhibit 3. Portable Computing Security Checklist

SUMMARY

The use of portable computing presents very specific data security threats. For every potential threat, some countermeasure should be implemented to ensure the company's proprietary information is protected. This involves identifying the potential threats and implementing the level of protection needed to minimize these threats. By providing a reasonably secure portable computing environment, users can enjoy the benefits of portable computing and the organization can remain competitive in the commercial marketplace.

Operations Security and Controls

Patricia A.P. Fisher

Operations security and controls safeguard information assets while the data is resident in the computer or otherwise directly associated with the computing environment. The controls address both software and hardware as well as such processes as change control and problem management. Physical controls are not included and may be required in addition to operations controls.

Operations security and controls can be considered the heart of information security because they control the way data is accessed and processed. No information security program is complete without a thoroughly considered set of controls designed to promote both adequate and reasonable levels of security. The operations controls should provide consistency across all applications and processes; however, the resulting program should be neither too excessive nor too repressive.

Resource protection, privileged-entity control, and hardware control are critical aspects of the operations controls. To understand this important security area, managers must first understand these three concepts. The following sections give a detailed description of them.

RESOURCE PROTECTION

Resource protection safeguards all of the organization's computing resources from loss or compromise, including main storage, storage media (e.g., tape, disk, and optical devices), communications software and hardware, processing equipment, standalone computers, and printers. The method of protection used should not make working within the organization's computing environment an onerous task, nor should it be so flexible that it cannot adequately control excesses. Ideally, it should obtain a balance between these extremes, as dictated by the organization's specific needs.

This balance depends on two items. One is the value of the data, which may be stated in terms of intrinsic value or monetary value. Intrinsic value is determined by the data's sensitivity — for example, health- and defense-related information have a high intrinsic value. The monetary value is the potential financial or physical losses that would occur should the data be violated.

The second item is the ongoing business need for the data, which is particularly relevant when continuous availability (i.e., round-the-clock processing) is required.

When a choice must be made between structuring communications to produce a user-friendly environment, in which it may be more difficult for the equipment to operate reliably, and ensuring that the equipment is better controlled but not as user friendly (emphasizing availability), control must take precedence. Ease of use serves no purpose if the more basic need for equipment availability is not considered.

Resource protection is designed to help reduce the possibility of damage that might result from unauthorized disclosure and alteration of data by limiting opportunities for misuse. Therefore, both the general user and the technician must meet the same basic standards against which all access to resources is applied.

A more recent aspect of the need for resource protection involves legal requirements to protect data. Laws surrounding the privacy and protection of data are rapidly becoming more restrictive. Increasingly, organizations that do not exercise due care in the handling and maintenance of data are likely to find themselves at risk of litigation. A consistent, well-understood user methodology for the protection of information resources is becoming more important to not only reduce information damage and limit opportunities for misuse but to reduce litigation risks.

Accountability

Access and use must be specific to an individual user at a particular moment in time; it must be possible to track access and use to that individual. Throughout the entire protection process, user access must be appropriately controlled and limited to prevent excess privileges and the opportunity for serious errors. Tracking must always be an important dimension of this control. At the conclusion of the entire cycle, violations occurring during access and data manipulation phases must be reported on a regular basis so that these security problems can be solved.

Activity must be tracked to specific individuals to determine accountability. Responsibility for all actions is an integral part of accountability; holding someone accountable without assigning responsibility is meaningless. Conversely, to assign responsibility without accountability makes it

impossible to enforce responsibility. Therefore, any method for protecting resources requires both responsibility and accountability for all of the parties involved in developing, maintaining, and using processing resources.

An example of providing accountability and responsibility can be found in the way some organizations handle passwords. Users are taught that their passwords are to be stored in a secure location and not disclosed to anyone. In some organizations, first-time violators are reprimanded; if they continue to expose organizational information, however, penalties may be imposed, including dismissal.

Violation Processing

To understand what has actually taken place during a computing session, it is often necessary to have a mechanism that captures the detail surrounding access, particularly accesses occurring outside the bounds of anticipated actions. Any activity beyond those designed into the system and specifically permitted by the generally established rules of the site should be considered a violation.

Capturing activity permits determination of whether a violation has occurred or whether elements of software and hardware implementation were merely omitted, therefore requiring modification. In this regard, tracking and analyzing violations are equally important. Violation tracking is necessary to satisfy the requirements for the due care of information. Without violation tracking, the ability to determine excesses or unauthorized use becomes extremely difficult, if not impossible. For example, a general user might discover that, because of an administrative error, he or she can access system control functions. Adequate, regular tracking highlights such inappropriate privileges before errors can occur.

An all-too-frequently overlooked component of violation processing is analysis. Violation analysis permits an organization to locate and understand specific trouble spots, both in security and usability. Violation analysis can be used to find:

- The types of violations occurring. For example:
  - — Are repetitive mistakes being made? This might be a sign of poor implementation or user training.
  - — Are individuals exceeding their system needs? This might be an indication of weak control implementation.
  - — Do too many people have too many update abilities? This might be a result of inadequate information security design.
- Where the violations are occurring, which might help identify program or design problems.
- Patterns that can provide an early warning of serious intrusions (e.g., hackers or disgruntled employees).

A specialized form of violation examination, intrusion analysis (i.e., attempting to provide analysis of intrusion patterns), is gaining increased attention. As expert systems gain in popularity and ability, their use in analyzing patterns and recognizing potential security violations will grow. The need for such automated methods is based on the fact that intrusions continue to increase rapidly in quantity and intensity and are related directly to the increasing number of personal computers connected to various networks. The need for automated methods is not likely to diminish in the near future, at least not until laws surrounding computer intrusion are much more clearly defined and enforced.

Currently, these laws are not widely enforced because damages and injuries are usually not reported and therefore cannot be proven. Overburdened law enforcement officials are hesitant to actively pursue these violations because they have more pressing cases (e.g., murder and assault). Although usually less damaging from a physical injury point of view, information security violations may be significantly damaging in monetary terms. In several well-publicized cases, financial damage has exceeded $10 million. Not only do violation tracking and analysis assist in proving violations by providing a means for determining user errors and the occasional misuse of data, they also provide assistance in preventing serious crimes from going unnoticed and therefore unchallenged.

Clipping Levels. Organizations usually forgive a particular type, number, or pattern of violations, thus permitting a predetermined number of user errors before gathering this data for analysis. An organization attempting to track all violations, without sophisticated statistical computing ability, would be unable to manage the sheer quantity of such data. To make a violation listing effective, a clipping level must be established.

The clipping level establishes a baseline for violation activities that may be normal user errors. Only after this baseline is exceeded is a violation record produced. This solution is particularly effective for small- to medium-sized installations. Organizations with large-scale computing facilities often track all violations and use statistical routines to cull out the minor infractions (e.g., forgetting a password or mistyping it several times).

If the number of violations being tracked becomes unmanageable, the first step in correcting the problems should be to analyze why the condition has occurred. Do users understand how they are to interact with the computer resource? Are the rules too difficult to follow? Violation tracking and analysis can be valuable tools in assisting an organization to develop thorough but useable controls. Once these are in place and records are produced that accurately reflect serious violations, tracking and analysis become the first line of defense. With this procedure, intrusions are discovered before major damage occurs and sometimes early enough to catch

the perpetrator. In addition, business protection and preservation are strengthened.

Transparency

Controls must be transparent to users within the resource protection schema. This applies to three groups of users. First, all authorized users doing authorized work, whether technical or not, need to feel that computer system protection requirements are reasonably flexible and are not counterproductive. Therefore, the protection process must not require users to perform extra steps; instead, the controls should be built into the computing functions, encapsulating the users' actions and producing the multiple commands expected by the system.

The second group of users consists of authorized users attempting unauthorized work. The resource protection process should capture any attempt to perform unauthorized activity without revealing that it is doing so. At the same time, the process must prevent the unauthorized activity. This type of process deters the user from learning too much about the protective mechanism yet controls permitted activities.

