element. In this case, segmentation is invoked to break the TSDU into a series of appropriately sized DT TPDUs. On receipt by the peer transport entity, the sequence of DT TPDUs representing a segmented TSDU will be reassembled into the single TSDU. When this complete TSDU has been received, a data service indication is issued to the complete TS user. The End of Transport (EOT) parameter in each DT TPDU is only set when a complete TSDU has been transferred, and is used to recognize a segmented TSDU by a receiving transport entity. Where TSDUs are contained entirely within DT TPDUs, the EOT is set on every DT TPDU.

The transport layer also provides for *concatenation and separation* of TPDUs. A number of TPDUs can be concatenated into a single NSDU for transmission and separation by the receiving transport entity on receipt. If a data TPDU is one of the group of concatenated TPDUs, then it must be the last TPDU of the concatenation, and as a result, it can be the only TPDU.

The *connection establishment* procedure is available in all classes of transport to establish a TC after successful assignment to a network connection. A transport connection is established by negotiation between peers by the exchange of appropriate PDUs, which is conveyed by the use of network normal data, N-DATA. As a result of negotiation, the QOS to be maintained and the transport class to be used over the network are determined. There are optional procedures associated with particular classes that are in themselves optional within the class, and so negotiation of these optional features is also carried out at this time. For example, "Expedited Data Transfer" and "Retention Until Acknowledgment of TPDU" are both optional features in Class 1.

Connection refusal is a procedure that is initiated by the responding transport entity in response to either a T-DISCONNECT request from the responding TS user, or an inability to conform to the requirements of the initiating transport entity conveyed in the CR TPDU. Connection refusal is achieved by sending a Disconnect Request (DR) TPDU to the initiator using network normal data.

There are two types of release procedures — *normal release* and *error release*. A normal release can be described through two variants — implicit and explicit. In Class 0, the implicit variant of the normal release is achieved by disconnecting the NC using the N-DISCONNECT request, the receipt of which is considered to imply the release of the associated TC. The explicit variant of normal release is associated with all other classes. Under the explicit variant, the TC is released by a confirmed activity involving the exchange between peers of Disconnect Request (DR) and Disconnect Confirm (DC) TPDUs, using network normal data. An error release is used only in Classes 0 and 2. This is used to release the transport connection after a

signaled error has been received from the NS provider. The TS user is notified of the release by a T-DISCONNECT indication.

The *association of TPDUs* with transport connections is a procedure used in all classes while data is being received. Three actions are taken when a transport entity receives an NSDU from an NS provider. First, a check is made to determine that the NSDU can be decoded into one or more concatenation of TPDUs. Second, if concatenation is detected, then the separation procedure is invoked. Finally, where multiple TCs are associated with an NC over which the NSDU is received, ensure the TPDUs are associated with the appropriate TC.

TPDU numbering is a feature required to ensure that certain procedures are successfully performed. This is a sequence number, identified as a parameter in the PCI, which is carried in each DT TPDU. The procedures include those involving flow control, resequencing, and recovery.

The *expedited data transfer* procedure places the TS user data provided by a T-EXPEDITED-DATA request into the data field of an Expedited Data (ED) TPDU. Although the transport expedited data service is unconfirmed, transport protocol demands that the peer entity procedure be confirmed, and so each ED TPDU must be acknowledged by the receiving peer transport entity by use of an expedited data acknowledge (EA) TPDU. No more than one acknowledged ED TPDU can be outstanding for each data flow direction of the TC at any time.

The *reassignment after failure* procedure is invoked when a network signaled error is received, indicating the loss of the NC to which a TC is assigned. The result will be that the TC is assigned to a different NC, which either already existed and was owned by the transport entity or is newly created for the purpose. The procedure, resynchronization, is invoked when this reassignment is achieved; however, should a reassignment not be achieved, the TC will be considered released and the transport reference frozen. The *frozen reference* procedure (described below in a paragraph on *frozen references*) is then used to ensure that a reference is not reassigned to another TC after being frozen.

Retention until acknowledgment of TPDUs provides mechanisms whereby the transmitting transport entity can retain "copies" of TPDUs until an explicit acknowledgment is received from the peer. Should no acknowledgment be received after a certain period of time has elapsed, or should a signaled error occur, then the TPDUs can be retransmitted. The persistent loss of TPDUs will cause the QOS to fall below the negotiated acceptable level and the TC to be terminated.

Resynchronization is a procedure used to restore the TC to normal after reassignment of a TC after NC failure or after a signaled event from the NS provider, which indicates a problem in the NC. The purpose of the resynchronizing transport entity is to resume the activity on the TC that was outstanding at the time of the triggering event. Resynchronization is only attempted by the initiating transport entity of the TC. The peer takes only a passive role in the resynchronization process. Since both entities are aware of the need for resynchronization, one of the peer transport entities must take a passive role or the resynchronization by both peers would result in unnecessary event collision resolutions. The passive entity responds by setting a timer for resynchronization-related TPDUs to be received from the TC initiator. If resynchronization does not occur, the timer expires and the entity considers the TC released and the reference frozen.

Multiplexing and demultiplexing procedures are available to Classes 2, 3, and 4. This process allows more than one TC to share a single NC. Multiplexing takes place where a transport entity transmits or receives TPDUs belonging to different TCs over the same NC. The transport entity receiving the TPDUs must perform demultiplexing. Demultiplexing is accomplished by invoking the association of TPDUs procedure where the TC to which individual TPDUs belong is determined. Network efficiencies are obtained where both multiplexing and concatenation procedures are used together, and a single NSDU is transferred containing concatenated TPDUs for different TCs.

Explicit flow control is a procedure available to Classes 2, 3, and 4. In Class 2 explicit flow control is optional and in Classes 3 and 4 it is mandatory. This procedure regulates the flow of DT TPDUs between peer transport entities over a TC within the transport layer and acts independently of flow control available in the network.

Checksum is an optional procedure used only in Class 4. The checksum is a value calculated according to an algorithm defined in the protocol specification, which has the octets comprising the TPDU with which it is associated as its arguments. The checksum is identified in the TPDU as the checksum parameter. After transmission over the network, the checksum is recalculated and compared to the value in the TPDU parameter. Corruption is assumed if the values are different. In this situation, the TPDU is discarded, no acknowledgment is sent, and the transmitting transport entity retransmits the TPDU.

Frozen references are used by Classes 1, 3, and 4. They are used to ensure that a reference is not reassigned to another TC after being frozen. References are information relating to the identity of a TC. *Retransmission on timeout* is a procedure used to provide retransmission by the sender of

TPDUs that appear to have become lost. In this situation, the transmitting transport entity detects lost TPDUs when it does not receive an acknowledgment during a fixed time period and when acknowledgments are known to be outstanding. When this happens, the first TPDU in the sequence of unacknowledged TPDUs is retransmitted, and the timer is reset and left to expire. After several retransmissions without acknowledgment, the sending transport entity will invoke the release procedure and inform the TS user of the failure. Only Class 4 uses this procedure.

The *resequencing* procedure is used to sort misordered DT TPDUs by the NS provider. This provides for correctly ordered octets delivered to the TS user by each TPDU regardless of the inconsistencies of the network, which may cause out-of-order TPDUs. Misordering can occur when a TPDU is segmented by the transport entity into many TPDUs and where splitting results in these TPDUs traveling between end systems spread over a number of network connections.

The procedure that addresses unsignaled termination of a network connection is *inactivity control*. This procedure, which is used only in Class 4, is invoked on the expiry of an inactivity timer maintained by the transport entity. It times the period over which no TPDU is received. Inactivity control expires after a fairly lengthy interval and then invokes the *normal release* procedure. To protect against termination because of inactivity due to traffic congestion, the interval must be long enough to avoid timing out a good connection.

The *treatment of protocol errors* procedure is used when a TPDU is received that cannot be interpreted under the rules of the standard, when no error has been received and there are no checksum errors. Several different appropriate actions are possible depending on the operational details of the errors. This procedure is used in all classes.

The TC is enabled to make use of multiple NCs through the procedure *splitting and recombining*. The result of this can be increased throughput or greater resilience against failure in particularly unreliable networks. Once an association exists between one TC and many NCs, TPDUs of that TC can be transmitted over any of the NCs. As a result, TPDUs may arrive at the peer transport entity out of sequence. This procedure is only available to Class 4.

EXPEDITED DATA

Expedited data is a special form of data transfer where data is guaranteed to arrive at the receiving user before any data subsequently transmitted by a call on any data service. The intention is that data transferred by the use of expedited data will arrive before normal data already submitted for transmission by the user that has not yet been delivered; however, it

will not arrive before any previously submitted, undelivered expedited data. While expedited data is known only generally at higher levels of the OSI model, it is at the Transport Layer where the mechanics of expedited data become visible.

Expedited data is class dependent. That is, expedited data is provided entirely within Classes 2, 3, and 4 but is not provided in Class 0. In these classes, expedited TSDUs are sent as ED TPDUs over network normal data service. In Class 1, the expedited effect is provided by the expedited mechanism within the Transport Layer, together with the use of the network expedited data service to convey ED TPDUs. If this network service is not available, then the network normal data service is used.

QUALITY OF SERVICE

An application signals its lower-layers communications requirements using the concept of quality of service (QOS). This signaling occurs via a QOS parameter, which accompanies a connection establishment request or connectionless data item passed from the upper layers to the lower layers across the Transport Layer service boundary. The Transport Layer uses a similar QOS parameter in a connection-establishment request or connectionless data item it passes to the Network Layer. If the Network Layer cannot provide an adequate QOS, the Transport Layer should upgrade the provided QOS to the requisite level by adding value in its own protocol. This is done by selecting the appropriate transport protocol class and options.

The QOS parameter can convey a great deal of information covering such requirements as throughput, residual error rate, and connection failure probability. QOS can be expressed as a set of performance criteria. They generally fall into two groups: speed and accuracy/reliability. The connection establishment phase criteria include QOS parameters for *establishment delay* and *establishment failure probability*. The connection release phase criteria consists of the QOS parameters *release delay* and *release failure probability*. The data transfer phase criteria include the QOS parameters *throughput*, *transit delay, residual error rate, connection resilience,* and *transfer failure probability*.

The component of QOS relevant to security is called protection QOS. It is used to indicate the security services that need to be invoked and the strength of the mechanism that needs to be used to support a security service. TLSP and NLSP use a definition of protection QOS which includes a component for each relevant security service. For each component, it is possible to specify an integer value which indicates a required level for that service. The range of integers available and the meanings of the particular values are not specified in a standard. They are implied by the

particular agreed-upon set of security rules for the security association in use. The use of integers implies an ordering relationship between levels, with a higher level implying a stronger mechanism.

The level-based approach to protection QOS can be supplemented by the passing of a security label between the layers, such as between the transport and network service layers. This label serves as an indicator of required QOS. The security labels used for this purpose may be the same labels used to support access control, but they would have a different meaning. For example, the label "unclassified but sensitive" might imply use of a commercial-grade confidentiality mechanism based on DES encryption, where the label "secret" implies use of a confidentiality mechanism with a higher-grade classified encryption algorithm.

At either the Transport Layer or Network Layer, the establishment of QOS for a connection involves negotiation between the two peer entities, with the aim of best matching the QOS requirements of the two service users with the capabilities of the two service providers. With protection QOS, another element is introduced. Either peer entity may inject, at the service-provider level, administration protection QOS constraints. These are minimum-security requirements imposed by system administration in order to satisfy the local system security policy. For example, a user application may request a connection with no security protection at all but, depending upon circumstances, the local system administration at one or both peer entities may upgrade the required QOS to make confidentiality protection of a certain level mandatory. The negotiation of protection QOS can take place partly in security association establishment and partly in the regular exchange of QOS parameters in the connection establishment protocol.

SECURITY ARCHITECTURE

The transport layer security protocol (TLSP) is located completely within the Transport Layer. Except for the passing of protection QOS parameters, the existence and operation of TLSP are completely transparent to both the upper layers and the underlying Network Layer. TLSP is designed to supplement the regular Transport Layer protocols rather than change them. The TLSP is designed to work in conjunction with the transport protocol data unit (TPDU) and associated processing procedures of the TPDU without any modification to procedures or formats by effectively adding another protocol sublayer. Regular TPDUs are protected by being encapsulated within TLSP PDUs at the sending end prior to being passed to the Network Layer. The encapsulation is removed at the receiving end to produce the regular TPDU, which then continues under normal protocol processing.

The processing procedures are explained in ISO/IEC 8073 for connection-oriented processing and in ISO/IEC 8602 for connectionless-oriented processing. The protection of all regular PDUs associated with one transport connection is governed by one security association in the connection-oriented case. In other words, the same form of protection is applied to all PDUs. The protection scheme, however, can become more complex where Transport Layer multiplexing is located below the TLSP. In this instance, different transport connections or different connectionless TPDUs can be provided with different types of protection, even though the PDUs may be multiplexed onto one network connection between the two end systems. Where Transport Layer concatenation procedures are used, the same security association must protect all the concatenated PDUs. Concatenation procedures are located above the TLSP. The concatenated sequence of TPDUs is processed by the TLSP similarly to a single TPDU without concatenation.

SECURITY MECHANISMS

The encapsulation function of the TLSP supports the provision of several security services and can involve any required combination of security mechanisms. These mechanisms are *security label, direction indicator, integrity check-value (ICV), encryption padding*, and *encryption*.

A *security label* is prefixed to the TPDU to support the provision of an access control service. Fields are provided to define a unique defining authority identifier plus a label value in a format controlled by the defining authority. No particular label format is defined in the OIS. A *direction indicator* is a flag field prefix containing a bit indicating the direction of the TPDU transfer. This prefix contains a reference to a recognized initiator/responder relationship determined at security association establishment and is used to repulse reflection attacks. The ICV is a value that is computed and appended involving a process where padded octets are added to the data before the ICV computation. The ICV is the primary mechanism for providing both connection integrity and connectionless integrity services. *Encryption padding* is the padding of octets into the data where it is required by the encryption algorithm or for purposes of hiding lengths of protected PDUs. *Encryption* is the mechanism for providing connection or connectionless confidentiality and for providing necessary protection to information generated by other security mechanisms.

For the connection-oriented case, some security services are provided through the combined behavior of the TLSP encapsulation function and the normal procedures of the Transport Layer. Sequence integrity is achieved using the sequence numbers provided by Class 2, 3, or 4 transport protocol, together with connection integrity. Separate sequence numbering systems are maintained for normal data and expedited data flows.

Integrity recovery is accomplished using the Class 4 transport protocol recovery procedures, in conjunction with connection integrity. Sequence integrity cannot be used with Class 0 or Class 1 transport protocol.

Entity authentication is effectively a two-stage process. The first stage is security association establishment, which results in each transport entity knowing a key that it can use to verify the other entity of its identity. With security association establishment complete, the second stage is entity authentication on connection establishment. This is accomplished through each entity demonstrating knowledge of the applicable key by using that key for ICV generation or encryption in the encapsulation of the connect request TPDU. As protection against replay, the connect request and connect confirm TPDUs use connection reference values which must be unique within the lifetime of the key. This is most easily achieved by having a sequential component in the connection references. The system would then increment this component for each new connection establishment attempted.

For the connectionless case, the same basic two-stage process is used for data origin authentication. The key used in the encapsulation process is used to obtain the required authentication for a connectionless TPDU by providing a demonstrated knowledge of that key. With the key used for authentication purposes, peer addresses in connection establishment or connectionless TPDUs are also required to be checked for consistency as further protection against masquerade attacks.

SECURITY ASSOCIATION ATTRIBUTES

The TLSP also incorporates features including *security association attributes* and *agreed set of security rules (ASSR)*. The term *security association* is used to model the collections of related information maintained in two or more systems for purposes of providing the same type of protection to a sequence of distinct data transfers. The information items maintained in a security association are known as attributes of that security association. *Security association identifiers* include a local identifier and a remote identifier, which are octet strings of a length determined by the ASSR.

The term *ASSR* is used to describe an agreement between two or more systems as to which security mechanisms are to be used and which values are to be applied to parameters of those mechanisms. This avoids having to negotiate mechanism details with every security association establishment by using an agreed-upon set of security rules in a predefined package of security mechanism information. These security rules are registered and assigned a unique identifier, which is then made known to all potential users.

Other security association attributes held by a TLSP entity include *integrity sequence numbers, ICV mechanisms, encryption mechanisms, initiator/responder indicator, protection QOS, label mechanism, security mechanism,* and *peer TLSP entity address.* The last sequence numbers sent or received for normal and expedited data streams are *integrity sequence number attributes. ICV mechanism attributes* and *encryption mechanism attributes* include an algorithm, key granularity, key reference, and block size for determining necessary padding. In setting the direction, the *initiator/responder indicator* indicates which TLSP entity takes the role of initiator and which takes the role of responder. As mentioned previously, the *protection QOS indicator* is defined as a QOS label plus an integer level value for each entity service. The ASSR defines the range of integer values and the QOS label format. The set of allowable security labels for the security association is referred to as *label mechanism attributes. Security mechanism attributes* indicate which security mechanisms are used (e.g., entity authentication, security labels, integrity check values, integrity sequence numbers, and encryption). Finally, the *peer TLSP entity address* is the connection reference that is stored if the security association is tied to a particular transport connection.

SECURITY ASSOCIATION PROTOCOL

A security association may be established through Application Layer protocol exchanges (even though the security exchange is used by a lower-layer protocol), or through protocol exchanges at the same architectural layer that uses the security exchange, or through unspecified means (which may or may not involve online data communications). In order to accommodate protocol exchanges at the same architectural layer that uses the security exchange, an optional *security association protocol* in the TLSP is used.

PDU formats capable of supporting security association establishment, security association release, and the establishment of a new data key (rekeying) within a live security association is defined by the security association protocol. Establishing initial data keys and values for all security association attributes is the function of security association establishment.

Application-Layer Security Protocols for Networks

Bill Stackpole, CISSP

We're Not In Kansas Anymore

The incredible growth of Internet usage has shifted routine business transactions from fax machine and telephones to e-mail and E-commerce. This shift can be attributed in part to the economical worldwide connectivity of the Internet but also to the Internet capacity for more sophisticated types of transactions. Security professionals must understand the issues and risks associated with these transactions if they want to provide viable and scalable security solutions for Internet commerce.

Presence on the Internet makes it possible to conduct international, multiple-party and multiple-site transactions regardless of time or language differences. This level of connectivity has, however, created a serious security dilemma for commercial enterprises. How can a company maintain transactional compatibility with thousands of different systems and still ensure the confidentiality of those transactions? Security measures once deemed suitable for text-based messaging and file transfers seem wholly inadequate for sophisticated multimedia and E-commerce transfers. Given the complexity of these transactions, even standardized security protocols like IPSec are proving inadequate.