The third type of user consists of unauthorized users attempting unauthorized work. With unauthorized users, it is important to deny access transparently to prevent the intruder from learning anything more about the system than is already known.

User Access Authorities

Resource protection mechanisms may be either manual or automatic. The size of the installation must be evaluated when the security administrator is considering the use of a manual methodology because it can quickly be outgrown, becoming impossible to control and maintain. Automatic mechanisms are typically more costly to implement but may soon recoup their cost in productivity savings.

Regardless of the automation level of a particular mechanism, it is necessary to be able to separate types of access according to user needs. The most effective approach is one of least privilege; that is, users should not be allowed to undertake actions beyond what their specific job responsibilities warrant. With this method, it is useful to divide users into several groups. Each group is then assigned the most restrictive authority available while permitting users to carry out the functions of their jobs.

There are several options to which users may be assigned. The most restrictive authority and the one to which most users should be assigned is read only. Users assigned to read only are allowed to view data but are not allowed to add, delete, or make changes.

The next level is read/write access, which allows users to add or modify data within applications for which they have authority. This level permits individuals to access a particular application and read, add, and write over data in files copied from the original location.

A third access level is change. This option permits the holder not only to read a file and write data to another file location but to change the original data, thereby altering it permanently.

When analyzing user access authorities, the security practitioner must distinguish between access to discretionary information resources (which is regulated only by personal judgment) and access to nondiscretionary resources (which is strictly regulated on the basis of the predetermined transaction methodology). Discretionary user access is defined as the ability to manipulate data by using custom-developed programs or a general-purpose utility program. The only information logged for discretionary access in an information security control mechanism is the type of data accessed and at what level of authority. It is not possible to identify specific uses of the data.

Nondiscretionary user access, on the other hand, is performed while executing specific business transactions that affect information in a predefined way. For this type of access, users can perform only certain functions in carefully structured ways. For example, in a large accounting system, many people prepare transactions that affect the ledger. Typically, one group of accounting analysts is able to enter the original source data but not to review or access the overall results. Another group has access to the data for review but is not able to alter the results. In addition, with nondiscretionary access, the broad privileges assigned to a user for working with the system itself should be analyzed in conjunction with the user's existing authority to execute the specific transactions needed for the current job assignment. This type of access is important when a user can be authorized to both read and add information but not to delete or change it. For example, bank tellers need access to customer account information to add deposits but do not need the ability to change any existing information.

At times, even nondiscretionary access may not provide sufficient control. In such situations, special access controls can be invoked. Additional restrictions may be implemented in various combinations of add, change, delete, and read capabilities. The control and auditability requirements that have been designed into each application are used to control the management of the information assets involved in the process.

Special Classifications. A growing trend is to give users access to only resource subsets or perhaps to give them the ability to update information only when performing a specific task and following a specific procedure.

This has created the need for a different type of access control in which authorization can be granted on the basis of both the individual requesting resource access and the intended use of that resource. This type of control can be exercised by the base access control mechanism (i.e., the authorization list, including user ID and program combinations).

Another method sometimes used provides the required access authority along with the programs the user has authorization for; this information is provided only after the individual's authority has been verified by an authorization program. This program may incorporate additional constraints (e.g., scoped access control) and may include thorough access logging along with ensuring data integrity when updating information.

Scoped access control is necessary when users need access only to selected areas or records within a resource, thereby controlling the access granted to a small group on the basis of an established method for separating that group from the rest of the data. In general, the base access control mechanism is activated at the time of resource initialization (i.e., when a data set is prepared for access). Therefore, scoped access control should be provided by the data base management system or the application program. For example, in personnel systems, managers are given authority to access only the information related to their employees.

PRIVILEGED-ENTITY CONTROL

Levels of privileges provide users with the ability to invoke the commands needed to accomplish their work. Every user has some degree of privilege. The term, however, has come to be applied more to those individuals performing specialized tasks that require broad capabilities than to the general user. In this context, a privilege provides the authority necessary to modify control functions (e.g., access control, logging, and violation detection) or may provide access to specific system vulnerabilities. (Vulnerabilities are elements of the system's software or hardware that can be used to gain unauthorized access to system facilities or data.) Thus, individuals in such positions as systems programming, operations, and systems monitoring are authorized to do more than general users.

A privilege can be global when it is applicable to the entire system, function-oriented when it is restricted to resources grouped according to a specific criterion, or application specific when it is implemented within a particular piece of application code. It should be noted that when an access control mechanism is compromised, lower-level controls may also be compromised. If the system itself is compromised, all resources are exposed regardless of any lower-level controls that may be implemented.

Indirect authorization is a special type of privilege by which access granted for one resource may give control over another privilege. For example, a user with indirect privileges may obtain authority to modify the

Class	Job Assignment	Class Access Privileges
A	General User	A
B	Programmer	B, A
C	Manager	C, A (sometimes B)
D	Security Administrator	D, B, A
E	Operator	E, D, B, A
F	System Programmer	F, E, D, B, A
G	Auditor	G, B, A

Exhibit 1. Sample Privileged-Entity Access

password of a privileged user (e.g., the security administrator). In this case, the user does not have direct privileges but obtains them by signing on to the system as the privileged user (although this would be a misuse of the system). The activities of anyone with indirect privileges should be regularly monitored for abuse.

Extended or special access to computing resources is termed privileged-entity access. Extended access can be divided into various segments, called classes, with each succeeding class more powerful than those preceding it. The class into which general system users are grouped is the lowest, most restrictive class; a class that permits someone to change the computing operating system is the least restrictive, or most powerful. All other system support functions fall somewhere between these two.

Users must be specifically assigned to a class; users within one class should not be able to complete functions assigned to users in other classes. This can be accomplished by specifically defining class designations according to job functions and not permitting access ability to any lower classes except those specifically needed (e.g., all users need general user access to log on to the system). An example of this arrangement is shown in Exhibit 1.

System users should be assigned to a class on the basis of their job functions; staff members with similar computing access needs are grouped together with a class. One of the most typical problems uncovered by information security audits relates to the implementation of system assignments. Often, sites permit class members to access all lesser functions (i.e., toward A in Exhibit 1). Although it is much simpler to implement this plan than to assign access strictly according to need, such a plan provides little control over assets.

The more extensive the system privileges given within a class, the greater the need for control and monitoring to ensure that abuses do not occur. One method for providing control is to install an access control mechanism, which may be purchased from a vendor (e.g., RACF, CA-TOP,

SECRET, and CA-ACF2) or customized by the specific site or application group. To support an access control mechanism, the computer software provides a system control program. This program maintains control over several aspects of computer processing, including allowing use of the hardware, enforcing data storage conventions, and regulating the use of I/O devices.

The misuse of system control program privileges may give a user full control over the system, because altering control information or functions may allow any control mechanism to be compromised. Users who abuse these privileges can prevent the recording of their own unauthorized activities, erase any record of their previous activities from the audit log, and achieve uncontrolled access to system resources. Furthermore, they may insert a special code into the system control program that can allow them to become privileged at any time in the future.

The following sections discuss the way the system control program provides control over computer processing.

Restricting Hardware Instructions. The system control program can restrict the execution of certain computing functions, permitting them only when the processor is in a particular functional state (known as privileged or supervisor state) or when authorized by architecturally defined tables in control storage. Programs operate in various states, during which different commands are permitted. To be authorized to execute privileged hardware instructions, a program should be running in a restrictive state that allows these commands.

Instructions permitting changes in the program state are classified as privileged and are available only to the operating system and its extensions. Therefore, to ensure adequate protection of the system, only carefully selected individuals should be able to change the program state and execute these commands.

Controlling Main Storage. The use of address translation mechanisms can provide effective isolation between different users' storage locations. In addition, main storage protection mechanisms protect main storage control blocks against unauthorized access. One type of mechanism involves assignment of storage protection keys to portions of main storage to keep unauthorized users out.

The system control program can provide each user section of the system with a specific storage key to protect against read-only or update access. In this methodology, the system control program assigns a key to each task and manages all requests to change that key. To obtain access to a particular location in storage, the requesting routine must have an identical key or the master key.

Constraining I/O Operations. If desired, I/O instructions may be defined as privileged and issued only by the system control program after access authority has been verified. In this protection method, before the initiation of any I/O operations, a user's program must notify the system control program of both the specific data and the type of process requested. The system control program then obtains information about the data set location, boundaries, and characteristics that it uses to confirm authorization to execute the I/O instruction.

The system control program controls the operation of user programs and isolates storage control blocks to protect them from access or alteration by an unauthorized program. Authorization mechanisms for programs using restricted system functions should not be confused with the mechanisms invoked when a general user requests a computing function. In fact, almost every system function (e.g., the user of any I/O device, including a display station or printer) implies the execution of some privileged system functions that do not require an authorized user.

Privilege Definition

All levels of system privileges must be defined to the operating system when hardware is installed, brought online, and made available to the user community. As the operating system is implemented, each user ID, along with an associated level of system privileges, is assigned to a predefined class within the operating system. Each class is associated with a maximum level of activity.

For example, operators are assigned to the class that has been assigned those functions that must be performed by operations personnel. Likewise, systems auditors are assigned to a class reserved for audit functions. Auditors should be permitted to perform only those tasks that both general users and auditors are authorized to perform, not those permitted for operators. By following this technique, the operating system may be partitioned to provide no more access than is absolutely necessary for each class of user.

Particular attention must be given to password management privileges. Some administrators must have the ability and therefore the authorization to change another user's password, and this activity should always be properly logged. The display password feature, which permits all passwords to be seen by the password administrator, should be disabled or blocked. If not disabled, this feature can adversely affect accountability, because it allows some users to see other users' passwords.

Privilege Control and Recertification

Privileged-entity access must be carefully controlled, because the user IDs associated with some system levels are very powerful and can be used

inappropriately, causing damage to information stored within the computing resource. As with any other group of users, privileged users must be subject to periodic recertification to maintain the broad level of privileges that have been assigned to them. The basis for recertification should be substantiation of a continued need for the ID. Need, in this case, should be no greater than the regular, assigned duties of the support person and should never be allocated on the basis of organizational politics or backup.

A recertification process should be conducted on a regular basis, at least semi-annually, with the line management verifying each individual's need to retain privileges. The agreement should be formalized yet not bureaucratic, perhaps accomplished by initialing and dating a list of those IDs that are to be recertified. By structuring the recertification process to include authorization by managers of personnel empowered with the privileges, a natural separation of duties occurs. This separation is extremely important to ensure adequate control. By separating duties, overallocation of system privileges is minimized.

For example, a system programmer cannot receive auditor privileges unless the manager believes this function is required within the duties of the particular job. On the other hand, if a special project requires a temporary change in system privileges, the manager can institute such a change for the term of the project. These privileges can then be canceled after the project has been completed.

Emergency Procedures. Privileged-entity access is often granted to more personnel than is necessary to ensure that theoretical emergency situations are covered. This should be avoided and another process employed during emergencies — for example, an automated process in which support personnel can actually assign themselves increased levels of privileges. In such instances, an audit record is produced, which calls attention to the fact that new privileges have been assigned. Management can then decide after the emergency whether it is appropriate to revoke the assignment. However, management must be notified so the support person's subsequent actions can be tracked.

A much more basic emergency procedure might involve leaving a privileged ID password in a sealed envelope with the site security staff. When the password is needed, the employee must sign out the envelope, which establishes ownership of the expanded privileges and alerts management. Although this may be the least preferred method of control, it alerts management that someone has the ability to access powerful functions. Audit records can then be examined for details of what that ID has accessed. Although misuse of various privileged functions cannot be prevented with this technique, reasonable control can be accomplished without eliminating the ability to continue performing business functions in an efficient manner.

Activity Reporting. All activity connected with privileged IDs should be reported on logging audit records. These records should be reviewed periodically to ensure that privileged IDs are not being misused. Either a sample of the audit records should be reviewed using a predetermined methodology incorporating approved EDP auditing and review techniques or all accesses should be reviewed using expert system applications. Transactions that deviate from those normally conducted should be examined and, if necessary, fully investigated.

Under no circumstances should management skip the regular review of these activities. Many organizations have found that a regular review process deters curiosity and even mischief within the site and often produces the first evidence of attempted hacking by outsiders.

CHANGE MANAGEMENT CONTROLS

Additional control over activities by personnel using privileged access IDs can be provided by administrative techniques. For example, the most easily sidestepped control is change control. Therefore, every computing facility should have a policy regarding changes to operating systems, computing equipment, networks, environmental facilities (e.g., air-conditioning, water, heat, plumbing, electricity, and alarms), and applications. A policy is necessary if change is to be not only effective but orderly, because the purpose of the change control process is to manage changes to the computing environment.

The goals of the management process are to eliminate problems and errors and to ensure that the entire environment is stable. To achieve these goals, it is important to:

- *Ensure orderly change.* In a facility that requires a high level of systems availability, all changes must be managed in a process that can control any variables that may affect the environment. Because change can be a serious disruption, however, it must be carefully and consistently controlled.
- *Inform the computing community of the change.* Changes assumed to affect only a small subsection of a site or group may in fact affect a much broader cross-section of the computing community. Therefore, the entire computing community should receive adequate notification of impending changes. It is helpful to create a committee representing a broad cross-section of the user group to review proposed changes and their potential effect on users.
- *Analyze changes.* The presentation of an intended change to an oversight committee, with the corresponding documentation of the change, often effectively exposes the change to careful scrutiny. This analysis clarifies the originator's intent before the change is implemented and is helpful

in preventing erroneous or inadequately considered changes from entering the system.

- *Reduce the impact of changes on service.* Computing resources must be available when the organization needs them. Poor judgment, erroneous changes, and inadequate preparation must not be allowed in the change process. A well-structured change management process prevents problems and keeps computing services running smoothly.

General procedures should be in place to support the change control policy. These procedures must, at the least, include steps for instituting a major change to the site's physical facility or to any major elements of the system's software or hardware. The following steps should be included:

1. *Applying to introduce a change.* A method must be established for applying to introduce a change that will affect the computing environment in areas covered by the change control policy. Change control requests must be presented to the individual who will manage the change through all of its subsequent steps.
2. *Cataloging the change.* The change request should be entered into a change log, which provides documentation for the change itself (e.g., the timing and testing of the change). This log should be updated as the change moves through the process, providing a thorough audit trail of all changes.
3. *Scheduling the change.* After thorough preparation and testing by the sponsor, the change should be scheduled for review by a change control committee and for implementation. The implementation date should be set far enough in advance to provide the committee with sufficient review time. At the meeting with the change control committee, all known ramifications of the change should be discussed. If the committee members agree that the change has been thoroughly tested, it should be entered on the implementation schedule and noted as approved. All approvals and denials should be in writing, with appropriate reasons given for denials.
4. *Implementing the change.* The final step in the change process is application of the change to the hardware and software environment. If the change works correctly, this should be noted on the change control form. When the change does not perform as expected, the corresponding information should be gathered, analyzed, and entered on the change control form, as a reference to help avoid a recurrence of the same problem in the future.
5. *Reporting changes to management.* Periodically, a full report summarizing change activity should be submitted to management. This helps ensure that management is aware of any quality problems that may have developed and enables management to address any service problems.

These steps should be documented and made known to all involved in the change process. Once a change process has been established, someone must be assigned the responsibility for managing all changes throughout the process.

HARDWARE CONTROL

Security and control issues often revolve around software and physical needs. In addition, the hardware itself can have security vulnerabilities and exposures that need to be controlled. The hardware access control mechanism is supported by operating system software. However, hardware capabilities can be used to obtain access to system resources. Software-based control mechanisms, including audit trail maintenance, are ineffective against hardware-related access. Manual control procedures should be implemented to ensure that any hardware vulnerability is adequately protected.