This chapter covers three areas that are of particular concern: electronic messaging, World Wide Web (WWW) transactions, and monetary exchanges. All are subject to potential risk of significant financial losses as well as major legal and public relations liabilities. These transactions require security well beyond the capabilities of most lower-layer security protocols. They require application-layer security.

A Layer-by-Layer Look at Security Measures

Before going into the particulars of application-based security it may be helpful to look at how security is implemented at the different ISO layers. Exhibit 36.1 depicts the ISO model divided into upper-layer protocols (those associated with the application of data) and lower-layer protocols (those associated with the transmission of data). Examples of some of the security protocols used at each layer are listed on the right. Let's begin with Layer 1.

These are common methods for providing security at the physical layer:

- Securing the cabling conduits — encase them in concrete
- Shielding against spurious emissions — TEMPEST
- Using media that are difficult to tap — fiber optics

While effective, these methods are limited to things within your physical control.

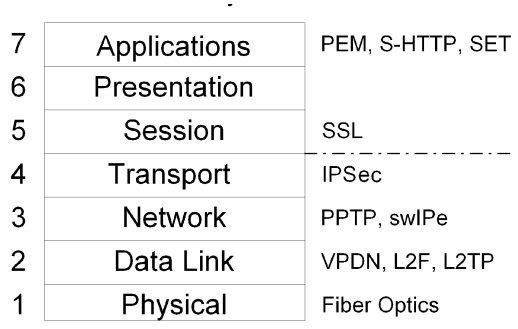

EXHIBIT 36.1 ISO seven layer model.

Common Layer-2 measures include physical address filtering and tunneling (i.e., L2F, L2TP). These measures can be used to control access and provide confidentiality across certain types of connections but are limited to segments where the end points are well known to the security implementer. Layer-3 measures provide for more sophisticated filtering and tunneling (i.e., PPTP) techniques. Standardized implementations like IPSec can provide a high degree of security across multiple platforms. However, Layer-3 protocols are ill-suited for multiple-site implementations because they are limited to a single network. Layer-4 transport-based protocols overcome the single network limitation but still lack the sophistication required for multiple-party transactions. Like all lower-layer protocols, transport-based protocols do not interact with the data contained in the payload, so they are unable to protect against payload corruption or content-based attacks.

Application-Layer Security — ALS 101

This is precisely the advantage of upper-layer protocols. Application-based security has the capability of interpreting and interacting with the information contained in the payload portion of a datagram. Take, for example, the application proxies used in most firewalls for FTP transfers. These proxies have the ability to restrict the use of certain commands even though the commands are contained within the payload portion of the packet. When an FTP transfer is initiated, it sets up a connection for passing commands to the server. The commands you type (e.g., LIST, GET, PASV) are sent to the server in the payload portion of the command packet as illustrated in Exhibit 36.2. The firewall proxy — because it is application-based — has the ability to "look" at these commands and can therefore restrict their use.

Lower-layer security protocols like IPSec do not have this capability. They can encrypt the commands for confidentiality and authentication, but they cannot restrict their use.

But what exactly is application-layer security? As the name implies, it is security provided by the application program itself. For example, a data warehouse using internally maintained access control lists to limit user access to files, records, or fields is implementing application-based security. Applying security at the application level makes it possible to deal with any number of sophisticated security requirements and accommodate additional requirements as they come along. This scenario works particularly well when all your applications are contained on a single host or secure intranet, but it becomes problematic when you attempt to extend its functionality across the Internet to thousands of different systems and applications. Traditionally, security in these environments has been addressed in a proprietary fashion within the applications themselves, but this is rapidly changing. The distributed nature of applications on the Internet has given rise to several standardized solutions designed to replace these *ad hoc*, vendor-specific security mechanisms.

Interoperability — The Key to Success for ALS

Interoperability is crucial to the success of any protocol used on the Internet. Adherence to standards is crucial to interoperability. Although the ALS protocols discussed in this chapter cover three distinctly different areas, they are all based on a common set of standards and provide similar security services. This section introduces some of these common elements. Not all common elements are included, nor are all those covered found in every ALS implementation, but there is sufficient commonality to warrant their inclusion.

Cryptography is the key component of all modern security protocols. However, the management of cryptographic keys has in the past been a major deterrent to its use in open environments like the Internet. With the advent of digital certificates and public key management standards, this deterrent has been largely overcome. Standards like the Internet Public Key Infrastructure X.509 (pkix) and the Simple Public Key Infrastructure (spki) provide the mechanisms necessary to issue, manage, and validate cryptographic keys across multiple domains and platforms. All of the protocols discussed in this chapter support the use of this Public Key Infrastructure.

Standard Security Services — Maximum Message Protection

All the ALS protocols covered in this chapter provided these four standard security services:

1. Confidentiality (a.k.a. privacy) — the assurance that only the intended recipient can read the contents of the information sent to them.
2. Integrity — the guarantee that the information received is exactly the same as the information that was sent.
3. Authentication — the guarantee that the sender of a message or transmission is really who he claims to be.
4. Non-repudiation — the proof that a message was sent by its originator even if the originator claims it was not.

Each of these services relies on a form of cryptography for its functionality. Although the service implementations may vary, they all use a fairly standard set of algorithms.

Algorithms Tried and True

The strength of a cryptographic algorithm can be measured by its longevity. Good algorithms continue to demonstrate high cryptographic strength after years of analysis and attack. The ALS protocols discussed here support three types of cryptography — symmetric, asymmetric, and hashing — using time-tested algorithms.

Symmetric (also called secret key) *cryptography* is primarily used for confidentiality functions because it has high cryptographic strength and can process large volumes of data quickly. In ALS implementations, DES is the most commonly supported symmetric algorithm. *Asymmetric or public key cryptography* is most commonly used in ALS applications to provide confidentiality during the initialization or set-up portion of a transaction. Public keys and digital certificates are used to authenticate the participating parties to one another and exchange the symmetric keys used for the remainder of the transaction. The most commonly supported asymmetric algorithm in ALS implementations is RSA.

Cryptographic hashing is used to provide integrity and authentication in ALS implementations. When used separately, authentication validates the sender and the integrity of the message, but using them in combination provides proof that the message was not forged and therefore cannot be refuted (non-repudiation). The three most commonly used hashes in ALS applications are MD2, MD5, and SHA. In addition to a common set of algorithms, systems wishing to interoperate in an open environment must be able to negotiate and validate a common set of security parameters. The next section introduces some of the standards used to define and validate these parameters.

Standardized Gibberish Is Still Gibberish!

For applications to effectively exchange information they must agree upon a common format for that information. Security services, if they are to be trustworthy, require all parties to function in unison. Communication parameters must be established, security services, modes, and algorithms agreed upon, and cryptographic keys

exchanged and validated. To facilitate these processes the ALS protocols covered in this chapter support the following formatting standards:

- X.509. The X.509 standard defines the format of digital certificates used by certification authorities to validate public encryption keys.
- PKCS. The Public Key Cryptography Standard defines the underlying parameters (object identifiers) used to perform the cryptographic transforms and to validate keying data.
- CMS. The Cryptographic Message Syntax defines the transmission formats and cryptographic content types used by the security services. CMS defines six cryptographic content types ranging from no security to signed and encrypted content. They are data, signedData, envelopedData, signedAndEnvelopedData, digestData, and encryptedData.
- MOSS. The MIME Object Security Services defines two additional cryptographic content types for multipart MIME (Multimedia Internet Mail Extensions) objects that can be used singly or in combination. They are multipart-signed and multipart-encrypted.

Encryption is necessary to ensure transaction confidentiality and integrity on open networks, and the Public Key/Certification Authority architecture provides the infrastructure necessary to manage the distribution and validation of cryptographic keys. Security mechanisms at all levels now have a standard method for initiating secure transactions, thus eliminating the need for proprietary solutions to handle secure multiple-party, multiple-site, or international transactions. A case in point is the new SET credit card transaction protocol.

Setting the Example — Visa's Secure Electronic Transaction Protocol

SET (Secure Electronic Transaction) is an application-based security protocol jointly developed by Visa and MasterCard. It was created to provide secure payment card transactions over open networks. SET is the electronic equivalent of a face-to-face or mail-order credit card transaction. It provides confidentially and integrity for payment transmissions and authenticates all parties involved in the transaction. Let's walk through a SET transaction to see how this application-layer protocol handles a sophisticated multi-party financial transaction.

A SET transaction involves five different participants: the *cardholder*, the *issuer* of the payment card, the *merchant*, the *acquirer* that holds the merchant's account, and a *payment gateway* that processes SET transactions on behalf of the acquirer. The policies governing how transactions are conducted are established by a sixth party, the *brand* (i.e., Visa), but they do not participate in payment transactions.

A SET transaction requires two pairs of asymmetric encryption keys and two digital certificates: one for exchanging information and the other for digital signatures. The keys and certificates can be stored on a "smart" credit card or embedded into any SET-enabled application (i.e., Web browser). The keys and certificates are issued to the cardholder by a certification authority (CA) on behalf of the issuer. The merchant's keys and digital certificates are issued to them by a certification authority on behalf of the acquirer. They provide assurance that the merchant has a valid account with the acquirer. The cardholder and merchant certificates are digitally signed by the issuing financial institution to ensure their authenticity and to prevent them from being fraudulently altered. One interesting feature of this arrangement is that the cardholder's certificate does not contain his account number or expiration date. That information is encoded using a secret key that is only supplied to the payment gateway during the payment authorization. Now that we know all the players, let's get started.

Step 1

The cardholder goes shopping, selects his merchandise, and sends a purchase order to the merchant requesting a SET payment type. (The SET specification does not define how shopping is accomplished so it has no involvement in this portion of the transaction.) The cardholder and merchant, if they haven't already, authenticate themselves to each other by exchanging certificates and digital signatures. During this exchange the merchant also supplies the payment gateway's certificate and digital signature information to the cardholder. You will see how this is used later. Also established in this exchange is a pair of randomly generated symmetric keys that will be used to encrypt the remaining cardholder–merchant transmissions.

Step 2

Once the above exchanges have been completed, the merchant contacts the payment gateway. Part of this exchange includes language selection information to ensure international interoperability. Once again, certificate and digital signature information is used to authenticate the merchant to the gateway and establish random symmetric keys. Payment information (PI) is then forwarded to the gateway for payment authorization. Notice that only the *payment* information is forwarded. This is done to satisfy regulatory requirements regarding the use of strong encryption. Generally, the use of strong cryptography by financial institutions is not restricted if the transactions *only contain monetary values*.

Step 3

Upon receipt of the PI, the payment gateway authenticates the cardholder. Notice that the cardholder is authenticated without contacting the purchase gateway directly. This is done through a process called dual-digital signature. The information required by the purchase gateway to authenticate the cardholder is sent to the merchant with a different digital signature than the one used for merchant–cardholder exchanges. This is possible because the merchant sent the purchase gateway certificates to the cardholder in an earlier exchange! The merchant simply forwards this information to the payment gateway as part of the payment authorization request. Another piece of information passed in this exchange is the secret key the gateway needs to decrypt the cardholder's account number and expiration date.

Step 4

The gateway reformats the payment information and forwards it via a private circuit to the issuer for authorization. When the issuer authorizes the transaction, the payment gateway notifies the merchant, who notifies the cardholder, and the transaction is complete.

Step 5

The merchant finalizes the transaction by issuing a Payment Capture request to the payment gateway causing the cardholder's account to be debited, and the merchant's account to be credited for the transaction amount.

A single SET transaction like the one outlined above is incredibly complex, requiring more than 59 different actions to take place successfully. Such complexity requires application-layer technology to be managed effectively. The beauty of SET, however, is its ability to do just that in a secure and ubiquitous manner. Other protocols are achieving similar success in different application areas.

From Postcards to Letters — Securing Electronic Messages

Electronic messaging is a world of postcards. As messages move from source to destination, they are openly available (like writing on a postcard) to be read by those handling them. If postcards are not suitable for business communications, it stands to reason that electronic mail on an open network is not either. Standard business communications require confidentiality, and other more sensitive communications require additional safeguards like proof of delivery or sender verification, features that are not available in the commonly used Internet mail protocols. This has led to the development of several security-enhanced messaging protocols. PEM is one such protocol.

Privacy Enhanced Mail (PEM) is an application-layer security protocol developed by the IETF (Internet Engineering Task Force) to add confidentiality and authentication services to electronic messages on the Internet. The goal was to create a standard that could be implemented on any host, be compatible with existing mail systems, support standard key management schemes, protect both individually addressed and list-addressed mail, and not interfere with nonsecure mail delivery. When the standard was finalized in 1993 it had succeeded on all counts. PEM supports all four standard security services, although all services are not necessarily part of every message. PEM messages can be MIC-CLEAR messages that provide integrity and authentication only; MIC-ONLY messages that provide integrity and authentication with support for certain gateway implementations; or ENCRYPTED messages that provide integrity, authentication, and confidentiality.

These are some of PEM's key features:

- *End-to-end confidentiality*. Messages are protected against disclosure from the time they leave the sender's system until they are *read* by the recipient.
- *Sender and forwarder authentication*. PEM digital signatures authenticate both senders and forwarders and ensure message integrity. PEM utilizes an integrity check that allows messages to be received in any order and still be verified — an important feature in environments like the Internet where messages can be fragmented during transit.
- *Originator non-repudiation*. This feature authenticates the *originator* of a PEM message. It is particularly useful for forwarded messages because a PEM digital signature only authenticates the last sender. Non-repudiation verifies the originator no matter how many times the message is forwarded.
- *Algorithm independence*. PEM was designed to easily accommodate new cryptographic and key management schemes. Currently PEM supports common algorithms in four areas: DES for data encryption, DES and RSA for key management, RSA for message integrity, and RSA for digital signatures.
- *PKIX support*. PEM fully supports interoperability on open networks using the Internet Public Key Infrastructure X.509.
- *Delivery system independence*. PEM achieves delivery-system independence because its functions are contained in the body of a standard message and use a standard character set as illustrated in Exhibit 36.3.
- *X.500 distinguished name support*. PEM uses the distinguished name (DN) feature of the X.500 directory standard to identify senders and recipients. This feature separates mail from specific individuals allowing organizations, lists, and systems to send and receive PEM messages.

RIPEM (Riordan's Internet Privacy Enhanced Mail) is a public domain implementation of the PEM protocol although not in its entirety. Because the author, Mark Riordan, placed the code in the public domain, it has been ported to a large number of operating systems. Source and binaries are available via FTP to U.S. and Canadian citizens from **ripem.msu.edu**. Read the **GETTING_ACCESS** file in the **/pub/crypt/** directory before attempting any downloads.

Secure/Multipurpose Internet Mail Extensions (S/MIME) is another application-layer protocol that provides all four standard security services for electronic messages. Originally designed by RSA Data Security, the S/MIME specification is currently managed by the IETF S/MIME Working Group. Although S/MIME is not an IETF standard, it has already garnered considerable vendor support, largely because it is based on well-proven standards that provide a high degree of interoperability. Most notable is, of course, the popular and widely used MIME standard, but S/MIME also utilizes the CMS, PKCS, and X.509 standards. Like PEM, S/MIME is compatible with most existing Internet mail systems and does not interfere with the delivery of nonsecure messages. However, S/MIME has the added benefit of working seamlessly with other MIME transports (i.e., HTTP) and can even function in mixed-transport environments. This makes it particularly attractive for use with automated transfers like EDI and Internet FAX.

There are two S/MIME message types: *signed*, and *signed and enveloped*. Signed messages provide integrity and sender authentication, while signed and enveloped messages provide integrity, authentication, and confidentiality. The remaining features of S/MIME are very similar to PEM and do not warrant repeating here.

A list of commercial S/MIME products that have successfully completed S/MIME interoperability testing is available on the RSA Data Security Web site at **www.rsa.com/smime/html/interop_center.html.** A public domain version of S/MIME written in PERL by Ralph Levien is available at **www.c2.org/~raph/premail.html**.

Open Pretty Good Privacy (OpenPGP), sometimes called PGP/MIME, is another emerging ALS protocol on track to becoming an IETF standard. It is based on PGP, the most widely deployed message security program on the Internet. OpenPGP is very similar in features and functionality to S/MIME, but the two are not interoperable because they use slightly different encryption algorithms and MIME encapsulations. A list of PGP implementations and other OpenPGP information is available at **http://www-ns.rutgers.edu/~mione/openpgp/**. Freeware implementations of OpenPGP are available at the North American Cryptography Archives (**www.cryptography.org**).

Taming HTTP — Web Application Security

Web-based applications are quickly becoming the standard for all types of electronic transactions because they are easy to use and highly interoperable. These features are also their major security failing. Web transactions

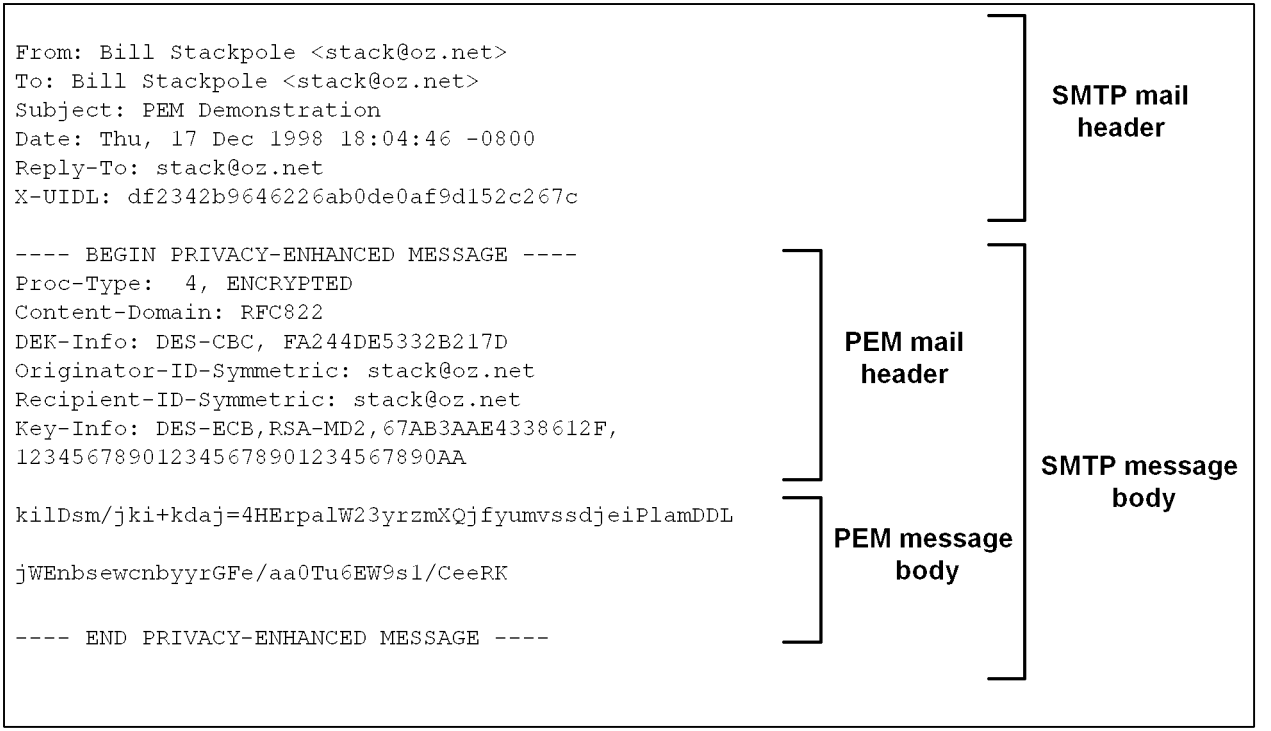

EXHIBIT 36.3 Delivery system independence.

traverse the network in well-known and easily intercepted formats, making them quite unsuitable for most business transactions. This section will cover some of the mechanisms used to overcome these Web security issues.

Secure HyperText Transfer Protocol (S/HTTP) is a message-oriented security protocol designed to provide end-to-end confidentiality, integrity, authentication, and non-repudiation services for HTTP clients and servers. It was originally developed by Enterprise Integration Technologies (now Verifone, Inc.) in 1995. At this writing, S/HTTP is still an IETF draft standard, but it is already widely used in Web applications. Its success can be attributed to a flexible design that is rooted in established standards. The prominent standard is, of course, HTTP, but the protocol also utilizes the NIST Digital Signature Standard (DSS), CMS, MOSS, and X.509 standards. S/HTTP's strict adherence to the HTTP messaging model provides delivery-system independence and makes it easy to integrate S/HTTP functions into standard HTTP applications. Algorithm independence and the ability to negotiate security options between participating parties assures S/HTTP's interoperability for years to come. Secure HTTP modes of operation include message protection, key management, and a transaction freshness mechanism.

Secure HTTP protection features include the following:

- *Support for MOSS and CMS*. Protections are provided in both content domains using the CMS "application/s-http" content-type or the MOSS "multipart-signed" or "multipart-encrypted" header.
- *Syntax compatibility*. Protection parameters are specified by extending the range of HTTP message headers, making S/HTTP messages syntactically the same as standard HTTP messages, except the range of the headers is different and the body is usually encrypted.
- *Recursive protections*. Protections can be used singly or applied one layer after another to achieve higher levels of protection. Layering the protections makes it easier for the receiving system to parse them. The message is simply parsed one protection at a time until it yields a standard HTTP content type.
- *Algorithm independence*. The S/HTTP message structure can easily incorporate new cryptographic implementations. The current specification requires supporting MD5 for message digests, MD5-HMAC for authentication, DES-CBC for symmetric encryption, and NIST-DSS for signature generation and verification.
- *Freshness feature*. S/HTTP uses a simple challenge–response to ensure that the data being returned to the server is "fresh." In environments like HTTP, where long periods of time can pass between messages, it is difficult to track the state of a transaction. To overcome this problem, the originator of an HTTP message sends a freshness value (nonce) to the recipient along with the transaction data. The recipient returns the nonce with a response. If the nonces match, the data is fresh, and the transaction can continue. Stale data indicates an error condition.

Secure HTTP Key management modes include:

- *Manual exchange*. Shared secrets are exchanged through a simple password and mechanism like PAP. The server simply sends the client a dialog box requesting a userID and password then authenticates the response against an existing list of authorized users.
- *Public key exchange*. Keys are exchanged using the Internet Public Key Infrastructure with full X.509 certificate support. S/HTTP implementations are required to support Diffie–Hellman for in-band key exchanges.
- *Out-of-band key exchange*. Symmetric keys can be prearranged through some other media (i.e., snail mail). This feature, unique to the S/HTTP, permits parties that do not have established public keys to participate in secure transactions.
- *In-band symmetric key exchange*. S/HTTP can use public key encryption to exchange random symmetric keys in instances where the transaction would benefit from the higher performance of symmetric encryption.

Many commercial Web browsers and servers implement the S/HTTP protocol, but the author was unable to find any public domain implementations. A full implementation of S/HTTP including the C source code is available in the SecureWeb Toolkit™ from Terisa (www.spyrus.com). The kit also contains the source code for SSL.

Secure Socket Layer (SSL) is a client/server protocol designed by Netscape to provide secure communications for its Web browser and server products. It was quickly adopted by other vendors and has become the

de facto standard for secure Web transactions. However, SSL is not limited to Web services; it can provide confidentiality, integrity, authentication, and non-repudiation services between any two communicating applications. The current version of SSL (SSL V3.0) is on track to becoming an IETF standard. While included here as an application-layer protocol, SSL is actually designed to function at the session and application-layers. The SSL Record Protocol provides security services at the session layer — the point where the application interfaces to the TCP/IP transport sockets. It is used to encapsulate higher-layer Protocols and data for compression and transmission. The SSL Handshake protocol is an application-based service used to authenticate the client and server to each other and negotiate the security parameters for each communication session.

The SSL Handshake Protocol utilizes public key encryption with X.509 certificate validation to negotiate the symmetric encryption parameters used for each client/server session. SSL is a stateful protocol. It transitions through several different states during connection and session operations. The Handshake Protocol is used to coordinate and maintain these states. One SSL session may include multiple connections, and participating parties may have multiple simultaneous sessions. The session state maintains the peer certificate information, compression parameters, cipher parameters, and the symmetric encryption key. The connection state maintains the MAC and asymmetric keys for the client and server as well as the vectors (if required) for symmetric encryption initialization. SSL was designed to be fully extensible and can support multiple encryption schemes. The current version requires support for these schemes:

- DES, RC2, RC4, and IDEA for confidentiality
- RSA and DSS for peer authentication
- SHA and MD5 for message integrity
- X.509 and FORTEZZA certificates for key validation
- RSA, Diffie–Hellman, and FORTEZZA for key exchange

SSL also supports NULL parameters for unsigned and unencrypted transmissions. This allows the implementer to apply an appropriate amount of security for their application. The support for the FORTEZZA hardware encryption system is unique to the SSL as is the data compression requirement. SSL uses a session caching mechanism to facilitate setting up multiple sessions between clients and servers and resuming disrupted sessions.

There is an exceptional public domain implementation of SSL created by Eric Young and Tim Hudson of Australia called SSLeay. It includes a full implementation of Netscape's SSL version 2 with patches for Telnet, FTP, Mosaic, and several Web servers. The current version is available from the SSLeay Web site at www.ssleay.org. The site includes several SSL white papers and an excellent *Programmers' Reference*.

Don't Show Me the Money — Monetary Transaction Security

The success of commerce on the Internet depends upon its ability to conduct monetary transactions securely. Although purchasing seems to dominate this arena, bill payment, fund and instrument transfers, and EDI are important considerations. The lack of standards for electronic payment has fostered a multitude of proprietary solutions, including popular offerings from Cybercash (Cybercoin), Digital (Millicent), and Digicash. However, proprietary solutions are not likely to receive widespread success in a heterogeneous environment like the Internet. This section will concentrate on standardized solutions. Since the SET protocol has been covered in some detail already, only SET implementations will be mentioned here.

Secure Payment (S/PAY) is a developer's toolkit based on the SET protocol. It was developed by RSA Data Security, although the marketing rights currently belong to the Trintech Group (www.trintech.com). The S/PAY library fully implements the SET v1.0 cardholder, merchant, and acquirer functions and the underlying encryption and certificate management functions for Windows 95/NT and major UNIX platforms. Included in the code is support for hardware-based encryption engines, smart card devices, and long-term private key storage. Trintech also offers full implementations of SET merchant, cardholder, and acquirer software. This includes their PayWare Net-POS product, which supports several combinations of SSL and SET technologies aimed at easing the transition from Web SSL transactions to fully implemented SET transactions.

Open Financial Exchange (OFX) is an application-layer protocol created by Checkfree, Intuit, and Microsoft to support a wide range of consumer and small business banking services over the Internet. OFX is an open specification available to any financial institution or vendor desiring to implement OFX services. OFX uses SSL with digital certificate support to provide confidentiality, integrity, and authentication services to its

transactions. The protocol has gained considerable support in the banking and investment industry because it supports just about every conceivable financial transaction. Currently, the OFX committee is seeking to expand OFX's presence through interoperability deals with IBM and other vendors. Copies of the OFX specification are available from the Open Financial Exchange Web site (www.ofx.net).

Micro Payment Transfer Protocol (MPTP) is part of The World Wide Web Consortium (W3C) Joint Electronic Payment Initiative. Currently, MPTP is a W3C working draft. The specification is based on variations of Rivest and Shamir's Pay-Word, Digital's Millicent, and Bellare's iKP proposals. MPTP is a very flexible protocol that can be layered upon existing transports like HTTP or MIME to provide greater transaction scope. It is highly tolerant of transmission delays allowing much of the transaction processing to take place off-line. MPTP is designed to provide payments through the services of a third-party broker. In the current version, the broker must be common to both the customer and the vendor, although inter-broker transfers are planned for future implementations. This will be necessary if MPTP is going to scale effectively to meet Internet demands.

Customers establish an account with a broker. Once established, they are free to purchase from any vendor common to their broker. The MPTP design takes into consideration the majority of risks associated with electronic payment and provides mechanisms to mitigate those risks, but it does not implement a specific security policy. Brokers are free to define policies that best suit their business requirements.

MPTP relies on S/Key technology using MD5 or SHA algorithms to authorize payments. MPTP permits the signing of messages for authentication, integrity, and non-repudiation using public or secret key cryptography and fully supports X.509 certificates. Although MPTP is still in the draft stages, its exceptional design, flexibility, and high performance destine it to be a prime contender in the electronic payment arena.

Java Electronic Commerce Framework (JECF) is our final item of discussion. JECF is not an application protocol. It is a framework for implementing electronic payment processing using active-content technology. Active-content technology uses an engine (i.e., a JAVA virtual machine) installed on the client to execute program components (e.g., applets) sent to it from the server. Current JECF active-content components include the Java Commerce Messages, Gateway Security Model, Commerce JavaBeans, and Java Commerce Client (JCC).

JECF is based around the concept of an electronic wallet. The wallet is an extensible client-side mechanism capable of supporting any number of E-commerce transactions. Vendors create Java applications consisting of service modules (applets) called Commerce JavaBeans that plug in to the wallet. These applets implement the operations and protocols (i.e., SET) necessary to conduct transactions with the vendor. There are several significant advantages of this architecture:

- Vendors are not tied to specific policies for their transactions. They are free to create modules containing policies and procedures best suited to their business.
- Clients are not required to have specialized applications. Because JavaBean applets are active content, they can be delivered and dynamically loaded on the customer's system as the transaction is taking place.
- Applications can be updated dynamically. Transaction applets can be updated or changed to correct problems or meet growing business needs without having to send updates to all the clients. The new modules will be loaded over the old during their next transaction.
- Modules can be loaded or unloaded on-the-fly to accommodate different payment, encryption, or language requirements. OFX modules can be loaded for banking transactions and later unloaded when the customer requires SET modules to make a credit card purchase.
- JavaBean modules run on any operating system, browser, or application supporting Java. This gives vendors immediate access to the largest possible customer base.

The flexibility, portability, and large Java user base make the Java Electronic Commerce Framework (JECF) a very attractive E-commerce solution. It is sure to become a major player in the electronic commerce arena.

If It's Not Encrypted Now. . .

The Internet has dramatically changed the way we do business, but that has not come without a price. Security for Internet transactions and messaging is woefully lacking, making much of what we are doing on the Internet an open book for all to read. This can not continue. Despite the complexity of the problems we are facing, there are solutions. The technologies outlined in this chapter provide real solutions for mitigating Internet

business risks. We can secure our messages, Web applications, and monetary exchanges. Admittedly, some of these applications are not as polished as we would like, and some are difficult to implement and manage, but they are nonetheless effective and most certainly a step in the right direction.

Someday all of our business transactions on the Internet will be encrypted, signed, sealed, and delivered, but I am not sure we can wait for that day. Business transactions on the Internet are increasing, and new business uses for the Internet are going to be found. Waiting for things to get better is only going to put us further behind the curve. Someone has let the Internet bull out of the cage and we are either going to take him by the horns or get run over! ALS now!

Application Layer: Next Level of Security

Keith Pasley, CISSP

Business applications and business data are the core backbone of most enterprises today. A current trend in business is to increase providing direct access via the Internet to certain business data to entities external to an enterprise. The two most relied upon business applications accessible from the Internet are e-mail and Web-enabled applications.

This rapidly growing trend supports various business goals that include increased competitive advantage, reduced costs, strengthened customer loyalty, establishing additional revenue streams, increased productivity, and many others. However, exposing critical business application access via the Internet does increase the risk profile for businesses. The following are possible elements of such a risk profile:

- Business operations become more dependent on the application
- Increased opportunity for exploiting application vulnerabilities
- Cost of disruption increases
- Increased targeting of the application by malicious entities
- Increased number of application-based vulnerabilities
- Speed-to-market pressures alter the performance/security dynamic of application

Such a risk profile does not necessarily imply that it is a bad or negative idea to deploy Internet-facing applications. In fact, businesses take calculated risks every day and can reap significant financial and competitive advantages by doing so. A similar disciplined approach to analyzing the relative benefits and liabilities of deploying Internet applications involves the application of risk management techniques. Essentially, risk management involves enumerating what could go wrong, how much it could cost, the likelihood of the event happening, and then deciding what responses to the event would be acceptable to the business.

Within the framework of application security, risk management involves an examination of the above on an application-by-application basis. One approach is to review the actual software code of the application as part of the software development life cycle. Goals of such a review could include subjecting the code to examination by qualified people other than the developers who originated the code. A so-called "second set of eyes" could, for example, identify vulnerabilities, check for unintended functionality, and identify bad coding practices (assuming there is an established standard against which to measure).

In some environments, code review is impractical due to the sheer volume of lines of code in a program, the time it would take for such a review, or the organizational structure may prohibit the capability of a central code review group's ability to enforce the results of the review. Additionally, in some environments where software code is changed very frequently with very little, if any, change in management

discipline, code review may simply not be appropriate. For such environments, another approach might be appropriate.

Another approach to this is to enforce a consistent application security policy via technology. One such technology is an emerging class of security components generally known as an *application firewall.* An application firewall is a security component that analyzes data at the application layer, which is often the easiest path for attackers to gain unauthorized access to enterprise resources. Most network firewalls and traditional intrusion detection systems (IDSs), in practical terms, can only control Internet Protocol (IP) packet-based network access and detect port- and protocol-type security events based on static rules or signatures. Although essential as a primary element in a comprehensive enterprise security architecture, network firewalls and IDSs are recognized as security components that can be easily vaulted over by their very nature. For example, most enterprise firewall policies allow in- and outbound access to internal or DMZ-based Web servers without meaningful inspection of the application data contained in data packets traversing the firewall. Potentially, an attacker could either send malicious data into the Web application or, conversely, extract sensitive data from the application. Application firewalls aim to consistently enforce application security policy as a security layer around an enterprise's application infrastructure.

Application firewalls are increasingly being offered by security vendors in the form of rack-mountable appliances that integrate operating system and security software preloaded on purposed-built hardware, and are engineered to balance security functionality with performance.

This chapter focuses on effective strategies for enhancing the security of Web-enabled and e-mail application infrastructures. Each is described in this chapter, yet the focus of this chapter is on the business impact of application security. As such, no detailed discussions of specific application vulnerabilities are included.

The Problem: Applications Are the Highest-Risk Attack Vector

As the Internet has created more business opportunity — for example, extending the boundaries of the enterprise outside the physical facilities of a business — so has business exposure to risk increased. If one were to identify and prioritize resources by value to the business, one would find in most cases that specific data and applications would be counted among the highest in value to an organization. Most businesses would not be able to operate competitively if data and applications were somehow taken away, either by malicious acts or by accident. Another, more granular way to look at this situation would be to imagine if the existing traditional network security controls of a data-centric business failed, would the business' critical data and applications still be protected? Not surprisingly, the answer is no. This is a realization that is being brought to the attention of data owners and security professionals by either circumstance or critical infrastructure analysis. From a technical perspective, this means that the traditional perimeter security approach of deploying firewalls and intrusion detection systems as the sole defense mechanisms is flawed with respect to current and emerging threats. Why?

One of the most important issues facing e-mail and Web-enabled businesses today is the open port problem; that is, most business firewalls allow Web application server access via port 80 and e-mail server access via port 25. Unfortunately, most traditional network firewalls are not capable of actually analyzing the data payload for malicious attacks. The majority of firewalls can only see data at the packet, or network, level — information such as source/destination IP address, TCP port number, and other packet routing information headers. This means that if an attacker can hide an attack within the data payload itself, then the attack will go through the firewall and into the target application infrastructure. The traditional network-centric approach, which only addresses perimeter security, is no longer thought of as being effective in protecting the heart and soul of a business — its business data.

Web Services Security

Another emerging Web-enabled application is Web services. Web services comprise the sum total of application components whose functionality and interfaces are exposed to potential users through the

use of Web technology standards such as SOAP, XML, UDDI, WSDL, and HTTP. Web services are application-to-application, computer-to-computer transaction-based communications using predefined data formats in a platform- and language-neutral context. Traditional Web-enabled applications are interactive and Web-browser based. Application-level security strategies are complicated by the automated intent of Web services. Security standards are emerging and are being integrated into available security products. Application scanning and application firewall technologies are now emerging that allow for security checks against Web service data and protocols. The use of Web services to extend core business applications to external entities is expected to grow significantly in a relatively short time as businesses recognize the value of this capability. Therefore, the security issues of Web-enabled applications based on Web services will need to be checked from a perspective of automated processing between two or more security domains. Aside from the method of access, an approach similar to the Web-enabled application security strategy discussed in this chapter can be used.