When the system control program is initialized, the installation personnel select the desired operating system and other software code. However, by selecting a different operating system or merely a different setup of the operating system (i.e., changing the way the hardware mechanisms are used), software access control mechanisms can be defeated.

Some equipment provides hardware maintenance functions that allow main storage display and modification in addition to the ability to trace all program instructions while the system is running. These capabilities enable someone to update system control block information and obtain system privileges for use in compromising information. Although it is possible to access business information directly from main storage, the information may be encrypted. It is simpler to obtain privileges and run programs that can turn encrypted data into understandable information.

Another hardware-related exposure is the unauthorized connection of a device or communications line to a processor that can access information without interfacing with the required controls. Hardware manufacturers often maintain information on their hardware's vulnerabilities and exposures. Discussions with specific vendors should provide data that will help control these vulnerabilities.

Problem Management

Although problem management can affect different areas within computer services, it is most often encountered in dealing with hardware. This control process reports, tracks, and resolves problems affecting computer services. Management should be structured to measure the number and types of problems against predetermined service levels for the area in which the problem occurs. This area of management has three major objectives:

1. Reducing failures to an acceptable level.
2. Preventing recurrences of problems.
3. Reducing impact on service.

Problems can be organized according to the types of problems that occur, enabling management to better focus on and control problems and thereby providing more meaningful measurement. Examples of the problem types include:

- Performance and availability.
- Hardware.
- Software.
- Environment (e.g., air-conditioning, plumbing, and heating).
- Procedures and operations (e.g., manual transactions).
- Network.
- Safety and security.

All functions in the organization that are affected by these problems should be included in the control process (e.g., operations, system planning, network control, and systems programming).

Problem management should investigate any deviations from standards, unusual or unexplained occurrences, unscheduled initial program loads, or other abnormal conditions. Each is examined in the following sections.

Deviations from Standards. Every organization should have standards against which computing service levels are measured. These may be as simple as the number of hours a specific CPU is available during a fixed period of time. Any problem that affects the availability of this CPU should be quantified into time and deducted from the available service time. The resulting total provides a new, lower service level. This can be compared with the desired service level to determine the deviation.

Unusual or Unexplained Occurrences. Occasionally, problems cannot be readily understood or explained. They may be sporadic or appear to be random; whatever the specifics, they must be investigated and carefully analyzed for clues to their source. In addition, they must be quantified and grouped, even if in an Unexplained category. Frequently, these types of problems recur over a period of time or in similar circumstances, and patterns begin to develop that eventually lead to solutions.

Unscheduled Initial Program Loads. The primary reason a site undergoes an unscheduled initial program load (IPL) is that a problem has occurred. Some portion of the hardware may be malfunctioning and therefore slowing down, or software may be in an error condition from which it cannot recover. Whatever the reason, an occasional system queue must be

cleared, hardware and software cleansed and an IPL undertaken. This should be reported in the problem management system and tracked.

Other Abnormal Conditions. In addition to the preceding problems, such events as performance degradation, intermittent or unusual software failures, and incorrect systems software problems may occur. All should be tracked.

Problem Resolution

Problems should always be categorized and ranked in terms of their severity. This enables responsible personnel to concentrate their energies on solving those problems that are considered most severe, leaving those of lesser importance for a more convenient time.

When a problem can be solved, a test may be conducted to confirm problem resolution. Often, however, problems cannot be easily solved or tested. In these instances, a more subjective approach may be appropriate. For example, management may decide that if the problem does not recur within a predetermined number of days, the problem can be considered closed. Another way to close such problems is to reach a major milestone (e.g., completing the organization's year-end processing) without a recurrence of the problem.

SUMMARY

Operations security and control is an extremely important aspect of an organization's total information security program. The security program must continuously protect the organization's information resources within data center constraints. However, information security is only one aspect of the organization's overall functions. Therefore, it is imperative that control remain in balance with the organization's business, allowing the business to function as productively as possible. This balance is attained by focusing on the various aspects that make information security not only effective but as simple and transparent as possible.

Some elements of the security program are basic requirements. For example, general controls must be formulated, types of system use must be tracked, and violations must be tracked in any system. In addition, use of adequate control processes for manual procedures must be in place and monitored to ensure that availability and security needs are met for software, hardware, and personnel. Most important, whether the organization is designing and installing a new program or controlling an ongoing system, information security must always remain an integral part of the business and be addressed as such, thus affording an adequate and reasonable level of control based on the needs of the business.

DATA CENTER SECURITY: USEFUL INTRANET SECURITY METHODS AND TOOLS

John R. Vacca

INSIDE

INTRODUCTION

Information technology (IT) is now used universally to support critical enterprise business decisions. It has evolved beyond basic applications such as billing and inventory, to the point where it directly supports customers and the manufacturing process. This sophisticated enterprise business information technology is entirely dependent on the diverse (and often incompatible) operating systems and hardware data center environments needed for their execution. All these systems must be managed and maintained if they are to continue to provide support for the ever-increasing applications on which the enterprise's data center depends. Information technology has a significant impact on the effectiveness of the intranet as a whole. Consequently, competitive performance of the enterprise is now directly affected by the management and control of data center computer resources.

The measure of IT management's success or failure to support the enterprise is based on its ability to establish and meet required levels of performance, reliability, and availability — while staying within budgetary constraints.

PAYOFF IDEA

This article provides IT managers with a set of data center management and intranet security software tools and methods. The information presented in this article will enable IT management to better meet the challenges inherent in managing data center services, costs, and security as the use of distributed systems becomes evermore critical to the enterprise.

The management and control of complex intranets and data centers are, however, daunting challenges to be met by IT professionals in the next decade. Some key areas that must be achieved are to:

- establish and consistently meet service-level agreements with end users
- control costs to meet service levels at the lowest possible level of investment
- protect the wealth of enterprise information and key resources that often span multiple operating systems and hardware platforms

In addition, IT management must not only achieve and maintain all these goals, but it must do this while ensuring complete system integrity at all times. An increasingly large role in enterprise computing is being played by intranet and client/server configurations of midrange and desktop computing environments, and open systems such as UNIX-based data center environments. Downsizing and decentralizing of processing resources is a result of the evolution toward a more global view — one that is replacing the traditional mainframe view of IT management.

In other words, IT management recognizes more and more that it needs both diverse and complementary information processing technologies if it is to meet the needs of the enterprise. Consequently, there has been substantial growth in complex heterogeneous systems that span multiple computing platforms. This leaves systems and data center intranet security management to contemplate some new concerns: it must now be recognized that midrange and desktop computing environments collectively represent a significant investment in information processing power. It must bring to each computing platform the standard systems management functionality that has been required on large mainframe systems: the need for the same level of automation, resource management, intranet security, and data integrity. Data center intranet security management is essential today for distributed systems, and this provides IT management with new challenges.

INTRANET SECURITY SOFTWARE AND SYSTEMS MANAGEMENT

In many ways, the challenges of distributed systems and data center intranet security management are the same as those of distributed applications. End-user applications, such as manufacturing and general ledger systems, are built on known database structures and application objectives. Distributed systems and data center intranet security management solutions, however, must address a very diverse and often perplexing variety of environments.

There are vast differences in the various operating systems of each platform, and management for distributed systems and data center intra-

net security must adjust accordingly. In order to present a unified whole, the goal is to insulate the administrator from the specific vagaries of each system.

Having the software solutions needed to provide comprehensive systems and data center intranet security management on each platform in the intranet is a significant part of mastering distributed systems and intranet security management. These solutions alone are only effective, however, if they can be tied together into a single point of management. Systems and intranet security administrators must be able to manage all or any desired part of the enterprise from any location within the intranet. Single point of management allows administrators to implement and enforce overall enterprise policies while continuing to provide the local controls necessary in a constantly changing environment to ensure responsiveness.