The foundation of Web services is Extensible Markup Language (XML). A protocol for communicating XML-based messages, Simple Object Access Protocol (SOAP), is itself based on XML: SXML is used to create specific message formats with which two or more parties agree to comply when sending messages between applications. Defining protocols for assuring the confidentiality, integrity, and availability of Web services is a technological and business challenge that is currently being addressed by industry standards bodies. For example, IBM and Microsoft are working together to define a core set of facilities for protecting the confidentiality and integrity of an XML-based message. Their work also includes defining authentication and authorization mechanisms for creating and validating security assertions of Web service participants.

Hackers know that most business firewalls allow Web and e-mail traffic, that Web and e-mail applications are notoriously vulnerable to attack, and that many businesses focus on network perimeter security, not Web application security.

Any business connected to the Internet has a need for some level of protection beyond traditional perimeter security. Surprisingly, given the high risk of exposing e-mail and Web-enabled internal applications to wide access, many companies do not even monitor application-level events. As a result, a company may not even know that an application has been attacked.

Wide access to e-mail and Web-enabled applications is both a goal and a security risk. As a business goal, Web applications fulfill a business need to provide information and expose business logic to increase business efficiency. However, the ability to access such business architecture means that attackers have more of an opportunity to exploit known and unknown weaknesses in the architecture. Just as the decision to deploy Internet-accessible applications is a business decision, so it is that implementing application-level security must be addressed from a business management decision perspective. There are compelling and significant business management issues that can justify application-level security.

A Management Issue

Application security is both a business issue (see Exhibit 37.1) and a technical issue (see Exhibit 37.2). It is a technical issue in that more effective technology is needed to address the higher risk of exposed businesses. It is a business issue in that an ineffective security strategy means increased risk.

EXHIBIT 37.1 The SANS Institute List of Seven Management Errors that Lead to Computer Security Vulnerabilities

7. Pretend the problem will go away if they ignore it.
6. Authorize reactive, short-term fixes so problems re-emerge rapidly.
5. Fail to realize how much money their information and organizational reputations are worth.
4. Rely primarily on a firewall.
3. Fail to deal with the operational aspects of security: make a few fixes and then not allow the follow-through necessary to ensure the problems stay fixed.
2. Fail to understand the relationship of information security to the business problem: they understand physical security but do not see the consequences of poor information security.
1. Assign untrained people to maintain security and provide neither the training nor the time to make it possible to do the job.

Source: SANS Institute, http://www.sans.org/resources/errors.php.

EXHIBIT 37.2 The Open Web Application Security Project (OWASP) List of Ten Common Web Application Vulnerabilities

1. *Unvalidated Parameters:* Information from Web requests is not validated before being used by a Web application. Attackers can use these flaws to attack backside components through a Web application.
2. *Broken Access Control:* Restrictions on what authenticated users are allowed to do are not properly enforced. Attackers can exploit these flaws to access other users' accounts, view sensitive files, or use unauthorized functions.
3. *Broken Account and Session Management:* Account credentials and session tokens are not properly protected. Attackers that can compromise passwords, keys, session cookies, or other tokens can defeat authentication restrictions and assume other users' identities.
4. *Cross-Site Scripting (XSS) Flaws:* The Web application can be used as a mechanism to transport an attack to an end user's browser. A successful attack can disclose the end user's session token, attack the local machine, or spoof content to fool the user.
5. *Buffer Overflows:* Web application components in some languages that do not properly validate input can be crashed, and, in some cases, used to take control of a process. These components can include CGI, libraries, drivers, and Web application server components.
6. *Command Injection Flaws:* Web applications pass parameters when they access external systems or the local operating system. If an attacker can embed malicious commands in these parameters, the external system might execute those commands on behalf of the Web application.
7. *Error Handling Problems:* Error conditions that occur during normal operation are not handled properly. If an attacker can cause errors to occur that the Web application does not handle, they can gain detailed system information, deny service, cause security mechanisms to fail, or crash the server.
8. *Insecure Use of Cryptography:* Web applications frequently used cryptographic functions to protect information and credentials. These functions and the code to integrate them have proven difficult to code properly, frequently resulting in weak protection.
9. *Remote Administration Flaws:* Many Web applications allow administrators to access the site using a Web interface. If these administrative functions are not very carefully protected, an attacker can gain full access to all aspects of a site.
10. *Web and Application Server Misconfiguration:* Having a strong server configuration standard is critical to a secure Web application. These servers have many configuration options that affect security and are not secure out of the box.

Source: OWASP, http://www.owasp.org/.

Part of the problem of ineffective application security is denial of the problem. In many instances, program developers and software vendors assume that because no vulnerability has been reported on an application, that it must be secure. This way of thinking is also found in business management circles with respect to already-deployed Web applications. The thinking goes: why invest in application infrastructure security when the company has had no attacks on its key business applications?

The answer to this question must be framed in terms that the audience can relate to. Business audiences think in terms of quantifiable returns on the investment. Technical audiences usually respond to things that make their jobs easier, enhance their status, or increase their value to employers. This chapter focuses on the business justification for application security.

One could surmise from the SANS list of seven management errors (Exhibit 37.1) that executive management's attitude toward recognizing and understanding the business impact of security breaches can actually influence the likelihood of a security breach. Providing business impact awareness of relevant application security vulnerabilities to business managers is a valuable role of security professionals. However, security risk management, being a continual process that must be managed, must be embraced — from the executive management level on down — throughout an organization to be effective.

The Business Risk

Competitor company B accesses company A's Web-accessible database, which contains company A's future marketing campaign strategy, by exploiting a well-known Web vulnerability. Company B, now having advanced knowledge of the upcoming marketing changes, is able to preempt company A's market opportunity for competitive advantage. A costly mistake could have been minimized or even avoided. Indeed, cost avoidance and cost reduction are two reasons to apply an application security strategy within a business.

As noted earlier, the two business applications most relied upon for Internet-connected business operations are Web-enabled applications and e-mail applications. Each of these applications relies on several related network infrastructure components. The sum total of the application itself and the network services that support the functioning of the application can be referred to as the "application infrastructure." The application infrastructure can be visualized using a three-layer model.

To isolate the various points of attack, the layered components of an application infrastructure can be reduced down to a simple model that includes a proxy layer, an internal application server layer, and a business database layer. These layers comprise the essence of an application infrastructure, although they are dependent on *network infrastructure* components, as described later.

For example, using the above model, it is possible to map the components of an e-mail infrastructure.

- *Proxy layer:* mail relay/mail exchanger/Webmail Web server
- *Internal application server layer:* internal mail server
- *Business database layer:* internal mail store/user database

An example Web application infrastructure would include:

- *Proxy layer:* web listener/web server
- *Internal application server layer:* business application server
- *Business database layer:* database server

Additionally, various network infrastructure services that are critical and common to the operation of both application architectures include Domain Name Service (DNS) servers, network routing/switch fabric (including load balancers), time servers, malicious code (including anti-virus) scanners, and protocol accelerators (e.g., SSL accelerators).

The risk to businesses that Internet-accessible applications bring is greater opportunity for attack and more points of attacks. This risk translates into lost revenue, increased costs, and lost productivity due to recovering from a security breach.

Managing Risk: Application Layer Security Primer

As discussed, Internet-accessible applications are comprised of multiple components that can be represented using a four-tier model. Isolating the functionality of Internet applications helps in understanding the various access points and potential weaknesses of a particular application architecture. However, one vulnerable component of the overall architecture can allow an attacker to undermine the entire system.

For example, if a DNS server that is relied upon by an Internet application is subverted by someone maliciously modifying the record that tells where mail for a certain domain should be routed, then it makes no difference how strong the e-mail anti-virus protection is; the attacker has undermined the entire system. This example highlights the fact that application security must be addressed using a holistic, comprehensive, and systems approach.

Many vulnerabilities in applications are caused by poor programming technique, invalid design, and lack of security awareness by software developers. However, as noted, application security is both a management and a technical issue. Therefore, the solution begins with an awareness of the issues by business managers. Business managers ultimately determine the priorities of software development teams. An example of business managers effecting a change of priority from functionality to default security is found in Microsoft. Although many are skeptical of the commitment of Microsoft to design software products with security as a priority, there have been tremendous steps made in the right direction by Microsoft management. Microsoft's secure product development program included sending all of its application developers to classes on secure coding practices, tying code security goals to performance compensation, and establishing security oversight teams to check for compliance, among other steps. Indeed, management has a clear role to play in reducing the risk of business applications.

Due to the pervasiveness of simple tools for hacking Web access, together with the proliferation of Web applications, the incidence of attack will only increase in the future. Web attacks are becoming more common than pure network-based attacks, with a resulting increase in the severity and damage done. The cost of recovering from a Web attack is growing as the sophistication of attacks increases. As the cost of an attack reaches the value of the target application, while budget dollars are decreasing, it becomes increasingly important to balance spending on security components according to highest return on asset value. Significantly, many companies were found to overspend on security tools, deploying expensive security components in areas that did not justify the expense.

To a determined attacker, the application itself yields the highest rewards. However, the Web application currently poses the greatest risk to businesses. Each application is different, with its own set of specific risks. One way to determine if enough has been done to secure a Web application is to have a Web application assessment performed on the entire Web application infrastructure, including the Web application itself. There are security consulting firms that are starting to appear in the marketplace that specialize in Web application security. These companies typically use a combination of automated security tools and hands-on experience to assess the security posture of Web applications. In some cases, security or IT groups within a company may perform their own assessment. However, expertise in this area is scarce and relatively expensive.

If employing a consulting firm to perform an application assessment, ask about the credentials and experience of its consultants who will be doing the assessment. Ask for the names and types of testing tools that will be used. Find out if the consultants provide remediation services or just a simple findings report. It may make sense to have the same consulting company that performed the assessment recommend which remediation products to use, because it may already have in-depth knowledge of the application architecture, it may have already done the technology research to save time, or it may have the necessary expertise to install and manage the security tools. With such a high impact to the business if not done properly, risk can be reduced if professionals who are specifically skilled in Web application security execute this application security strategy.

Another factor to consider is cost of fix after deployment versus cost of fix early in the development cycle. Early IT software development practice evolved with an emphasis on testing application functionality. The idea then was to reduce application total cost of ownership (TCO) by identifying bugs in the software early in the development cycle. This approach is still used today. Similarly, performing application *security* scanning early in the development cycle has been proven to significantly reduce the total cost of ownership of an application due to decreased vulnerability/exploit/fix cycles.

Organizational Standards for Software Development

One approach to integrated Web application security is to embed the application security scan function into the application quality assurance (QA) cycle. As a step in the QA process, this strategy provides an opportunity to apply a consistent security baseline against all of a company's Web applications. Once established, the same application scan could be run after any significant changes are made to the Web application throughout its life cycle to ensure that the security posture has not been altered. Existing applications can be scanned as part of a regular security assessment.

In some environments it is either not possible or very difficult to perform Web application scans due to lack of direct control of the application-hosting environment. This is the case if the application is hosted by a third-party facility, the application belongs to a business partner, or other similar situations. A strategy of implementing a security check of application data streams at the network perimeter, as a first hop-in/last hop-out application scan, can be effective. An application firewall inserted just inside the network firewall configured to intercept the Web data to and from the third party would allow a similar enforcement capability as proactive scanning of the application itself. Application firewall technology is discussed in the following section.

Technology

It is important to remember that any security solution includes the combination of people, processes, and technology. This is an important consideration, particularly in the case of application security. If a person makes a configuration mistake that leads to a security breach, the technology cannot be blamed. Similarly, if a flawed process is implemented, the technology cannot be blamed. This highlights the fact that a good practice for developing an application security policy includes mapping out the interaction of process, people, and technology. This section discusses strategies for implementing this interaction.

There are currently two classes of security technology that address application-level security: the application scanner and the application firewall/security gateway.

Web Application Scanner: More Than Just Securing a Host

The application scanner is a tool used to test applications for known and unknown vulnerabilities, unintended functionality, and poor coding practice, among other tests. The Web application scanner is usually implemented as software running on a laptop or designated desktop computer. Scanning can be done from outside the network perimeter or inside the network, just in from the Web server layer component. Web application scanning tools provide a report that lists vulnerabilities found, along with some remediation suggestions. Some of the tools provide specialized tests for particular Web application environments (e.g., IBM Websphere, BEA, Oracle). Popular products that provide Web-enabled application scanning include Sanctum's AppScan, Kavado's Scando, and SpiDynamics's WebInspect.

Application Firewall: Not Just Looking at Network Packets

The other class of application security tool is the application firewall/security gateway. A Web application firewall is inserted in the path between the user and the Web server layer of the Web application infrastructure. In most cases, this means at the network perimeter or in a DMZ "quarantine" area of a network. A Web application firewall intercepts all HTTP and HTML traffic going to and from a Web application and looks for anything that indicates improper behavior. For example, an application could detect and block users from browsing outside a site's allowed URL list, attempts to masquerade via cookie modification, buffer overflow attempts, incorrect form data entry via form field validation, and attempts to add data to a site or attempts to access restricted areas of a site via improper GET and POST methods. Most Web application firewalls include a "learning mode" that allows the device to record the proper behavior of a Web application. After a few days of "learning" proper site behavior, the Web application firewall would then dynamically create a policy and enforce "proper" site behavior based on "learned" knowledge. Additionally, Web application firewalls can be configured manually. No modification to the protected Web application itself is necessary. Multiple Web applications can be protected simultaneously by one device, or, if needed, the devices can be scaled out via load balancing and managed by the Web application firewall's central management console.

E-Mail Application-Level Firewalls: More than Just Anti-Virus

Similar in function to a Web application-level firewall, an e-mail application-level firewall can protect e-mail application infrastructures. E-mail application-level firewalls can be installed at the network perimeter, in a DMZ, or in some cases directly on the Internet. The architectural idea is that this device is the first-hop-in/last-hop-out checkpoint for e-mail application attacks. Thus positioned, the e-mail application-level firewall bears the brunt of an attack leaving the e-mail infrastructure intact and operational during the attack. The technical value of an e-mail application-level firewall lies in that it buys time to allow for patching or updating the target e-mail infrastructure component. Additionally, a consistent e-mail security posture can be maintained using the e-mail application-level firewall as an additional security layer. The e-mail application-level firewall inspects e-mail protocols and e-mail messages for attack attempts and enforces policy via mechanisms such blocking, logging, or alerting on detection. Although there are a few vendors of the firewalls themselves, a significant market-leading, single-purpose-

built e-mail application-level security scanning tool is yet to emerge. Current testing tools for e-mail application infrastructures include a hodgepodge of open source and commercial network vulnerability assessment tools.

An emerging and highly segmented market, e-mail application-level firewalls provide some level of hardening for self-protection and multiple controls against a wide variety of threats to the e-mail infrastructure. The threat profile of e-mail application infrastructures includes redirecting mail via DNS poisoning, malicious code attacks to disrupt or corrupt e-mail message integrity, large volumes of unsolicited e-mails or server connections aimed at reducing the availability of e-mail service — mail bombs and spam attacks. E-mail application-level firewalls proxy e-mail connections between external e-mail servers and internal e-mail servers, never allowing direct connection from the outside. The e-mail application-level firewall can also enforce a message retention policy by archiving messages to archiving hosts for later retrieval as needed.

E-mail application-level firewalls are a different class of device than the popular software-based mail server add-on products. Mail server add-on products typically provide specific mail security functionality, such as content filtering, anti-virus, and anti-spam — similar to e-mail application-level firewalls. However, they are implemented on the actual mail server itself. Software-based mail server security products generally do not have the capability to examine a message before it enters the e-mail infrastructure and they commonly introduce e-mail processing performance degradation. Scalability becomes an issue in the larger, more complex e-mail architectures. A special case involves Web mail: Web browser accessible e-mail systems. There are two classes of Web mail from a protection strategy perspective that should be considered: Web mail service provided by a company to its community of users, and external consumer-oriented Web mail services such as Yahoo, MSN, and AOL accessed from inside a company network. When planning a strategy in this regard, remember that all Web mail should be considered hostile until proven otherwise. This means that the e-mail application-level firewall should be capable of inspecting Web mail traffic for protocol and syntax attacks, similar in result to Internet mail protocols (SMTP, POP3, IMAP4) and syntax checking.

As mentioned, such devices are usually best implemented as a security appliance. A security appliance approach provides specific functionality implemented on optimized hardware, with the results including higher performance at a lower cost, decreased ongoing maintenance costs, and scalability efficiency. The software-based approach means that the customer must assume increased costs of integrating hardware, operating system, and application. Additionally, the host operating system should be hardened. Such hardening of the operating system requires expertise and ongoing diligence in managing the host operating system, applying patches, and hardware upgrades.

Vendors offering products in the Web application firewall market segment include Sanctum (AppShield), Kavado (InterDo), and Teros\Stratum8 (APS 100). E-mail application firewall vendors include CipherTrust (IronMail) and Borderware (MxTreme).

The Bottom Line: Balancing Security Protection against Assets Being Protected

The traditional network firewall has a respected and necessary place in most enterprise security environments. It provides a first line of defense, access control, and a security control point. However, many businesses open bi-directional access to critical business applications, such as e-mail and Web-enabled applications that have historically been vulnerable to numerous attacks. Access to these applications is provided by opening up the network firewall, port 80 for Web and port 25 for e-mail. Hackers are now predominantly sneaking in through these open ports to run application-level exploits against the application infrastructure, those components that form the essence of a Web-enabled or e-mail application. E-mail and many Web-enabled business applications are core, mission-critical assets that, if disabled, could cause significant damage and prove very costly to recover from — if even possible. If there is more

risk of attacks at the higher-value assets, e-mail and Web-enabled applications, then it makes sense to balance security spending appropriately to protect these critical applications.

Conclusion

This chapter discussed the technology available at the time of writing. Although current application security technology provides some level of protection, there is much room for improvement. Network security technology components — such as network-based firewalls, VPNs, and intrusion detection and response — continue to make up the essential first line of defense; however, the threat horizon has changed. This change in attack vectors requires a reorientation toward the emerging sources and targets of attack — attackers coming through application ports to target application vulnerabilities of core business information systems.

Security of Communication Protocols and Services

William Hugh Murray, CISSP

The information security manager is confronted with a wide variety of communications protocols and services. At one level, the manager would like to be able to ignore how the information gets from one place to another; he would like to be able to *assume* security. At another, he understands that he has only limited control over how the information moves; because the user may be able to influence the choice of path, the manager prefers not to rely upon it. However, that being said, the manager also knows that there are differences in the security properties of the various protocols and services that he may otherwise find useful.

This chapter describes the popular protocols and services, discusses their intended uses and applications, and describes their security properties and characteristics. It compares and contrasts similar protocols and services, makes recommendations for their use, and also recommends compensating controls or alternatives for increasing security.