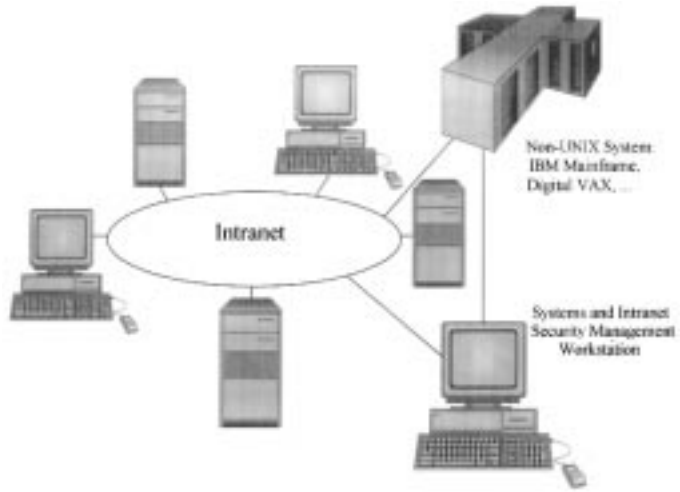
IT management must be able to provide the consistent, high service levels that are required by enterprises. Systems management and intranet security software should deliver integrated, total data center and intranet automation capabilities. At the same time, it should make possible the controlling of costs and ensuring protection of valuable data and resources. For example, enterprises provide distributed systems and intranet security management across multiple platforms. They also provide the ability to endorse and extend industry standards. This allows data center management software to be compliant with, fully support, and extend the capabilities of the Open Software Foundation's (OSF) initiatives for DCE (distributed computing environment) and DME (distributed management environment).

Systems and data center intranet security management software should provide a single point of management for complex heterogeneous systems. For example, data center management software should provide a single point of management through three strategic elements.

1. It meets the specific needs of the platform and exploits the special characteristics and benefits of each by providing robust solutions that are appropriate to each platform.
2. It has a flexible manager–agent architecture that enables each solution to work cooperatively with other solutions in the intranet; managing the flow of work; or performing work on behalf of other solutions in the intranet.
3. It provides a flexible user interface that enables each and every solution within the data center environment to be managed from a single location or multiple locations if desired.

This third element is known as the systems and data center intranet security management workstation, as shown in Exhibit 1, it provides sys-

EXHIBIT 1 — The Systems Management and Intranet Security Workstation



tems and data center intranet security management for a homogeneous or heterogeneous intranet.

INTRANET SECURITY AND SYSTEMS MANAGEMENT WORKSTATION

When managing all of the solutions in the data center environment, a systems and intranet security management workstation should provide the systems and intranet security administrator with a GUI (graphical user interface)-based user interface. Such a workstation could be used to administer a single UNIX system, a remote IBM mainframe, an OS/2 or Novell-based LAN, or even a heterogeneous intranet containing all of these components and others such as the IBM AS/400 and Digital VAX/VMS. The systems and intranet security management workstation should operate on a lower cost X-terminal.

For example, in an enterprise's systems management workstation, the modern interface reduces the complexity of systems and intranet security management. It also provides an intuitive and logical view of otherwise complex issues. The GUI adjusts for the particular aspects of each environment, where necessary. For example, the user interface is identical when managing a multi-node job scheduler for defining jobs within job sets; or, schedules and their relationships to one another. However, when opening up a job detail window for actually setting up individual jobs, the GUI would present a job from an IBM MVS system as a collection of JCL (Job Control Language) statements. A job on UNIX would display as

a shell script, while a job on Digital VAX/VMS would contain Digital Control Language (DCL) in place of JCL or shell statements.

Control and flexibility of this type is essential for distributed systems and data center intranet security management. Being able to manage each platform from a common location with a common interface, and preserving the concepts and terminology across the intranet, are extremely useful — along with having the tools needed on each platform.

Investments in the training of systems and data center intranet security administration personnel can be leveraged into new platforms by maintaining the model for each solution across the system. For example, users familiar with ACF2 or TOP SECRET security systems on IBM MVS would find the workload management and intranet security provided through UNIX familiar and easily understood.

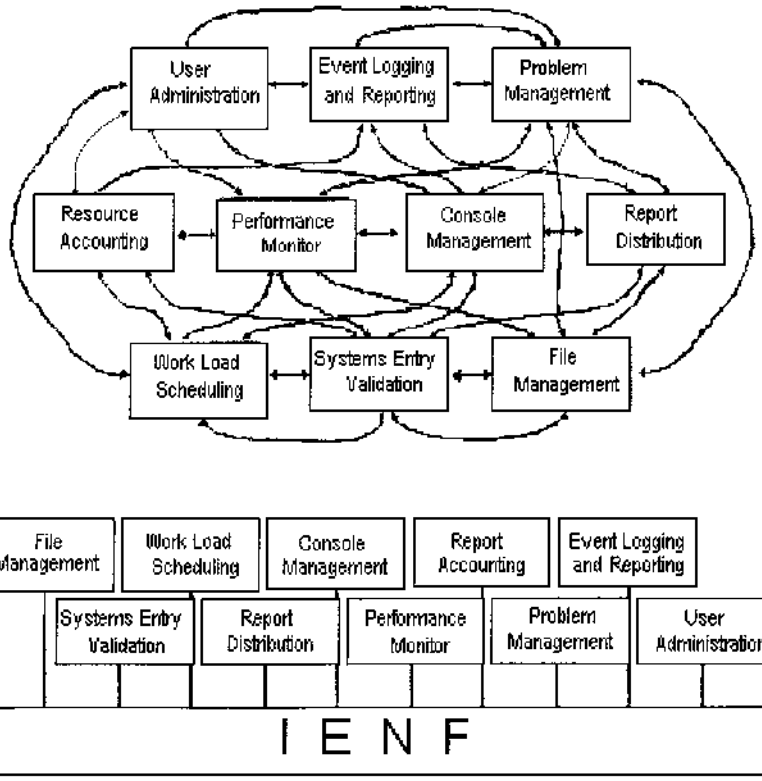
THE CONNECTIVITY FACTOR

An enterprise's systems and intranet security management software should cover a broad range of interrelated functions required to manage and control data center and intranet activity. In addition, it should utilize service layers to interact with each other, adding value to the intranet's information technology systems as a whole.

Furthermore, an enterprise's blueprint for a software architecture and its underlying guiding principles should try to provide a comprehensive strategy for software development for the IT community. This approach, where all components work together across multiple platforms, is essential in maintaining sufficient responsiveness to the continually evolving priorities of enterprise-driven information processing requirements.

Automating each area of systems and data center intranet security management does not in itself result in a complete and successful approach to systems management. Each component of the systems and intranet security management solution must support and communicate with every other component in order to achieve total data center and intranet automation. For example, intranet-wide information security cannot be ensured if each systems management solution uses its own security tables. Problem and change management cannot keep pace with the dynamic activities of large and complex data center environments if software that addresses functions such as scheduling, report distribution, storage management, and security cannot automatically open and update problem incidents. Clearly, global workload management is unattainable unless each platform provides workload scheduling and resource balancing capabilities that interface with all other platforms. Therefore, complete and effective integration requires both a design for integration and an architecture that support development and enhancement of the completely integrated solution. As shown in Exhibit 2 for an IENF, an enterprise's services enable the integration of systems and data center intranet

EXHIBIT 2 — An Integration Event Notification Facility (IENF)



security management functions without an uncontrollable and unmanageable explosion of interfaces.

POWERFUL SOLUTIONS

The rule-based policies that govern data center procedures are particularly well-suited to automation and can be handled by systems and intranet security management software. This automation capability is essential in addressing the complex activities of multi-vendor and multi-operating system intranet environments where a variety of procedures are generally followed due to the variation in capabilities provided by the native platforms. An enterprise's systems management and intranet security software should simplify the management of these complex data center environments by extending native platform capabilities wherever necessary to ensure operational consistency, regardless of platform.

EXHIBIT 3 — Systems and Intranet Security Management

The otherwise numerous and complex procedures are significantly reduced, enabling operations staff to become familiar with all aspects of a streamlined, unified system. This dramatically reduces the training required of operational staff, particularly in complicated subsystem procedures, and eliminates the need for multiple subsystem specialists to closely monitor data center and intranet activities. An enterprise's systems management and intranet security software should provide a robust, fully integrated, distributed solution that covers the essential disciplines of automated production control, automated storage management, performance management and accounting, data center administration, and security, control, and audit (see Exhibit 3).