Introduction

For the past century, we have trusted the dial-switched voice-analog network. It was operated by one of the most trusted enterprises in the history of the world. It was connection-switched and point-to-point. While there was some eavesdropping, most of it was initiated by law enforcement and was, for the most part, legitimate. While a few of us carefully considered what we would say, most of us used the telephone automatically and without worrying about being overheard. Similarly, we were able to recognize most of the people who called us; we trusted the millions of copies of the printed directories; and we trusted the network to connect us only to the number we dialed. While it is not completely justified, we have transferred much of that automatic trust to the modern digital network and even to the Internet.

All other things being equal, the information security manager would like to be able to ignore how information moves from one place to another. He would like to be able to assume that he can put it into a pipe at point A and have it come out reliably only at point B. Of course, in the real world of the modern integrated network, this is not the case. In this world the traffic is vulnerable to eavesdropping, misdirection, interference, contamination, alteration, and even total loss.

On the other hand, relatively little of this happens; the vast majority of information is delivered when and how it is intended and without any compromise. This happens in part despite the way the information is moved and in part because of how it is moved. The various protocols and services have different security properties and qualities. Some provide error detection, corrective action such as retransmission, error correction, guaranteed delivery, and even information hiding.

The different levels of service exist because they have different costs and performance. They exist because different traffic, applications, and environments have different requirements. For example, the transfer of a program file has a requirement for bit-for-bit integrity; in some cases, if you lose a bit, it is as bad as losing the whole file. On the other hand, a few seconds, or even tens of seconds, of delay in the transfer of the file may have little impact. However, if one is moving voice traffic, the loss of tens of bits may be perfectly acceptable, while delay in seconds is intolerable. These costs must be balanced against the requirements of the application and the environment.

While the balance between performance and cost is often struck without regard to security, the reality is that there are security differences. The balance between performance, cost, and security is the province of the information security manager. Therefore, he needs to understand the properties and characteristics of the protocols so he can make the necessary trade-offs or evaluate those that have already been made.

Finally, all protocols have limitations and many have fundamental vulnerabilities. Implementations of protocols can compensate for such vulnerabilities only in part. Implementers may be faced with hard design choices, and they may make errors resulting in implementation-induced vulnerabilities. The manager must understand these so he will know when and how to compensate.

Protocols

A protocol is an agreed-upon set of rules or conventions for communicating between two or more parties. "Hello" and "goodbye" for beginning and ending voice phone calls are examples of a simple protocol. A slightly more sophisticated protocol might include lines that begin with tags, like "This is (name) calling."

Protocols are to codes as sentences and paragraphs are to words. In a protocol, the parties may agree to addressing, codes, format, packet size, speed, message order, error detection and correction, acknowledgments, key exchange, and other things.

This section deals with a number of common protocols. It describes their intended use or application, characteristics, design choices, and limitations.

Internet Protocol

The Internet Protocol, IP, is a primitive and application-independent protocol for addressing and routing packets of data within a network. It is the "IP" in TCP/IP, the protocol suite that is used in and defines the Internet. It is intended for use in a relatively flat, mesh, broadcast, connectionless, packet-switched net like the Internet.

IP is analogous to a postcard in the 18th century. The sender wrote the message on one side of the card and the address and return address on the other. He then gave it to someone who was going in the general direction of the intended recipient. The message was not confidential; everyone who handled it could read it and might even make an undetected change to it.

IP is a "best efforts" protocol; it does not guarantee message delivery nor provide any evidence as to whether or not the message was delivered. It is unchecked; the receiver does not know whether or not he received the entire intended message or whether or not it is correct. The addresses are unreliable; the sender cannot be sure that the message will go only where he intends or even when he intends. The receiver cannot be sure that the message came from the address specified as the return address in the packet.

The protocol does not provide any checking or hiding. If the application requires these, they must be implied or specified someplace else, usually in a higher (i.e., closer to the application) protocol layer.

IP specifies the addresses of the sending or receiving hardware device;* but if that device supports multiple applications, IP does not specify which of those it is intended for.

*There is a convention of referring to all network addressable devices as "hosts." Such usage in other documents equates to the use of device or addressable device here. IPv6 defines "host."

EXHIBIT 38.1 IP Network Address Formats

Network Class	Description	Address Class	Network Address	Device Address
A	National	0 in bit 0	1–7	8–31
B	Enterprise	10 in bits 0–1	2–15	16–31
C	LAN	110 in 0–2	3–23	24–31
D	Multicast	1110 in 0–3	4–31	
E	Reserved	1111 in 0–3		

IP uses 32-bit addresses. However, the use or meaning of the bits within the address depends upon the size and use of the network. Addresses are divided into five classes. Each class represents a different design choice between the number of networks and the number of addressable devices within the class. Class A addresses are used for very large networks where the number of such networks is expected to be low but the number of addressable devices is expected to be very high. Class A addresses are used for nation states and other very large domains such as .mil, .gov, and .com. As shown in Exhibit 38.1, a zero in bit position 0 of an address specifies it as a class A address. Positions 1 through 7 are used to specify the network, and positions 8 through 31 are used to specify devices within the network. Class C is used for networks where the possible number of networks is expected to be high but the number of addressable devices in each net is less than 128. Thus, in general, class B is used for enterprises, states, provinces, or municipalities, and class C is used for LANs. Class D is used for multicasting, and Class E is reserved for future uses.

You will often see IP addresses written as nnn.nnn.nnn.nnn.

While security is certainly not IP's long suit, it is responsible for much of the success of the Internet. It is fast and simple. In practice, the security limitations of IP simply do not matter much. Applications rely upon higher-level protocols for security.

Internet Protocol v6.0 (IPng)

IPv6 or "next generation" is a backwardly compatible new version of IP. It is intended to permit the Internet to grow both in terms of the number of addressable devices, particularly class A addresses, and in quantity of traffic. It expands the address to 128 bits, simplifies the format header, improves the support for extensions and options, adds a "quality-of-service" capability, and adds address authentication and message confidentiality and integrity. IPv6 also formalizes the concepts of packet, node, router, host, link, and neighbors that were only loosely defined in v4.

In other words, IPng addresses most of the limitations of IP, specifically including the security limitations. It provides for the use of encryption to ensure that information goes only where it is intended to go. This is called secure-IP. Secure-IP may be used for point-to-point security across an arbitrary network. More often, it is used to carve virtual private networks (VPNs) or secure virtual networks (SVNs)* out of such arbitrary networks.

Many of the implementations of secure-IP are still proprietary and do not guarantee interoperability with all other such implementations.

User Datagram Protocol (UDP)

UDP is similar to IP in that it is connectionless and offers "best effort" delivery service, and it is similar to TCP in that it is both checked and application specific.

*VPN is used here to refer to the use of encryption to connect private networks across the public network, gateway-to-gateway. SVN is used to refer to the use of encryption to talk securely, end-to-end, across arbitrary networks. While the term VPN is sometimes used to describe both applications, different implementations of secure-IP may be required for the two applications.

EXHIBIT 38.2 UDP Datagram

Bit Positions	Usage
0–15	Source Port Address
16–31	Destination Port Address
32–47	Message Length (n)
48–63	Checksum
64–n	Data

Exhibit 38.2 shows the format of the UDP datagram. Unless the UDP source port is on the same device as the destination port, the UDP packet will be encapsulated in an IP packet. The IP address will specify the physical device, while the UDP address will specify the logical port or application on the device.

UDP implements the abstraction of "port," a named logical connection or interface to a specific application or service within a device. Ports are identified by a positive integer. Port identity is local to a device, that is, the use or meaning of port number is not global. A given port number can refer to any application that the sender and receiver agree upon. However, by convention and repeated use, certain port numbers have become identified with certain applications. Exhibit 38.3 lists examples of some of these conventional port assignments.

Transmission Control Protocol (TCP)

TCP is a sophisticated composition of IP that compensates for many of its limitations. It is a connection-oriented protocol that enables two applications to exchange streams of data synchronously and simultaneously in both directions. It guarantees both the delivery and order of the packets. Because packets are given a sequence number, missing packets will be detected, and packets can be delivered in the same order in which they were sent; lost packets can be automatically resent. TCP also adapts to the latency of the network. It uses control flags to enable the receiver to automatically slow the sender so as not to overflow the buffers of the receiver.

TCP does not make the origin address reliable. The sequence number feature of TCP resists address spoofing. However, it does not make it impossible. Instances of attackers pretending to be trusted nodes have been reported to have toolkits that encapsulate the necessary work and special knowledge to implement such attacks.

Like many packet-switched protocols, TCP uses path diversity. This means some of the meaning of the traffic may not be available to an eavesdropper. However, eavesdropping is still possible. For example, user identifiers and passphrases usually move in the same packet. "Password grabber" programs have been detected in the network. These programs simply store the first 256 or 512 bits of packets on the assumption that many will contain passwords.

Finally, like most stateful protocols, some TCP implementations are vulnerable to denial-of-service attacks. One such attack is called *SYN flooding*. Requests for sessions, SYN flags, are sent to the target, but the acknowledgments are ignored. The target allocates memory to these requests and is overwhelmed.

EXHIBIT 38.3 Sample UDP Ports

Port Number	Application	Description
23	Telnet	
53	DNS	Domain name service
43		Whois
69	TFTP	Trivial file transfer service
80	HTTP	Web service
119	Net News	
137		NetBIOS name service
138		NetBIOS datagrams
139		NetBIOS session data

Telnet

The Telnet protocol describes how commands and data are passed from one machine on the network to another over a TCP/IP connection. It is described in RFC 855. It is used to make a terminal or printer on one machine and an operating system or application on another appear to be local to each other. The user invokes the Telnet client by entering its name or clicking its icon on his local system and giving the name or address and port number of the system or application that he wishes to use. The Telnet client must listen to the keyboard and send the characters entered by the user across the TCP connection to the server. It listens to the TCP connection and displays the traffic on the user's terminal screen. The client and server use an escape sequence to distinguish between user data and their communication with each other.

The Telnet service is a frequent target of attack. By default, the Telnet service listens for login requests on port 23. Connecting this port to the public network can make the system and the network vulnerable to attack. When connected to the public net, this port should expect strong authentication or accept only encrypted traffic.

File Transfer Protocol (FTP)

FTP is the protocol used on the Internet for transferring files between two systems. It divides a file into IP packets for sending it across the Internet. The object of the transfer is a file. The protocol provides automatic checking and retransmission to provide for bit-for-bit integrity. (See section titled Services below.)

Serial Line Internet Protocol (SLIP)

SLIP is a protocol for sending IP packets over a serial line connection. It is described in RFC 1055. SLIP is often used to extend the path from an IP-addressable device, like a router at an ISP, across a serial connection, a dial connection (e.g., a dial connection) to a non-IP device (e.g., a serial port on a PC). It is a mechanism for attaching non-IP devices to an IP network.

SLIP encapsulates the IP packet and bits in the code used on the serial line. In the process, the packet may gain some redundancy and error correction. However, the protocol itself does not provide any error detection or correction. This means that errors may not be detected until the traffic gets to a higher layer. Because SLIP is usually used over relatively slow (56 Kb) lines, this may make error correction at that layer expensive. On the other hand, the signaling over modern modems is fairly robust. Similarly, SLIP traffic may gain some compression from devices (e.g., modems) in the path but does not provide any compression of its own.

Because the serial line has only two endpoints, the protocol does not contain any address information; that is, the addresses are implicit. However, this limits the connection to one application; any distinctions in the intended use of the line must be handled at a higher layer.

Because SLIP is used on point-to-point connections, it may be slightly less vulnerable to eavesdropping than a shared-media connection like Ethernet. However, because it is closer to the endpoint, the data may be more meaningful. This observation also applies to PPP below.

Point-to-Point Protocol (PPP)

PPP is used for applications and environments similar to those for SLIP but is more sophisticated. It is described in RFC 1661, July 1994. It is *the* Internet standard for transmission of IP packets over serial lines. It is more robust than SLIP and provides error-detection features. It supports both asynchronous and synchronous lines and is intended for simple links that deliver packets between two peers. It enables the transmission of multiple network-layer protocols (e.g., IP, IPX, SPX) simultaneously over a single link. For example, a PC might run a browser, a Notes client, and an e-mail client over a single link to the network.

To facilitate all this, PPP has a Link Control Protocol (LCP) to negotiate encapsulation formats, format options, and limits on packet format.

Optionally, a PPP node can require that its partner authenticate itself using CHAP or PAP. This authentication takes place after the link is set up and before any traffic can flow. (See CHAP and PAP below.)

HyperText Transfer Protocol (HTTP)

HTTP is used to move data objects, called pages, between client applications, called browsers, running on one machine, and server applications, usually on another. HTTP is the protocol that is used on and that defines the World Wide Web. The pages moved by HTTP are compound data objects composed of other data and objects. Pages are specified in a language called HyperText Markup Language, or HTML. HTML specifies the appearance of the page and provides for pages to be associated with one another by cross-references called hyperlinks.

The fundamental assumption of HTTP is that the pages are public and that no data-hiding or address reliability is necessary. However, because many electronic commerce applications are done on the World Wide Web, other protocols, described below, have been defined and implemented.

Security Protocols

Most of the traffic that moves in the primitive TCP/IP protocols is public; that is, none of the value of the data derives from its confidentiality. Therefore, the fact that the protocols do not provide any data-hiding does not hurt anything. The protocols do not add any security, but the data does not need it. However, there is some traffic that is sensitive to disclosure and which does require more security than the primitive protocols provide. The absolute amount of this traffic is clearly growing, and its proportion may be growing also. In most cases, the necessary hiding of this data is done in alternate or higher-level protocols.

A number of these secure protocols have been defined and are rapidly being implemented and deployed. This section describes some of those protocols.

Secure Socket Layer (SSL)

Arguably, the most widely used secure protocol is SSL. It is intended for use in client–server applications in general. More specifically, it is widely used between browsers and Web servers on the WWW. It uses a hybrid of symmetric and asymmetric key cryptography, in which a symmetric algorithm is used to hide the traffic and an asymmetric one, RSA, is used to negotiate the symmetric keys.

SSL is a session-oriented protocol; that is, it is used to establish a secure connection between the client and the server that lasts for the life of the session or until terminated by the application.

SSL comes in two flavors and a number of variations. At the moment, the most widely used of the two flavors is *one-way SSL*. In this implementation, the server side has a private key, a corresponding public key, and a certificate for that key-pair. The server offers its public key to the client. After reconciling the certificate to satisfy itself as to the identity of the server, the client uses the public key to securely negotiate a session key with the server. Once the session key is in use, both the client and the server can be confident that only the other can see the traffic.

The client side has a public key for the key-pair that was used to sign the certificate and can use this key to verify the bind between the key-pair and the identity of the server. Thus, the one-way protocol provides for the authentication of the server to the client but not the other way around. If the server cares about the identity of the client, it must use the secure session to collect evidence about the identity of the client. This evidence is normally in the form of a user identifier and a passphrase or similar, previously shared, secret.

The other flavor of SSL is *two-way SSL*. In this implementation both the client and the server know the public key of the other and have a certificate for this key. In most instances the client's certificate is issued by the server, while the server's certificate was issued by a mutually trusted third party.

Secure-HTTP (S-HTTP)

S-HTTP is a secure version of HTTP designed to move individual pages securely on the World Wide Web. It is page oriented as contrasted to SSL, which is connection or session oriented. Most browsers (thin clients) that implement SSL also implement S-HTTP, may share key-management code, and may be used in ways that are not readily distinguishable to the end user. In other applications, S-HTTP gets the nod where very high performance is required and where there is limited need to save state between the client and the server.

Secure File Transfer Protocol (S-FTP)

Most of the applications of the primitive File Transfer Protocol are used to transfer public files in private networks. Much of it is characterized as "anonymous;" that is, one end of the connection may not even recognize the other. However, as the net spreads, FTP is increasingly used to move private data in public networks.

S-FTP adds encryption to FTP to add data-hiding to the integrity checking provided in the base protocol.

Secure Electronic Transaction (SET)

SET is a special protocol developed by the credit card companies and vendors and intended for use in multi-party financial transactions like credit card transactions across the Internet. It provides not only for hiding credit card numbers as they cross the network, but also for hiding them from some of the parties to the transaction and for protecting against replay.

One of the limitations of SSL when used for credit card numbers is that the merchant must become party to the entire credit card number and must make a record of it to use in the case of later disputes. This creates a vulnerability to the disclosure and reuse of the credit card number. SET uses public key cryptography to guarantee the merchant that he will be paid without his having to know or protect the credit card number.

Point-to-Point Tunneling* Protocol (PPTP)

PPTP is a protocol (from the PPTP Forum) for hiding the information in IP packets, including the addresses. It is used to connect (portable computer) clients across the dial-switched point-to-point network to the Internet and then to a (MS) gateway server to a private (enterprise) network or to (MS) servers on such a network. As its name implies, it is a point-to-point protocol. It is useful for implementing end-to-end secure virtual networks (SVNs) but less so for implementing any-gateway-to-any-gateway virtual private networks (VPNs).

It includes the ability to:

- Query the status of Comm Servers
- Provide in-band management
- Allocate channels and place outgoing calls
- Notify server on incoming calls
- Transmit and receive user data with flow control in both directions
- Notify server on disconnected calls

One major advantage of PPTP is that it is included in MS 32-bit operating systems. (At this writing, the client-side software is included on 32-bit MS Windows operating systems Dial Up Networking [rel.

*Tunneling is a form of encapsulation in which the encrypted package, the passenger, is encapsulated inside a datagram of the carrier protocol.

1.2 and 1.3]. The server-side software is included in the NT Server operating system. See L2TP below.) A limitation of PPTP, when compared to secure-IP or SSL, is that it does not provide authentication of the endpoints. That is, the nodes know that other nodes cannot see the data passing between but must use other mechanisms to authenticate addresses or user identities.

Layer 2 Forwarding (L2F)

L2F is another mechanism for hiding information on the Internet. The encryption is provided from the point where the dial-switched point-to-point network connects the Internet service provider (ISP) to the gateway on the private network. The advantage is that no additional software is required on the client computer; the disadvantage is that the data is protected only on the Internet and not on the dial-switched network.

L2F is a router-to-router protocol used to protect data from acquisition by an ISP, across the public digital packet-switched network (Internet) to receipt by a private network. It is used by the ISP to provide data-hiding servers to its clients. Because the protocol is implemented in the routers (Cisco), its details and management are hidden from the end users.

Layer 2 Tunneling Protocol (L2TP)

L2TP is a proposal by MS and Cisco to provide a client-to-gateway data-hiding facility that can be operated by the ISP. It responds to the limitations of PPTP (must be operated by the owner of the gateway) and L2F (does not protect data on the dial-switched point-to-point net). Such a solution could protect the data on both parts of the public network but as a service provided by the ISP rather than by the operator of the private network.

Secure Internet Protocol (Secure-IP or IPSec)

IPSec is a set of protocols to provide for end-to-end encryption of the IP packets. It is being developed by the Internet Engineering Task Force (IETF). It is to be used to bind endpoints to one another and to implement VPNs and SVNs.

Internet Security Association Key Management Protocol (ISAKMP)

ISAKMP is a proposal for a public-key certificate-based key-management protocol for use with IPSec. Because in order to establish a secure session the user will have to have both a certificate and the corresponding key and because the session will not be vulnerable to replay or eavesdropping, ISAKMP provides "strong authentication." What is more, because the same mechanism can be used for encryption as for authentication, it provides economy of administration.

Password Authentication Protocol (PAP)

As noted above, PPP provides for the parties to identify and authenticate each other. One of the protocols for doing this is PAP. (See also CHAP below). PAP works very much like traditional login using a shared secret. A sends a prompt or a request for authentication to B, and B responds with an identifier and a shared secret. If the pair of values meets A's expectation, then A acknowledges B.

This protocol is vulnerable to a replay attack. It is also vulnerable to abuse of B's identity by a privileged user of A.

Challenge Handshake Authentication Protocol (CHAP)

CHAP is a standard challenge–response peer-to-peer authentication mechanism. System A chooses a random number and passes it to B. B encrypts this challenge under a secret shared with A and returns it to A. A also computes the value of the challenge encrypted under the shared secret and compares this value to the value returned by B. If this response meets A's expectation, then A acknowledges B.

Many implementations of PPP/CHAP provide that the remote party be periodically reauthenticated by sending a new challenge. This resists any attempt at "session stealing."

Services

Telnet

File Transfer

FTP is the name of a protocol, but it is also the name of a service that uses the protocol to deliver files. The service is symmetric in that either the server or the client can initiate a transfer in either direction, either can get a file or send a file, either can do a get or a put. The client may itself be a server. The server may or may not recognize its user, and may or may not restrict access to the available files.

Where the server does restrict access to the available files, it usually does that through the use of the control facilities of the underlying file system. If the file server is built upon the UNIX operating system and file system or the Windows operating systems, then it will use the rules-based file access controls of the file system. If the server is built upon the NT operating system, then it will use the object-oriented controls of the NT file system. If the file service is built on MVS, and yes that does happen, then it is the optional access control facility of MVS that will be used.

Secure Shell (SSH 2)

Secure Shell is a UNIX-to-UNIX client-server program that uses strong cryptography for protecting all transmitted data, including passwords, binary files, and administrative commands between systems on a network. One can think of it as a client-server command processor or shell. While it is used primarily for system management, it should not be limited to this application.

SSH2 implements Secure-IP and ISAKMP at the application layer, as contrasted to the network layer, to provide a secure network computing environment. It provides node identification and authentication, node-to-node encryption, and secure command and file transfer. It compensates for most of the protocol limitations noted above. It is now preferred to and used in place of more limited or application-specific protocols or implementations such as Secure-FTP.

Conclusions

Courtney's first law says that nothing useful can be said about the security of a mechanism except in the context of an application and an environment. Of course, the converse of that law says that, in such a context, one can say quite a great deal.

The Internet is an open, not to say hostile, environment in which most everything is permitted. It is defined almost exclusively by its addresses and addressing schema and by the protocols that are honored in it. Little else is reliable.

Nonetheless, most sensitive applications can be done there as long as one understands the properties and limitations of those protocols and carefully chooses among them. We have seen that there are a large number of protocols defined and implemented on the Internet. No small number of them are fully adequate for all applications. On the other hand, the loss in performance, flexibility, generality, and function in order to use those that are secure for the intended application and environment is small. What is more, as the cost of performance falls, the differences become even less significant.

The information security manager must understand the needs of his applications, and know the tools, protocols, and what is possible in terms of security. Then he must choose and apply those protocols and implementations carefully.

Security Management for the World Wide Web

Lynda L. McGhie
Phillip Q. Maier

Companies continue to flock to the Internet in ever-increasing numbers, despite the fact that the overall and underlying environment is not secure. To further complicate the matter, vendors, standards bodies, security organizations, and practitioners cannot agree on a standard, compliant, and technically available approach. As a group of investors concerned with the success of the Internet for business purposes, it is critical that we pull our collective resources and work together to quickly establish and support interoperable security standards; open security interfaces to existing security products and security control mechanisms within other program products; and hardware and software solutions within heterogeneous operating systems which will facilitate smooth transitions.

Interfaces and teaming relationships to further this goal include computer and network security and information security professional associations (CSI, ISSA, NCSA), professional technical and engineering organizations (I/EEE, IETF), vendor and product user groups, government and standards bodies, seminars and conferences, training companies/institutes (MIS), and informal networking among practitioners.

Having the tools and solutions available within the marketplace is a beginning, but we also need strategies and migration paths to accommodate and integrate Internet, intranet, and World Wide Web (WWW) technologies into our existing IT infrastructure. While there are always emerging challenges, introduction of newer technologies, and customers with challenging and perplexing problems to solve, this approach should enable us to maximize the effectiveness of our existing security investments, while bridging the gap to the long awaited and always sought after perfect solution!

Security solutions are slowly emerging, but interoperability, universally accepted security standards, application programming interfaces (APIs) for security, vendor support and cooperation, and multiplatform security products are still problematic. Where there are products and solutions, they tend to have niche applicability, be vendor-centric or only address one of a larger set of security problems and requirements. For the most part, no single vendor or even software/vendor consortium has addressed the overall security problem within "open" systems and public networks. This indicates that the problem is very large, and that we are years away from solving today's problem, not to mention tomorrow's.

This chapter establishes and supports the need for an underlying baseline security framework that will enable companies to successfully evolve to doing business over the Internet and using internal intranet- and World Wide Web-based technologies most effectively within their own corporate computing and networking infrastructures. It presents a solution set that exploits existing skills, resources, and security implementations.

By acknowledging today's challenges, bench-marking today's requirements, and understanding our "as is condition" accordingly, we as security practitioners can best plan for security in the twenty-first century. Added benefits adjacent to this strategy will hopefully include a more cost-effective and seamless integration of security policies, security architectures, security control mechanisms, and security management processes to support this environment.

For most companies, the transition to "open" systems technologies is still in progress and most of us are somewhere in the process of converting mainframe applications and systems to distributed network-centric client-server infrastructures. Nevertheless, we are continually challenged to provide a secure environment today, tomorrow, and in the future, including smooth transitions from one generation to another. This chapter considers a phased integration methodology that initially focuses on the update of corporate policies and procedures, including most security policies and procedures; secondly, enhances existing distributed security architectures to accommodate the use of the Internet, intranet, and WWW technologies; thirdly, devises a security implementation plan that incorporates the use of new and emerging security products and techniques; and finally, addresses security management and infrastructure support requirements to tie it all together.

It is important to keep in mind, as with any new and emerging technology, Internet, intranet, and WWW technologies do not necessarily bring new and unique security concerns, risks, and vulnerabilities, but rather introduce new problems, challenges and approaches within our existing security infrastructure.

Security requirements, goals, and objectives remain the same, while the application of security, control mechanisms, and solution sets are different and require the involvement and cooperation of multidisciplined technical and functional area teams. As in any distributed environment, there are more players, and it is more difficult to find or interpret the overall requirements or even talk to anyone who sees or understands the big picture. More people are involved than ever before, emphasizing the need to communicate both strategic and tactical security plans broadly and effectively throughout the entire enterprise. The security challenges and the resultant problems become larger and more complex in this environment. Management must be kept up-to-date and thoroughly understand overall risk to the corporation's information assets with the implementation or decisions to implement new technologies. They must also understand, fund, and support the influx of resources required to manage the security environment.

As with any new and emerging technology, security should be addressed early in terms of understanding the requirements, participating in the evaluation of products and related technologies, and finally in the engineering, design, and implementation of new applications and systems. Security should also be considered during all phases of the systems development life cycle. This is nothing new, and many of us have learned this lesson painfully over the years as we have tried to retrofit security solutions as an adjunct to the implementation of some large and complex system. Another important point to consider throughout the integration of new technologies, is "technology does not drive or dictate security policies, but the existing and established security policies drive the application of new technologies." This point must be made to management, customers, and supporting IT personnel.

For most of us, the WWW will be one of the most universal and influential trends impacting our internal enterprise and its computing and networking support structure. It will widely influence our decisions to extend our internal business processes out to the Internet and beyond. It will enable us to use the same user interface, the same critical systems and applications, work towards one single original source of data, and continue to address the age-old problem: how can I reach the largest number of users at the lowest cost possible?"

THE PATH TO INTERNET/BROWSER TECHNOLOGIES

Everyone is aware of the staggering statistics relative to the burgeoning growth of the Internet over the last decade. The use of the WWW can even top that growth, causing the traffic on the Internet to double every six months. With five internal Web servers being deployed for every one external Web server, the rise of the intranet is also more than just hype. Companies are predominately using the Web technologies on the intranet to share

information and documents. Future application possibilities are basically any enterprise-wide application such as education and training; corporate policies and procedures; human resources applications such as a resume, job posting, etc.; and company information. External Web applications include marketing and sales.

For the purpose of this discussion, we can generally think of the Internet in three evolutionary phases. While each succeeding phase has brought with it more utility and the availability of a wealth of electronic and automated resources, each phase has also exponentially increased the risk to our internal networks and computing environments.

Phase I, the early days, is characterized by a limited use of the Internet, due in the most part to its complexity and universal accessibility. The user interface was anything but user friendly, typically limited to the use of complex UNIX-based commands via line mode. Security by obscurity was definitely a popular and acceptable way of addressing security in those early days, as security organizations and MIS management convinced themselves that the potential risks were confined to small user populations centered around homogeneous computing and networking environments. Most companies were not externally connected in those days, and certainly not to the Internet.

Phase II is characterized by the introduction of the first versions of data base search engines, including Gopher and Wide Area Information System (WAIS). These tools were mostly used in the government and university environments and were not well known nor generally proliferated in the commercial sector.

Phase III brings us up to today's environment, where Internet browsers are relatively inexpensive, readily available, easy to install, easy to use through GUI frontends and interfaces, interoperable across heterogeneous platforms, and ubiquitous in terms of information access.

The growing popularity of the Internet and the introduction of the "Internet" should not come as a surprise to corporate executives who are generally well read on such issues and tied into major information technology (IT) vendors and consultants. However, quite frequently companies continue to select one of two choices when considering the implementation of WWW and Internet technologies. Some companies, who are more technically astute and competitive, have jumped in totally and are exploiting Internet technologies, electronic commerce, and the use of the Web. Others, of a more conservative nature and more technically inexperienced, continue to maintain a hard-line policy on external connectivity, which basically continues to say "NO."

Internet technologies offer great potential for cost savings over existing technologies, representing huge investments over the years in terms of

revenue and resources now supporting corporate information infrastructures and contributing to the business imperatives of those enterprises. Internet-based applications provide a standard communications interface and protocol suite ensuring interoperability and access to the organization's heterogeneous data and information resources. Most WWW browsers run on all systems and provide a common user interface and ease of use to a wide range of corporate employees.

Benefits derived from the development of WWW-based applications for internal and external use can be categorized by the cost savings related to deployment, generally requiring very little support or end-user training. The browser software is typically free, bundled in vendor product suites, or very affordable. Access to information, as previously stated, is ubiquitous and fairly straightforward.

Use of internal WWW applications can change the very way organizations interact and share information. When established and maintained properly, an internal WWW application can enable everyone on the internal network to share information resources, update common use applications, receive education and training, and keep in touch with colleagues at their home base, from remote locations, or on the road.

INTERNET/WWW SECURITY OBJECTIVES

As mentioned earlier, security requirements do not change with the introduction and use of these technologies, but the emphasis on where security is placed and how it is implemented does change. The company's Internet, intranet, and WWW security strategies should address the following objectives, in combination or in prioritized sequence, depending on security and access requirements, company philosophy, the relative sensitivity of the company's information resources, and the business imperative for using these technologies.

- Ensure that Internet- and WWW-based application and the resultant access to information resources are protected, and that there is a cost-effective and user-friendly way to maintain and manage the underlying security components over time as new technology evolves and security solutions mature in response.
- Information assets should be protected against unauthorized usage and destruction. Communication paths should be encrypted as well as transmitted information that is broadcast over public networks.
- Receipt of information from external sources should be decrypted and authenticated. Internet- and WWW-based applications, WWW pages, directories, discussion groups, and data bases should all be secured using access control mechanisms.
- Security administration and overall support should accommodate a combination of centralized and decentralized management.

- User privileges should be linked to resources, with privileges to those resources managed and distributed through directory services.
- Mail and real-time communications should also be consistently protected. Encryption key management systems should be easy to administer, compliant with existing security architectures, compatible with existing security strategies and tactical plans, and secure to manage and administer.
- New security policies, security architectures, and control mechanisms should evolve to accommodate this new technology; not change in principle or design.

Continue to use risk management methodologies as a baseline for deciding how many of the new Internet, intranet, and WWW technologies to use and how to integrate them into the existing Information Security Distributed Architecture. As always, ensure that the optimum balance between access to information and protection of information is achieved during all phases of the development, integration, implementation, and operational support life cycle.

INTERNET AND WWW SECURITY POLICIES AND PROCEDURES

Having said all of this, it is clear that we need new and different policies, or minimally, an enhancement or refreshing of current policies supporting more traditional means of sharing, accessing, storing, and transmitting information. In general, high-level security philosophies, policies, and procedures should not change. In other words, who is responsible for what (the fundamental purpose of most high-level security policies) does not change. These policies are fundamentally directed at corporate management, process, application and system owners, functional area management, and those tasked with the implementation and support of the overall IT environment. There should be minimal changes to these policies, perhaps only adding the Internet and WWW terminology.

Other high-level corporate policies must also be modified, such as the use of corporate assets, responsibility for sharing and protecting corporate information, etc. The second-level corporate policies, usually more procedure oriented typically addressing more of the "how," should be more closely scrutinized and may change the most when addressing the use of the Internet, intranet, and Web technologies for corporate business purposes. New classifications and categories of information may need to be established and new labeling mechanisms denoting a category of information that cannot be displayed on the Internet or new meanings to "all allow" or "public" data. The term "public," for instance, when used internally, usually means anyone authorized to use internal systems. In most companies, access to internal networks, computing systems, and information is

severely restricted and "public" would not mean unauthorized users, and certainly not any user on the Internet.

Candidate lower-level policies and procedures for update to accommodate the Internet and WWW include external connectivity, network security, transmission of data, use of electronic commerce, sourcing and procurement, E-mail, nonemployee use of corporate information and electronic systems, access to information, appropriate use of electronic systems, use of corporate assets, etc.

New policies and procedures (most likely enhancements to existing policies) highlight the new environment and present an opportunity to dust off and update old policies. Involve a broad group of customers and functional support areas in the update to these policies. The benefits are many. It exposes everyone to the issues surrounding the new technologies, the new security issues and challenges, and gains buy-in through the development and approval process from those who will have to comply when the policies are approved. It is also an excellent way to raise the awareness level and get attention to security up front.

The most successful corporate security policies and procedures address security at three levels, at the management level through high-level policies, at the functional level through security procedures and technical guidelines, and at the end-user level through user awareness and training guidelines. Consider the opportunity to create or update all three when implementing Internet, intranet, and WWW technologies.

Since these new technologies increase the level of risk and vulnerability to your corporate computing and network environment, security policies should probably be beefed up in the areas of audit and monitoring. This is particularly important because security and technical control mechanisms are not mature for the Internet and WWW and therefore more manual processes need to be put in place and mandated to ensure the protection of information.

The distributed nature of Internet, intranet, and WWW and their inherent security risks can be addressed at a more detailed level through an integrated set of policies, procedures, and technical guidelines. Because these policies and processes will be implemented by various functional support areas, there is a great need to obtain by-in from these groups and ensure coordination and integration through all phases of the systems' life cycle. Individual and collective roles and responsibilities should be clearly delineated to include monitoring and enforcement.

Other areas to consider in the policy update include legal liabilities, risk to competition-sensitive information, employees' use of company time while "surfing" the Internet, use of company logos and trade names by

	Auth.	Trans. Controls	Encryption	Audit	Ownership
External Public Data				(X)	X
Internal Public Data				(X)	X

External Cntl. Data	X	X	X	X	X
Update Applications	X	X		X	X

Exhibit 1. Sample Data Protection Classification Hierarchy

employees using the Internet, defamation of character involving company employees, loss of trade secrets, loss of the competitive edge, ethical use of the Internet, etc.

DATA CLASSIFICATION SCHEME

A data classification scheme is important to both reflect existing categories of data and introduce any new categories of data needed to support the business use of the Internet, electronic commerce, and information sharing through new intranet and WWW technologies. The whole area of nonemployee access to information changes the approach to categorizing and protecting company information.

The sample chart below (Exhibit 1) is an example of how general to specific categories of company information can be listed, with their corresponding security and protection requirements to be used as a checklist by application, process, and data owners to ensure the appropriated level of protection, and also as a communication tool to functional area support personnel tasked with resource and information protection. A supplemental chart could include application and system names familiar to corporate employees, or types of general applications and information such as payroll, HR, marketing, manufacturing, etc.

Note that encryption may not be required for the same level of data classification in the mainframe and proprietary networking environment, but in "open" systems and distributed and global networks transmitted data are much more easily compromised. Security should be applied based on a thorough risk assessment considering the value of the information, the risk introduced by the computing and network environment, the technical control mechanisms feasible or available for implementation, and the ease of administration and management support. Be careful to apply the right "balance" of security. Too much is just as costly and ineffective as too little in most cases.

APPROPRIATE USE POLICY

It is important to communicate management's expectation for employee's use of these new technologies. An effective way to do that is to supplement the corporate policies and procedures with a more user-friendly bulletined

Examples of *Unacceptable* Use include but not limited to the following:

1. Using company equipment, functions or services for nonbusiness-related activities while on company time; which in effect is mischarging
2. Using the equipment or services for financial or commercial gain
3. Using the equipment or services for any illegal activity
4. Dial-in usage from home for Internet services for personal gain
5. Accessing nonbusiness-related news groups or BBS
6. Willful intent to degrade or disrupt equipment, software or system performance
7. Vandalizing the data or information of another user
8. Gaining unauthorized access to resources or information
9. Invading the privacy of individuals
10. Masquerading as or using an account owned by another user
11. Posting anonymous messages or mail for malicious intent
12. Posting another employee's personal communication or mail without the original author's consent; this excludes normal business E-mail forwarding
13. Downloading, storing, printing, or displaying files or messages that are profane, obscene, or that use language or graphics which offends or tends to degrade others
14. Transmitting company data over the network to noncompany employees without following proper release precedures
15. Loading software obtained from outside the standard company's procurement channels onto a company system without proper testing and approval
16. Initiating or forwarding electronic chain mail.