To completely automate information technology systems and derive maximum benefit, all of these components must be present for all platforms. Vendors that offer only a part of this functionality and limit the functionality to specific platforms cannot effectively assist IT management in meeting its service-level objectives.

AUTOMATED PRODUCTION CONTROL SOLUTIONS

A data center should provide an integrated set of solutions for automated production control. These solutions cover all areas of functionality, including workload management; rerun, restart, and recovery; console management; report distribution; control language validation; report balancing; and production documentation.

Automated Workload Management

Workload management is concerned with complete automated management of production workloads, including workload balancing, automatic submission and tracking of work based on user-defined scheduling criteria, priority, and system resource availability. This ensures that work is completed correctly and that critical deadlines are met.

Automated Rerun, Restart, and Recovery

Rerun, restart, and recovery automates the often complex, manual-intensive, and error-prone rerun and recovery process, thus enabling processing to restart at the optimum recovery point. In addition, it automatically handles the otherwise time-consuming manual procedures such as job setup, data set recovery, and backout.

Automated Console Management

Console management improves operating efficiency and reduces errors by automating the handling of console messages. It provides an advanced message/action capability that can alter, suppress, or reply to messages or initiate other actions, such as automatically issuing IPL/IMLs, alerts (through voice and pager notification capabilities), commands or invoking programs based on the content, and frequency and other characteristics of the message traffic. In addition, selective action based on specific console and terminal IDs allows the assignment of consoles to specialized applications, such as intranet monitoring, system monitoring, or tape mount processing. A simulation capability is also provided to assist in the development and verification of these event/action criteria.

When used in conjunction with a programmable workstation, this software provides a single focal point for all console operation activities in a multi-CPU, multi-operating system, and intranet environment. In addition, remote access to perform console management is available through remote dial-ups (PC, remote TSO, CICS, session) or through the telephone using the latest voice and touch-tone technology.

Automated Report Distribution Function

Report distribution provides extensive capabilities for the flexible and efficient production, tracking, and distribution of reports. This results in speeding the delivery time, increasing the accuracy, and improving the tracking of reports. Facilities are provided that automatically identify pages from existing reports, place them into bundles, and sort them by delivery location prior to actual printing.

These capabilities provide end users with the information they want, when and where they need it, while reducing or eliminating redundant information and the materials and efforts that are wasted in its distribu-

tion. Automated report distribution software also provides online viewing capabilities that can reduce the need for a hard copy of reports as well as the option to select all or parts of reports for printing. Report archiving capabilities enable the storing of reports offline for auditing purposes and for future viewing or reprinting.

A data center's report management software on intelligent workstations should extend report management capabilities by enabling end users to receive reports as files on their local computer. The ability to merge, annotate, or change reports using a familiar computer should be automated by the workstation-based software, and redistribution of these new reports should be provided through interaction with the software on the host system.

Advanced Control Language Validation

Virtually all systems in use today provide an interpretive control language for defining the execution of batch and online processing. Examples of these languages include IBM Job Control Language (JCL) and the UNIX Shell Script language. A data center's design for systems and intranet security management should include complete advanced control language validation capabilities that reduce or eliminate errors that can cause failures during production execution, and that aid the end user in diagnosing problems with control language programs. In addition, this software should enforce site-specific standards while providing the reports and cross-reference information that are needed for future maintenance.

Automated Report and File Balancing

Report balancing consists of extensive, automated report and file balancing capabilities that enable a quality level to be achieved that is unavailable through manual efforts. In addition to automatically ensuring the accuracy of reports after they are printed, this software can uniquely catch errors during the execution of production work cycles (both enabling fast and accurate resolution of problems), and prevent the completion of in-error production runs and the distribution of incorrect report output.

Production Control Documentation

Production documentation provides complete and consistent centralized online documentation system for the production control environment. Integration with other production control software enables documentation efforts to be automated and centralized, ensuring accessible and accurate information essential to data center operations, and particularly for contingency planning, disaster recovery, and future maintenance.

AUTOMATED STORAGE MANAGEMENT SOFTWARE

Automated storage management (ASM) software significantly extends the native operating system's capabilities of storage and resource management. This software optimizes performance and access to information. It ensures availability, integrity, and reliability — regardless of the various media device types and differing configurations of mainframes, midrange computers, PCs, and LANs that define the IT processing environment.

Backup Management

Backup management provides the ability to back up files based on creation date and version, as well as supporting backups of multiple versions of the same file. It keeps track of which volume each file has been backed up to.

It also enables users, system, and intranet security administrators to view the media (tape versus disk) and version of each backed-up file — and easily initiate a restore if needed. Backup management eliminates the problem of keeping track of where backed-up files are kept, and how to find them when a restore is needed.

Archive Management

Archive management makes sure that files have been removed from the online disk system and stored on other media that are based on storage management policies and are available when needed. It ensures that enough storage is always available on the file system to keep users working.

Archive Transparent Restore Processing

Through an automated storage management (ASM) common file catalog, the archive management function can locate and initiate a restore of an archived file without user intervention. This function is known as automatic transparent restore, or IXR. With IXR processing, the user request, process, or program attempting to access an archived file is automatically suspended, the file is restored by ASM, and the process is allowed to continue without failure. IXR helps to ensure a successful file management plan by removing the greatest fear that users have of any storage management system — not having their data when they need it.

Threshold-Based Archiving

A specialized capability of an archive management function is threshold-based archiving. Regardless of how careful systems and intranet security administrators are in defining archive policies, inevitably there will come a time when a process unexpectedly demands more storage from the file system than was anticipated. Sudden and unexpected file shortages can

be disastrous to planned work and the users of the system — as the file system becomes exhausted and work halts. Up until now, the only answer was to run another backup as quickly as possible, and try to guess which files could be deleted without causing too much other disruption. This process was slow, disruptive, and error-prone at best. Threshold-based archiving utilizes a common file catalog to determine which of the next set of files eligible for archive are currently backed up. The catalog is then updated to indicate that the files have been archived, and deletes it from the disk file system. No additional backups are taken, no best guesses are made, and no costly disruption of work in progress results. IXR, of course, stands ready to bring back any file needed.

MULTIMEDIA STORAGE MANAGEMENT

Multimedia management uses a rule-based, policy-oriented design to provide comprehensive storage resource functions for a wide variety of media, both permanently mounted file storage devices and removable tape, WORM, and erasable optical technologies. These functions include space management, allocation control and management, I/O optimization, volume defragmentation, and mount management. Each of these capabilities is designed to provide the best possible utilization of the storage devices available, while maintaining the service levels defined by the enterprise's storage management policies.

Extended Data Storage Management

Extended data management enhances and fully automates all data management functions, regardless of platform. It includes reformatting, sorting, compression, and optimization of data seamlessly and independent of physical file organization and data format.

Performance and Error Management

Through data integrity and device failure recovery facilities, system throughput can be optimized and disruptions caused by failures can be minimized. In addition, high-cost, high-performance options of disk devices can be exploited to their full potential.

Finally, take a look at yet another useful data center intranet security method and tool — xswatch.

WHAT IS XSWATCH?

Xswatch, like its predecessors, was built to watch log files for interesting information. Most log files that grow at a reasonably fast rate have a lot of data, but little useful information. There are several extant implementations that either scan an entire log file or use the equivalent of *tail -f* to monitor the file as new lines are added to it. They then cull log mes-

sages that are deemed important or interesting to the implementor. These implementations can be as simple as *tail -f | grep pattern* to ones that are as complex as a full-blown C program complete with its own macro language.

All of these programs have the same basic structure: match a line of text against a pattern/action pair. If the pattern matches, execute the associated action. The application is up to the end user. For example, watching /var/adm/messages for *file system full,* then executing a job to remove all core files older than one day from the file system. Another example is monitoring for authentication failures. A third might be to send a page to an operator in case of an intranet fault.