Examples of *Acceptable Use* include but not limited to the following:

1. Accessing the Internet, computer resources, fax machines, and phones for information directly related to your work assignment
2. Off-hour usage of computer systems for degree-related school work where allowed by local site practices
3. Job related On Job Training (OJT)

Exhibit 2. Appropriate Use Policy

---

list of requirements. The list should be specific, highlight employee expectations and outline what employees can and cannot do on the Internet, intranet, and WWW. The goal is to communicate with each and every employee, leaving little room for doubt or confusion. An Appropriate Use Policy (Exhibit 2) could achieve these goals and reinforce the higher level. Areas to address include the proper use of employee time, corporate computing and networking resources, and acceptable material to be viewed or downloaded to company resources.

Most companies are concerned with the Telecommunications Act and their liabilities in terms of allowing employees to use the Internet on company time and with company resources. Most find that the trade-off is highly skewed to the benefit of the corporation in support of the utility of the Internet. Guidelines must be carefully spelled out and coordinated with the legal department to ensure that company liabilities are addressed

through clear specification of roles and responsibilities. Most companies do not monitor their employee's use of the Internet or the intranet, but find that audit trail information is critical to prosecution and defense for computer crime.

Overall computer security policies and procedures are the baseline for any security architecture and the first thing to do when implementing any new technology. However, you are never really finished as the development and support of security policies is an iterative process and should be revisited on an ongoing basis to ensure that they are up-to-date, accommodate new technologies, address current risk levels, and reflect the company's use of information and network and computing resources.

There are four basic threats to consider when you begin to use Internet, intranet, and Web technologies:

- Unauthorized alteration of data
- Unauthorized access to the underlying operating system
- Eavesdropping on messages passed between a server and a browser
- Impersonation

Your security strategies should address all four. These threats are common to any technology in terms of protecting information. In the remainder of this chapter, we will build upon the general "good security practices and traditional security management" discussed in the first section and apply these lessons to the technical implementation of security and control mechanisms in the Internet, intranet, and Web environments.

The profile of a computer hacker is changing with the exploitation of Internet and Web technologies. Computerized bulletin board services and network chat groups link computer hackers (formerly characterized as loners and misfits) together. Hacker techniques, programs and utilities, and easy-to-follow instructions are readily available on the net. This enables hackers to more quickly assemble the tools to steal information and break into computers and networks, and it also provides the "would-be" hacker a readily available arsenal of tools.

INTERNAL/EXTERNAL APPLICATIONS

Most companies segment their networks and use firewalls to separate the internal and external networks. Most have also chosen to push their marketing, publications, and services to the public side of the firewall using file servers and Web servers. There are benefits and challenges to each of these approaches. It is difficult to keep data synchronized when duplicating applications outside the network. It is also difficult to ensure the security of those applications and the integrity of the information. Outside the firewall is simply *outside*, and therefore also outside the protections of the internal security environment. It is possible to protect that

information and the underlying system through the use of new security technologies for authentication and authorization. These techniques are not without trade-offs in terms of cost and ongoing administration, management, and support.

Security goals for external applications that bridge the gap between internal and external, and for internal applications using the Internet, intranet, and WWW technologies should all address these traditional security controls:

- Authentication
- Authorization
- Access control
- Audit
- Security administration

Some of what you already used can be ported to the new environment, and some of the techniques and supporting infrastructure already in place supporting mainframe-based applications can be applied to securing the new technologies.

Using the Internet and other public networks is an attractive option, not only for conducting business-related transactions and electronic commerce, but also for providing remote access for employees, sharing information with business partners and customers, and supplying products and services. However, public networks create added security challenges for IS management and security practitioners, who must devise security systems and solutions to protect company computing, networking, and information resources. Security is a CRITICAL component.

Two watchdog groups are trying to protect online businesses and consumers from hackers and fraud. The council of Better Business Bureaus has launched BBBOnline, a service that provides a way to evaluate the legitimacy of online businesses. In addition, the national computer security association, NCSA, launched a certification program for secure WWW sites. Among the qualities that NCSA looks for in its certification process are extensive logging, the use of encryption including those addressed in this chapter, and authentication services.

There are a variety of protection measures that can be implemented to reduce the threats in the Web/server environment, making it more acceptable for business use. Direct server protection measures include secure Web server products which use differing designs to enhance the security over user access and data transmittal. In addition to enhanced secure Web server products, the Web server network architecture can also be addressed to protect the server and the corporate enterprise which could be placed in a vulnerable position due to server enabled connectivity. Both

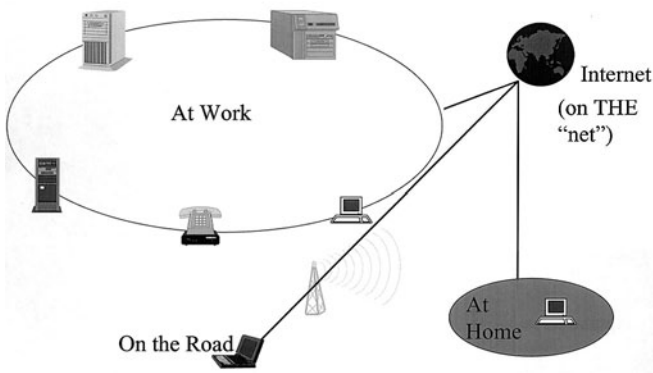

Exhibit 3. Where are your Users?

secure server and secure Web server designs will be addressed, including the application and benefits to using each.

WHERE ARE YOUR USERS?

Discuss how the access point where your users reside contributes to the risk and the security solutions set. Discuss the challenge when users are all over the place and you have to rely on remote security services that are only as good as the users' correct usage. Issues of evolving technologies can also be addressed. Concerns for multiple layering of controls and dissatisfied users with layers of security controls, passwords, hoops, etc. can also be addressed.

WEB BROWSER SECURITY STRATEGIES

Ideally, Web browser security strategies should use a network-based security architecture that integrates your company's external Internet and the internal intranet security policies. Ensure that users on any platform, with any browser, can access any system from any location if they are authorized and have a "need-to-know." Be careful not to adopt the latest evolving security product from a new vendor or an old vendor capitalizing on a hot marketplace.

Recognizing that the security environment is changing rapidly, and knowing that we don't want to change our security strategy, architecture, and control mechanisms every time a new product or solution emerges, we need to take time and use precautions when devising browser security solutions. It is sometimes a better strategy to stick with the vendors that you have already invested in and negotiate with them to enhance their existing products, or even contract with them to make product changes

specific or tailored to accommodate your individual company requirements. Be careful in these negotiations as it is extremely likely that other companies have the very same requirements. User groups can also form a common position and interface to vendors for added clout and pressure.

You can basically secure your Web server as much as or as little as you wish with the current available security products and technologies. The trade offs are obvious: cost, management, administrative requirements, and time. Solutions can be hardware, software and personnel intensive.

Enhancing the security of the Web server itself has been a paramount concern since the first Web server initially emerged, but progress has been slow in deployment and implementation. As the market has mushroomed for server use, and the diversity of data types that are being placed on the server has grown, the demand has increased for enhanced Web server security. Various approaches have emerged, with no single *de facto* standard yet emerging (though there are some early leaders — among them Secure Sockets Layer [SSL] and Secure Hypertext Transfer Protocol [S-HTTP]). These are two significantly different approaches, but both widely seen in the marketplace.

Secure Socket Layer (SSL) Trust Model

One of the early entrants into the secure Web server and client arena is Netscape's Commerce Server, which utilizes the Secure Sockets Layer (SSL) trust model. This model is built around the RSA Public Key/Private Key architecture. Under this model, the SSL-enabled server is authenticated to SSL-aware clients, proving its identity at each SSL connection. This proof of identity is conducted through the use of a public/private key pair issued to the server validated with x.509 digital certificates. Under the SSL architecture, Web server validation can be the only validation performed, which may be all that is needed in some circumstances. This would be applicable for those applications where it is important to the user to be assured of the identity of the target server, such as when placing company orders, or other information submittal where the client is expecting some important action to take place. Exhibit 4 diagrams this process.

Optionally, SSL sessions can be established that also authenticate the client and encrypt the data transmission between the client and the server for multiple I/P services (HTTP, Telnet, FTP). The multiservice encryption capability is available because SSL operates below the application layer and above the TCP/IP connection layer in the protocol stack, and thus other TCP/IP services can operate on top of a SSL-secured session.

Optionally, authentication of a SSL client is available when the client is registered with the SSL server, and occurs after the SSL-aware client connects and authenticates the SSL server. The SSL client then submits its digital

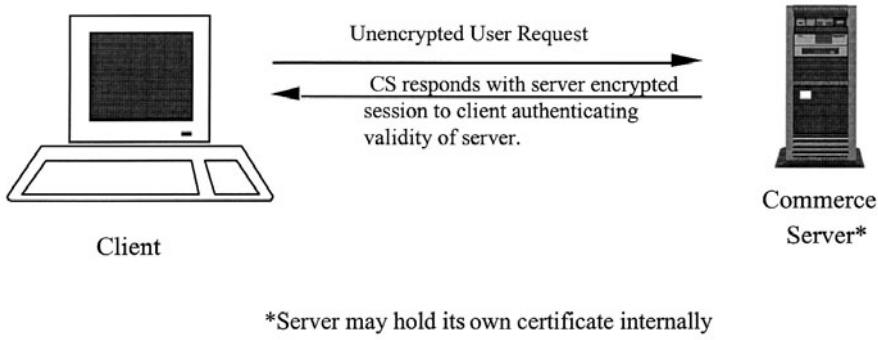

Exhibit 4. Server Authentication

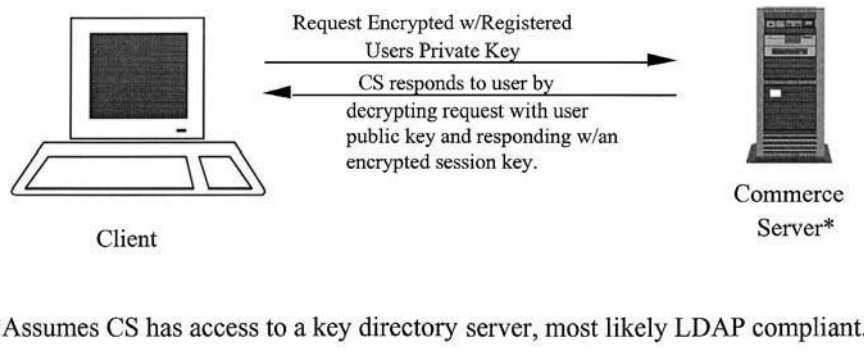

Exhibit 5. Client and Server Authentication

certificate to the SSL server, where the SSL server validates the client's certificate and proceeds to exchange a session key to provide encrypted transmissions between the client and the server. Exhibit 5 provides a graphical representation of this process for mutual client and server authentication under the SSL architecture. This type of mutual client/server authentication process should be considered when the data being submitted by the client are sensitive enough to warrant encryption prior to being submitted over a network transmission path.

Though there are some "costs" with implementing this architecture, these cost variables must be considered when proposing a SSL server implementation to enhance your Web server security. First of all, the design needs to consider whether to only provide server authentication, or both server and client authentication. The issue when expanding the

authentication to include client authentication includes the administrative overhead of managing the user keys, including a key revocation function. This consideration, of course, has to assess the size of the user base, potential for growth of your user base, and stability of your proposed user community. All of these factors will impact the administrative burden of key management, especially if there is the potential for a highly unstable or transient user community.

The positive considerations for implementing a SSL-secured server is the added ability to secure other I/P services for remote or external SSL clients. SSL-registered clients now have the added ability to communicate securely by utilizing Telnet and FTP (or other I/P services) after passing SSL client authentication and receiving their session encryption key. In general the SSL approach has very broad benefits, but these benefits come with the potential added burden of higher administration costs, though if the value of potential data loss is great, then it is easily offset by the administration cost identified above.

Secure Hypertext Transfer Protocol (S-HTTP)

Secure Hypertext Transfer Protocol, (S-HTTP) is emerging as another security tool and incorporates a flexible trust model for providing secure Web server and client HTTP communications. It is specifically designed for direct integration into HTTP transactions, with its focus on flexibility for establishing secure communications in a HTTP environment while providing transaction confidentiality, authenticity/integrity, and nonrepudiation. S-HTTP incorporates a great deal of flexibility in its trust model by leaving defined variable fields in the header definition which identifies the trust model or security algorithm to be used to enable a secure transaction. S-HTTP can support symmetric or asymmetric keys, and even a Kerberos-based trust model. The intention of the authors was to build a flexible protocol that supports multiple trusted modes, key management mechanisms, and cryptographic algorithms through clearly defined negotiation between parties for specific transactions.

At a high level the transactions can begin in a untrusted mode (standard HTTP communication), and "setup" of a trust model can be initiated so that the client and the server can negotiate a trust model, such as a symmetric key-based model on a previously agreed-upon symmetric key, to begin encrypted authentication and communication. The advantage of a S-HTTP-enabled server is the high degree of flexibility in securely communicating with Web clients. A single server, if appropriately configured and network enabled, can support multiple trust models under the S-HTTP architecture and serve multiple client types. In addition to being able to serve a flexible user base, it can also be used to address multiple data classifications on a single server where some data types require higher-level encryption or

protection then other data types on the same server and therefore varying trust models could be utilized.

The S-HTTP model provides flexibility in its secure transaction architecture, but focuses on HTTP transaction vs. SSL which mandates the trust model of a public/private key security model, which can be used to address multiple I/P services. But the S-HTTP mode is limited to only HTTP communications.

INTERNET, INTRANET, AND WORLD WIDE WEB SECURITY ARCHITECTURES

Implementing a secure server architecture, where appropriate, should also take into consideration the existing enterprise network security architecture and incorporate the secure server as part of this overall architecture. In order to discuss this level of integration, we will make an assumption that the secure Web server is to provide secure data dissemination for external (outside the enterprise) distribution and/or access. A discussion of such a network security architecture would not be complete without addressing the placement of the Web server in relation to the enterprise firewall (the firewall being the dividing line between the protected internal enterprise environment and the external "public" environment).

Setting the stage for this discussion calls for some identification of the requirements, so the following list outlines some sample requirements for this architectural discussion on integrating a secure HTTP server with an enterprise firewall.

- Remote client is on public network accessing sensitive company data
- Remote client is required to authenticate prior to receiving data
- Remote client only accesses data via HTTP
- Data is only updated periodically
- Host site maintains firewall
- Sensitive company data must be encrypted on public networks
- Company support personnel can load HTTP server from inside the enterprise

Based on these high-level requirements, an architecture could be set up that would place a S-HTTP server external to the firewall, with one-way communications from inside the enterprise "to" the external server to perform routine administration, and periodic data updates. Remote users would access the S-HTTP server utilizing specified S-HTTP secure transaction modes, and be required to identify themselves to the server prior to being granted access to secure data residing on the server. Exhibit 6 depicts this architecture at a high level. This architecture would support a secure HTTP distribution of sensitive company data, but doesn't provide absolute protection due to the placement of the S-HTTP server entirely external to

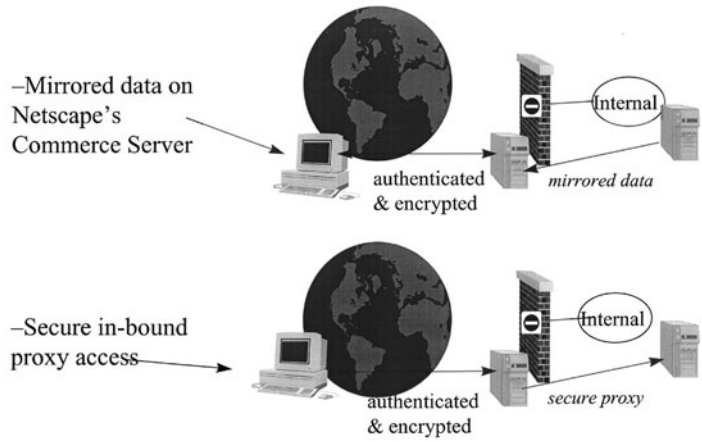

Exhibit 6. Externally Placed Server

the protected enterprise. There are some schools of thought that since this server is unprotected by the company-controlled firewall, the S-HTTP server itself is vulnerable, thus risking the very control mechanism itself and the data residing on it. The opposing view on this is that the risk to the overall enterprise is minimized, as only this server is placed at risk and its own protection is the S-HTTP process itself. This process has been a leading method to secure the data, without placing the rest of the enterprise at risk, by placing the S-HTTP server logically and physically outside the enterprise security firewall.

A slightly different architecture has been advertised that would position the S-HTTP server inside the protected domain, as Exhibit 7 indicates. The philosophy behind this architecture is that the controls of the firewall (and inherent audits) are strong enough to control the authorized access to the S-HTTP server, and also thwart any attacks against the server itself. Additionally, the firewall can control external users so that they only have S-HTTP access via a logically dedicated path, and only to the designated S-HTTP server itself, without placing the rest of the internal enterprise at risk. This architecture relies on the absolute ability of the firewall and S-HTTP of always performing their designated security function as defined; otherwise, the enterprise has been opened for attack through the allowed path from external users to the internal S-HTTP server. Because these conditions are always required to be true and intact, the model with the server external to the firewall has been more readily accepted and implemented.

Both of these architectures can offer a degree of data protection in a S-HTTP architecture when integrated with the existing enterprise firewall

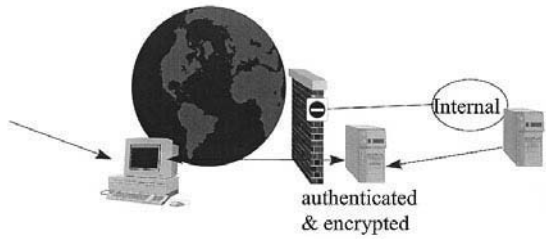

Exhibit 7. Internally Placed Server

architecture. As an aid in determining which architectural approach is right for a given enterprise, a risk assessment can provide great input to the decision. This risk assessment may include decision points such as:

- Available resources to maintain a high degree of firewall audit and S-HTTP server audit
- Experience in firewall and server administration
- Strength of their existing firewall architecture

SECURE WWW CLIENT CONFIGURATION

There is much more reliance on the knowledge and cooperation of the end user and the use of a combination of desktop and workstation software, security control parameters within client software, and security products all working together to mimic the security of the mainframe and distributed application's environments. Consider the areas below during the risk assessment process and the design of WWW security solution sets.