Xswatch extends this idea by creating a very general architecture that allows the end user to execute almost any arbitrary pattern/action pair. It takes advantage of the PERL programming language's ability to create code on-the-fly instead of imposing a specialized syntax. The result is a workbench for monitoring almost anything that uses a log file.

What Is the Motivation for Writing It?

The motivation for writing (yet another) log watching program was something that did not have a limited subset of the functionality of the language the engine was written in (PERL). Something was also needed that would monitor multiple files simultaneously. Also, an application was needed that had at least the ability to scale. Xswatch's architecture depends on forwarding syslog entries to a central server. On a large intranet, the number of syslog datagrams could consume a significant amount of intranet bandwidth. It seems better to have xswatch running on many machines, forward only the important data to a central server, and leave the uninteresting data on the local machine. Finally, writing xswatch is an experiment in code reuse and software integration. A primary design goal was to avoid reinventing the wheel wherever possible. For xswatch, there was at least partial success achieving these goals.

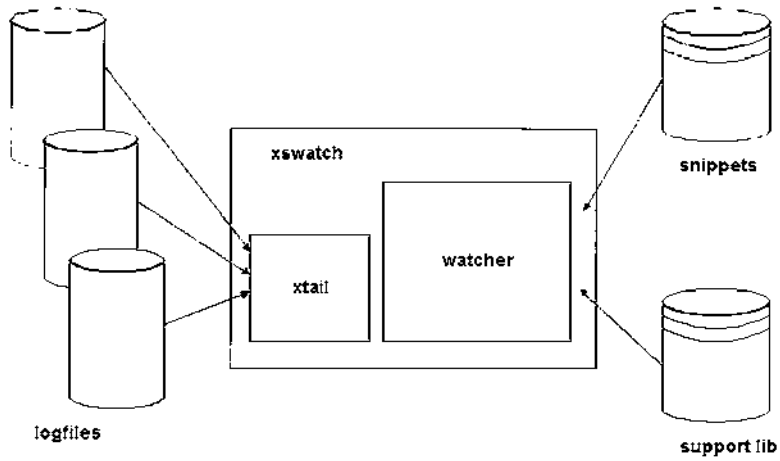
The Xswatch Components

Xswatch has four main components: an engine, snippets, support libraries, and log files, as shown in Exhibit 4. The engine is a small PERL program that essentially manages system resources for the user. The engine consists of four subparts: xtail, a signal handler, an event server, and a watcher function.

The Engine Itself

Xtail is a C program that tails off multiple log files at once. Xtail is the most operating system-dependent part of xswatch. It tracks each file for conditions such as rollovers, truncations, even appearance and disappearance of files.

EXHIBIT 4 — Xswatch Architecture



The signal handler is mostly for managing xswatch in the background. Sending a SIGHUP signal will tell xswatch to kill the current xtail process, reset internal variables, and reload all of the snippets and resume operation. In this way, one can add or remove snippets without halting a running xswatch process. Sending a SIGQUIT signal will tell xswatch to write out configuration information to /tmp. This is useful for debugging snippets. Sending a SIGINT or SIGTERM will tell xswatch to shut down gracefully.

The event server is a PERL module that handles the general housekeeping chores of managing system resources such as I/O, child processes, signals, and timers. The watcher function is a PERL function call (like any other PERL function), except that the function itself is created on-the-fly, based on snippets. Watcher provides the structure that holds the snippets together. Watcher will be called once by the event server for every line of input from xtail.

Snippets

Just what are snippets anyway? The Webster dictionary definition of snippet is a small part, piece, or thing; specifically, a brief quotable passage. For xswatch, a snippet is a small piece of PERL code that handles pattern/action pairs. They have a very simple structure. There is an initialization section that uses the standard PERL *BEGIN* block and then some code, the simplest of which can be:

```
/... some regular expression ... / && do {
... some action ...;
}
```

Snippets are catenated together and compiled into the watcher function. Watcher will be called each time there is a new line of input data written to a log file. The watcher function provides just two pieces of data: an input buffer in *$_*, and the name of the log file where the data came from in *$logfile*. Anything else is up to the snippets.

The snippets are organized in a directory with file names that mimic the *System V rc.d* directories, (*nn.Description*, where *nn* is a two-digit string ranging from 00 to 99). The description can be anything (hopefully informative), with its length determined by the limits of the underlying operating system. This provides a simple way to order execution of the snippets without cutting and pasting. It is also an easy way to temporarily disable snippets. By changing the name from *10.Snippet to stopl0.Snippet*, or anything that does not begin with *nn.*, xswatch will not load the code and compile it into the watcher function. There are no restrictions as to what goes into a snippet. So, if a programmer wanted to put all his code in a single file, xswatch would work just as well as with many smaller files.

The *BEGIN* block is where each snippet should register which log files it wants to monitor. This is done with the PERL *push* call:

```
BEGIN {
push @watchfiles, '/var/adm/messages';
}
```

Registering the same file more than once (that is, in more than one snippet), is allowed. Xswatch will reduce the log files to a unique list. This is because so many people can add or subtract snippets from a common directory and not worry about interfering with other snippets. Notice in the following code that there are a lot of *BEGIN* blocks, and they are actually inside the function call definition of *watcher.* Not to worry though; when PERL compiles the function, the *BEGIN* blocks are executed immediately, once, and never again. When the watcher function is actually called by the event server, the *BEGIN* blocks are not touched.

Support Libraries

Since the snippets are simply PERL scripts, support libraries can be anything one needs or wants. For example, one can use the *Term::Cap* module for setting screen attributes, or one of the date and time parsers to convert the log file time stamp into seconds. Or one can include one's own modules to send a message to one's pager or e-mail.

Useful Features

Xswatch has a number of useful features. First, it is simple. Second, it uses no new grammars. Third, the use of snippets is widely accepted.

Fourth, it can be extended using standard PERL libraries and contributed code. Finally, it is scalable.

A Simple Engine

The engine is simple. The main program is seven lines of code. It knows nothing about its inputs and does nothing with them except to pass them to the snippets in the form of the watcher function. This minimizes code maintenance:

```
$result = GetOptions(qw(help snippet-dir=s debug=i version));
usage("invalid parameters") unless $result;
usage("$0: v$version") if $opt_version;
parse_command_line;
init;
start_server;
exit(0);
```

No New Grammars

Instead of worrying about learning yet another macro language, parsing, and the accompanying errors, xswatch uses PERL itself. As previously mentioned, PERL is well-suited for creating code on-the-fly. It also cuts down on training time. If one knows how to code in PERL, one can write snippets for xswatch. One does not have to look around in the documentation for a syntax guide. Finally, PERL does a much better job at parsing and compiling code than one would ever want to write for a specialized tool like xswatch.

Shortening the Development Cycle

Prototyping and testing are simplified because snippets are written in PERL. One can use *perl -cw* to check the syntax just like any other PERL script. If what one is looking for in a log file has a time domain component, one can do several things: save a time stamp in a variable and set an alarm, or create a new event using the event server. The source code shows a more elaborate sample that checks that the number of authentication failures from log-in does not exceed a certain threshold. This is to handle cases where a user dials in on a noisy phone line. The log-in program will record an authentication failure, but this is not really something to worry about. On the other hand, if xswatch saw repeated login failures over a short period of time, one could guess that someone is trying to penetrate the intranet.

Finally, snippets are readable (well, as readable as PERL code gets). One can document snippets, put them under source code management, and essentially treat them like any other body of code:

```
BEGIN {
    push @watchfiles, '/var/log/authlog';
    require PagerTools;
}
if ($logfile eq '/var/log/authlog') {
TIMER_RESET:
    if (/INVALID|REPEATED|INCOMPLETE/) {
    if (!defined $auth-trigger) {
        $auth_trigger =
        register_timed_client([],600,sub ($hit-count=0});
    } else {
        cancel_registration($auth_trigger);
        if ($hit_count++ > 5) {
            Pager::call_pager oncall, 'Authentication alert';
        }
            undef $auth_trigger;
            goto TIMER_RESET;
            }
        }
    }
```

Scaling

As the number of systems to monitor increases, syslog packets flying back and forth might become a significant load on the intranet resources. By using xswatch to filter out information at the local machine level, one could create an intranet of xswatches that (using the standard PERL Sys::Syslog module) connects to a parent syslog daemon and forwards messages to a centralized server.

Distilling Data into Information

There are a number of applications for xswatch, and one of the most important is distilling data into information. One of a system and intranet security administrator's key duties is to reduce, or at least maintain, entropy. Systems and intranets have a natural tendency toward increasing entropy. System and intranet security administrators are constantly bombarded with log files, e-mail messages, pages, even voice mail. Anyone who has ever had to plow through */var/log/syslog* looking for some clue as to what went wrong knows that it would be far better if, somehow, the system knew what was important and notified a human being in real-time. Xswatch allows an administrator, or even a group of administrators, to consolidate empirical knowledge (about log files) into a single directory. Snippets contain bits of experience learned over time about what to look for in a log file, and what to do about it. Another approach is discard the expected; everything else must be a fault or of some interest. In reference to firewalls, one really does not care when the system resists

an attack, or someone tries to access a blocked port; the firewall has done its job. What one really wants to log is when something goes wrong.

Downsides of Xswatch

Xswatch has its flaws. During the development process, a few issues arose that should not come as a surprise — but did anyway. PERL-centrism is seductive. During the early development of xswatch, and after several ineffective attempts, it was clear that although PERL may be portable, there are some things that really are better implemented in C or some other compiled 3GL. PERL is not cheap. A long-running PERL process will consume about 2 MB of virtual memory on a SPARCstation 5 running SunOS. The resident set size hovered around 1200 KB. Even so, the good news is that there need be only one of these processes running on any given machine. Also, if one considers that an xterm process consumes almost 500 KB, one xswatch process does not hurt so much.

The holy grail of code reuse also has its problems. The most recent version of the EventServer module was incompatible with PERL. Contributed modules tend to lag behind releases of the main body of code, so it is important to track each revision carefully. There are also many PERL modules that, although useful and publicly available, would not work without some effort. Hopefully, as the body of available code matures, these library modules will become more stable.

Xswatch shows promise as an incremental refinement in the publicly available collection of log-watching programs. Note that there are now commercial products in the field that offer more integrated and scalable services. They might even be more affordable! Xswatch makes an effort to encourage code reuse and integration. The maintenance costs for tracking admittedly diverse software packages seem to be less than the cost of maintaining an equivalent amount of homegrown code. Xswatch was also an experiment in toolsmithing — to the extent that the main engine is seven lines of code long. It is modest in scope. The entire xswatch program is six heavily commented pages of PERL code, including the 15 pages of online documentation. Using xswatch is as simple as creating a few lines of PERL script with only two assumptions and installing the file into a directory. Finally, because xswatch does not have its own macro language, it is only limited by the functionality of PERL.

CONCLUSION

Distributed systems and intranet security management solutions must address a very diverse and often perplexing variety of data center environments, each with its own needs and challenges. Distributed systems and intranet security management must also adjust for the vast differences in the various operating systems of each platform, insulating the administra-

tor from the specific vagaries of each system in order to present a unified whole. Through the single point of IT management, overall enterprise policies can be implemented and enforced while continuing to provide the local controls necessary to ensure responsiveness to the constantly changing data center environment.

Finally, xswatch makes an effort to encourage code reuse and integration. Xswatch shows promise as an incremental refinement in the publicly available collection of log-watching programs.

John Vacca is an information technology consultant and internationally known author based in Pomeroy, OH. Since 1982, John has authored 25 books and more than 330 articles in the areas of Internet and intranet security, programming, systems development, rapid application development, multimedia, and the Internet. John was also a configuration management specialist, computer specialist, and the computer security official for the NASA space station program (Freedom) and the International Space Station Program, from 1988 until his early retirement from NASA in 1995. Physical Access Control

Dan M. Bowers, CISSP

The objective of physical access control is not to restrict access but to control it. That is, the data center manager should know who is granted access, when access is granted, and why. This chapter provides overview of the function of access control systems, the physical elements they can use, and the basic techniques they employ. It also describes two popular access control technologies, keypad access control and portable-key access control, and discusses their advantages and disadvantages. The chapter also examines two other technologies, proximity access control and physical-attribute access control, as well as several developing technologies.

Problems Addressed

Access control devices and systems are an important part of every security system. In a large-scale security system there may be intrusion alarms, motion detectors, exit alarms, closed-circuit television surveillance, guards and patrols, physical barriers and turnstiles, and a variety of other devices and systems. The combined advantages of these elements characterize an effective physical security system. This chapter provides a guide for the data center manager who must determine the optimal combination for an IS installation and networks.

Types of Access Control

This section discusses access control systems and devices and briefly describes the other elements that make up the total security system.

Portal Hardware

Portal hardware includes some simple and obvious devices. The simplest single-door access control system includes at least an electric strike to automatically unlock the door, a timer to make sure that the door does not stay open all day, and a bell or light to indicate when the door is opened or that it has not reclosed properly. There may also be sensors to ensure that bolts are fully engaged and exit switches or sensors to allow people to exit without activating an alarm.

Physical Barriers

To make certain that all persons entering a facility are scrutinized by the access control equipment, they must be prevented from entering areas in which there is no access control equipment. The design of such physical barriers as walls, fences, windows, air vents, and moats is an important part of a security system.

Turnstiles

These can be incorporated to ensure that only one person enters through a controlled portal at a time.

Guards

Many of the most effective security systems use guards and automated systems rather than relying wholly on one or the other.

Other Sensors and Annunciators

In addition to devices used in portal hardware, sensors are frequently useful and can usually be monitored directly by the access control system. These sensors can include intrusion detectors, motion detectors, object protection alarms, smoke detectors, and tamper alarms.

Multiple Systems

Usually, access control systems are provided in conjunction with other security and safety systems. Frequently, there are closed-circuit television cameras and monitors and object surveillance systems. There may be an extensive alarm-monitoring system. Access control is sometimes combined with a time-and-attendance or job-cost monitoring system, because the data required for these systems frequently can be collected at the access control point. Energy management and other forms of facility automation are increasingly being provided along with the security system. Clearly, the more functions that are provided, the more complex the total system design task becomes and the more vital it is that all of the systems efficiently mesh together.

Processors and Controllers

In a simple one-portal access control device, the controller can consist of a single-circuit board containing circuitry that can verify entry codes and energize a door strike. At the other end of the spectrum, a system encompassing access control, fire detection, alarm handling, time-and-attendance monitoring, and energy management will require a sizable computer and an extensive communications controller, along with a substantial software and maintenance investment. Between these extremes, there are a nearly-infinite number of ways in which the required control intelligence can be distributed within the system.

Central Alarm Station

For monitoring and controlling an electronic security system, one alternative to employing a dedicated in-house processor and response staff is to locate this function in a central alarm station.

Electrical Power System

Any security system relies on an electrical power system. Such systems, however, are subject to numerous aberrations, including blackouts (local or widespread) that must be accounted for in a complete system design.

People

Frequently, one of the last factors to be considered in the design of a system is that people are the reason for the existence of data security systems. There are people who must be admitted to the facility without delay, and there may be different sets of people who must be admitted to different areas of the facility, and perhaps only during certain times. There are people who must not be admitted to the facility at all. Consequently, a data security force is necessary to monitor admission activities, respond to alarms, and handle unusual situations.

Designing the Total Security System

In the design of the total security system, it is essential that the user begins with an analysis of risks and threats. However, it is not within the scope of this chapter to provide instruction in risk analysis. Some of the more important studies that should be conducted during this process are:

- *Identifying the most serious risks.* The lesser risks can frequently be resolved as by-products of the basic security provided.
- *Determining the requirements for authorized entrants.* Who is granted entry, how often, and at what times?