- Ensure that all internal and external company-used workstations have resident and active antivirus software products installed. Preferably use a minimum number of vendor products to reduce security support and vulnerabilities as there are varying vendor schedules for providing virus signature updates.
- Ensure that all workstation and browser client software is preconfigured to return all WWW and other external file transfers to temporary files on the desktop. Under no circumstances should client server applications or process-to-process automated routines download files to system files, preference files, bat files, start-up files, etc.
- Ensure that JAVA script is turned off in the browser client software desktop configuration.
- Configure browser client software to automatically flush the cache, either upon closing the browser or disconnecting from each Web site.
- When possible or available, implement one of the new security products that scans WWW downloads for viruses.

- Provide user awareness and education to all desktop WWW and Internet users to alert them to the inherent dangers involved in using the Internet and WWW. Include information on detecting problems, their roles and responsibilities, your expectations, security products available, how to set and configure their workstations and program products, etc.
- Suggest or mandate the use of screen savers, security software programs, etc., in conjunction with your security policies and distributed security architectures.

This is a list of current areas of concern from a security perspective. There are options that when combined can tailor the browser to the specifications of individual workgroups or individuals. These options will evolve with the browser technology. The list should continue to be modified as security problems are corrected or as new problems occur.

AUDIT TOOLS AND CAPABILITIES

As we move further and further from the "good old days" when we were readily able to secure the "glass house", we rely more on good and sound auditing practices. As acknowledged throughout this chapter, security control mechanisms are mediocre at best in today's distributed networking and computing environments. Today's auditing strategies must be robust, available across multiple heterogeneous platforms, computing and network based, real-time and automated, and integrated across the enterprise.

Today, information assets are distributed all over the enterprise, and therefore auditing strategies must acknowledge and accept this challenge and accommodate more robust and dicey requirements. As is the case when implementing distributed security control mechanisms, in the audit environment there are also many players and functional support areas involved in collecting, integrating, synthesizing, reporting, and reconciling audit trails and audit information. The list includes applications and applications developers and programs, data base management systems and data base administrators, operating systems and systems administrators, local area network (LAN) administrators and network operating systems (NOS), security administrators and security software products, problem reporting and tracking systems and helpline administrators, and others unique to the company's environment.

As well as real-time, the audit system should provide for tracking and alarming, both to the systems and network management systems, and via pagers to support personnel. Policies and procedures should be developed for handling alarms and problems, i.e., isolate and monitor, disconnect, etc.

There are many audit facilities available today, including special audit software products for the Internet, distributed client server environments,

WWW clients and servers, Internet firewalls, E-mail, News Groups, etc. The application of one or more of these must be consistent with your risk assessment, security requirements, technology availability, etc. The most important point to make here is the fundamental need to centralize distributed systems auditing (not an oxymoron). Centrally collect, sort, delete, process, report, take action and store critical audit information. Automate any and all steps and processes. It is a well-established fact that human beings cannot review large numbers of audit records and logs and reports without error. Today's audit function is an adjunct to the security function, and as such is more important and critical than ever before. It should be part of the overall security strategy and implementation plan.

The overall audit solutions set should incorporate the use of browser access logs, enterprise security server audit logs, network and firewall system authentication server audit logs, application and middle-ware audit logs, URL filters and access information, mainframe system audit information, distributed systems operating system audit logs, data base management system audit logs, and other utilities that provide audit trail information such as accounting programs, network management products, etc.

The establishment of auditing capabilities over WWW environments follows closely with the integration of all external WWW servers with the firewall, as previously mentioned. This is important when looking at the various options available to address a comprehensive audit approach.

WWW servers can offer a degree of auditability based on the operating system of the server on which they reside. The more time-tested environments such as UNIX are perceived to be difficult to secure, whereas the emerging NT platform with its enhanced security features supposedly make it a more secure and trusted platform with a wide degree of audit tools and capabilities (though the vote is still out on NT, as some feel it hasn't had the time and exposure to discover all the potential security holes, perceived or real). The point, though, is that in order to provide some auditing the first place to potentially implement the first audit is on the platform where the WWW server resides. Issues here are the use of privileged accounts and file logs and access logs for log-ins to the operating system, which could indicate a backdoor attack on the WWW server itself. If server-based log are utilized, they of course must be file protected and should be off-loaded to a nonserver-based machine to protect against after-the-fact corruption.

Though the server logs aren't the only defensive logs that should be relied upon in a public WWW server environment, the other components in the access architecture should be considered for use as audit log tools. As previously mentioned, the WWW server should be placed in respect to its required controls in relation to the network security firewall. If it is a S-HTTP server that is placed behind (Exhibit 4) the firewall then the firewall of

course has the ability to log all access to the S-HTTP server and provide a log separate from the WWW server-based logs, and is potentially more secure should the WWW server somehow become compromised.

The prevalent security architecture places externally accessible WWW servers wholly outside the firewall, thus virtually eliminating the capability of auditing access to the WWW server except from users internal to the enterprise. In this case, the network security audit in the form of the network management tool, which monitors the "health" of enterprise components can be called upon to provide a minimal degree of audit over the status of your external WWW server. This type of audit can be important when protecting data which resides on your external server from being subject to "denial of service" attacks, which are not uncommon for external devices. But by utilizing your network management tool to guard against such attacks, and monitoring log alerts on the status or health of this external server, you can reduce the exposure to this type of attack.

Other outside devices that can be utilized to provide audit include the network router between the external WWW server and the true external environment, though these devices are not normally readily set up for comprehensive audit logs, but in some critical cases they could be reconfigured with added hardware and minimal customized programming. One such example would be the "I/P Accounting" function on a popular router product line, which allows off-loading of addresses and protocols through its external interface. This could be beneficial to analyze traffic, and if an attack alert was generated from one of the other logs mentioned, then these router logs could assist in possibly identifying the origin of the attack.

Another possible source of audit logging could come from "back end" systems that the WWW server is programmed to "mine" data from. Many WWW environments are being established to serve as "front ends" for much larger data repositories, such as Oracle data bases, where the WWW server receives user requests for data over HTTP, and the WWW server launches SQL_Net queries to a back end Oracle data base. In this type of architecture the more developed logging inherent to the Oracle environment can be called upon to provide audits over the WWW queries. The detailed Oracle logs can specify the quantity, data type, and other activity over all the queries that the WWW server has made, thus providing a comprehensive activity log that can be consolidated and reviewed should any type of WWW server compromise be suspected. A site could potentially discover the degree of data exposure though these logs.

These are some of the major areas where auditing can be put in place to monitor the WWW environment while enhancing its overall security. It is important to note that the potential placement of audits encompasses the entire distributed computing infrastructure environment, not just the new WWW server itself. In fact, there are some schools of thought that consider

the more reliable audits to be those that are somewhat distanced from the target server, thus reducing the potential threat of compromise to the audit logs themselves. In general, the important point is to look at the big picture when designing the security controls and a supporting audit solution.

WWW/Internet Audit Considerations

After your distributed Internet, intranet, and WWW security policies are firmly established, distributed security architectures are updated to accommodate this new environment. When planning for audit, and security control mechanisms are designed and implemented, you should plan how you will implement the audit environment — not only which audit facilities to use to collect and centralize the audit function, but how much and what type of information to capture, how to filter and review the audit data and logs, and what actions to take on the violations or anomalies identified. Additional consideration should be given to secure storage and access to the audit data. Other considerations include:

- Timely resolution of violations
- Disk space storage availability
- Increased staffing and administration
- In-house developed programming
- Ability to alarm and monitor in real time

WWW SECURITY FLAWS

As with all new and emerging technology, many initial releases come with some deficiency. But this has been of critical importance when that deficiency can impact the access or corruption of a whole corporation or enterprise's display to the world. This can be the case with Web implementations utilizing the most current releases which have been found to contain some impacting code deficiencies, though up to this point most of these deficiencies have been identified before any major damage has been done. This underlines the need to maintain a strong link or connection with industry organizations that announce code shortcomings that impact a sites Web implementation. A couple of the leading organizations are CERT, the Computer Emergency Response Team, and CIAC, Computer Incident Advisory Capability.

Just a few of these types of code or design issues that could impact a sites Web security include initial issues with the Sun JAVA language and Netscape's JavaScript (which is an extension library of their HyperText Markup Language, HTML).

The Sun Java language was actually designed with some aspects of security in mind, though upon its initial release there were several functions that were found to be a security risk. One of the most impacting bugs in an

early release was the ability to execute arbitrary machine instructions by loading a malicious Java applet. By utilizing Netscape's caching mechanism a malicious machine instruction can be downloaded into a user's machine and Java can be tricked into executing it. This doesn't present a risk to the enterprise server, but the user community within one's enterprise is of course at risk.

Other Sun Java language bugs include the ability to make network connections with arbitrary hosts (though this has since been patched with the following release) and Java's ability to launch denial of service attacks though the use of corrupt applets.

These types of security holes are more prevalent than the security profession would like to believe, as the JavaScript environment also was found to contain capabilities that allowed malicious functions to take place. The following three are among the most current and prevalent risks:

- JavaScripts ability to trick the user into uploading a file on his local hard disk to an arbitrary machine on the Internet
- The ability to hand out the user's directory listing from the internal hard disk
- The ability to monitor all pages the user visits during a session

The following are among the possible protection mechanisms:

- Maintain monitoring through CERT or CIAC, or other industry organizations that highlight such security risks.
- Utilize a strong software distribution and control capability, so that early releases aren't immediately distributed, and that new patched code known to fix a previous bug is released when deemed safe.
- In sensitive environments it may become necessary to disable the browser's capability to even utilize or execute JAVA or JavaScript — a selectable function now available in many browsers.

In the last point, it can be disturbing to some in the user community to disallow the use of such powerful tools, because they can be utilized against trusted Web pages, or those that require authentication through the use of SSL or S-HTTP. This approach can be coupled with the connection to S-HTTP pages where the target page has to prove its identity to the client user. In this case, enabling Java or JavaScripts to execute on the browser (a user-selectable option) could be done with a degree of confidence.

Other perceived security risks exist in a browser feature referred to as HTTP "Cookies." This is a feature that allows servers to store information on the client machine in order to reduce the store and retrieve requirements of the server. The cookies file can be written to by the server, and that server, in theory, is the only one that can read back their cookies entry. Uses of the cookie file include storing user's preferences or browser history

on a particular server or page, which can assist in guiding the user on their next visit to that same page. The entry in the cookies file identifies the information to be stored and the uniform resource locator (URL) or server page that can read back that information, though this address can be masked to some degree so multiple pages can read back the information.

The perceived security concern is that pages impersonating cookies-readable pages could read back a user's cookies information without the user knowing it, or discover what information is stored in their cookie file. The threat depends on the nature of the data stored in the cookie file, which is dependent on what the server chooses to write into a user's cookie file. This issue is currently under review, with the intention of adding additional security controls to the cookie file and its function. At this point it is important that users are aware of the existence of this file, which is viewable in the Macintosh environment as a Netscape file and in the Win environment as a cookies.txt file. There are already some inherent protections in the cookie file: one is the fact that the cookie file currently has a maximum of 20 entries, which potentially limits the exposure. Also, these entries can be set up with expiration dates to they don't have an unlimited lifetime.

WWW SECURITY MANAGEMENT

Consider the overall management of the Internet, intranet, and WWW environment. As previously mentioned, there are many players in the support role and for many of them this is not their primary job or priority. Regardless of where the following items fall in the support infrastructure, also consider these points when implementing ongoing operational support:

- Implement WWW browser and server standards.
- Control release and version distribution.
- Implement secure server administration including the use of products and utilities to erase sensitive data cache (NSClean).
- Ensure prompt problem resolution, management, and notification.
- Follow industry and vendor discourse on WWW security flaws and bugs including CERT distribution.
- Stay current on new Internet and WWW security problems, Netscape encryption, JAVA, Cookies, etc.

WWW SUPPORT INFRASTRUCTURE

- WWW servers accessible from external networks should reside outside the firewall and be managed centrally.
- By special approval, decentralized programs can manage external servers, but must do so in accordance with corporate policy and be subjected to rigorous audits.

- Externally published company information must be cleared through legal and public relations departments (i.e., follow company procedures).
- External outbound http access should utilize proxy services for additional controls and audit.
- WWW application updates must be authenticated utilizing standard company security systems (as required).
- Filtering and monitoring software must be incorporated into the firewall.
- The use of discovery crawler programs must be monitored and controlled.
- Virus software must be active on all desktop systems utilizing WWW.
- Externally published information should be routinely updated or verified through integrity checks.

In conclusion, as information security practitioners embracing the technical challenges of the 21st century, we are continually challenged to integrate new technology smoothly into our existing and underlying security architectures. Having a firm foundation or set of security principles, frameworks, philosophies and supporting policies, procedures, technical architectures, etc. will assist in the transition and our success.

Approach new technologies by developing processes to manage the integration and update the security framework and supporting infrastructure, as opposed to changing it. The Internet, intranet, and the World Wide Web is exploding around us — what is new today is old technology tomorrow. We should continue to acknowledge this fact while working aggressively with other MIS and customer functional areas to slow down the train to progress, be realistic, disciplined, and plan for new technology deployment.

39

An Introduction to IPSec

Bill Stackpole, CISSP

The IP Security Protocol Working Group (IPSec) was formed by the Internet Engineering Task Force (IETF) in 1992 to develop a standardized method for implementing privacy and authentication services on IP version 4 and the emerging version 6 protocols. There were several specific goals in mind. For the architecture to be widely adopted it would have to be flexible. It must be able to accommodate changes in cryptographic technology as well as the international restrictions on cryptographic use. Second, the architecture must support all the client IP protocols (i.e., Transmission Control Protocol or TCP, User Datagram Protocol or UDP) in standard or cast (i.e., multicast) modes. Third, it must be able to secure communications between two hosts or multiple hosts, two subnets or multiple subnets, or a combination of hosts and subnets. Finally, there had to be a method for automatically distributing the cryptographic keys. This chapter will cover the key features of the IPSec security architecture, its major components, and the minimum mandatory requirements for compliance.

Features

The goals of IPSec were transformed into the following key architectural features.

Separate Privacy and Authentication Functions with Transform Independence

IPSec privacy and authentication services are independent of each other. This simplifies their implementation and reduces their performance impact upon the host system. It also gives end users the ability to select the appropriate level of security for their transaction. The security functions are independent of their cryptographic transforms. This allows new encryption technologies to be incorporated into IPSec without changing the base architecture and avoids conflicts with location-specific use and exportation restrictions. It also makes it possible for end users to implement transforms that best meet their specific security requirements. Users can select authentication services using hashed cryptography which have low implementation costs, minimal performance impacts, and few international use restrictions. These implementations can be widely distributed and they provide a substantial improvement in security for most of today's Internet transactions. Or, users can select privacy functions based on private key cryptography. These are more difficult to implement, have higher performance impacts, and are often subject to international use restrictions, so although they provide a much higher level of security, their distribution and use is often limited. Or they can combine these functions to provide the highest possible level of security.

Network Layer (IP) Implementation with Unidirectional Setup

Introducing security functionality at the network layer means all the client IP protocols can operate in a secure manner without individual customization. Routing protocols like Exterior Gateway Protocol (EGP) and Border Gateway Protocol (BGP) as well as connection and connectionless transport protocols like TCP and UDP can be secured. Applications using these client protocols require no modifications to take advantage of IPSec

security services. The addition of IPSec services makes it possible to secure applications with inherent security vulnerabilities (e.g., clear-text password) with a single system modification. And this modification will secure any such application regardless of the IP services or transports it utilizes.

This capability even extends to streaming services using multicast and unicast packets where the destination address is indeterminate. IPSec makes this possible by using a unidirectional initialization scheme to set up secure connections. The sending station passes a setup index to the receiving station. The receiving station uses this index to reference the table of security parameters governing the connection. The receiving station does not need to interact with the sending station to establish a secure unidirectional connection. For bidirectional connections the process is reversed. The receiving station becomes the sender, passing its setup index back to the originator. Sending and receiving stations can be either hosts or security gateways.

Host and Gateway Topologies

IPSec supports two basic connection topologies: host-to-host and gateway-to-gateway. In the host (sometimes called end-to-end) topology, the sending and receiving systems are two or more hosts that establish secure connections to transmit data among themselves. In the gateway (also called subnet-to-subnet) topology, the sending and receiving systems are security gateways that establish connection to external (untrusted) systems on behalf of trusted hosts connected to their own internal (trusted) subnetwork(s). A trusted subnet-work is defined as a communications channel (e.g., Ethernet) containing one or more hosts that trust each other not to be engaged in passive or active attacks. A gateway-to-gateway connection is often referred to as a tunnel or a virtual private network (VPN). A third scenario, host-to-gateway, is also possible. In this instance the security gateway is used to establish connection between external hosts and trusted hosts on an internal subnet(s). This scenario is particularly useful for traveling workers or telecommuters who require access to applications and data on internal systems via untrusted networks like the Internet.

Key Management

The ability to effectively manage and distribute encryption keys is crucial to the success of any cryptographic system. The IP Security Architecture includes an application-layer key management scheme that supports public and private key-based systems and manual or automated key distribution. It also supports the distribution of other principle session parameters. Standardizing these functions makes it possible to use and manage IPSec security functions across multiple security domains and vendor platforms.

Two other key features of the IPSec Security Architecture are support for systems with Multi-Level Security (MLS) and the use of IANA (Internet Assigned Numbers Authority) assigned numbers for all standard IPSec type codes.

Implementation and Structures

The IPSec Security Architecture is centered around two IP header constructs: the Authentication Header (AH) and the Encapsulation Security Payload (ESP) header. To fully understand how these mechanisms function it is first necessary to look at the concept of security associations. In order to achieve algorithm independence, a flexible method for specifying session parameters had to be established. Security associations (SAs) became that method.

Security Associations (SA)

A security association is a table or database record consisting of a set of security parameters that govern security operations on one or more network connections. Security associations are part of the unidirectional initialization scheme mentioned above. The SA tables are established on the receiving host and referenced by the sending host using an index parameter known as the Security Parameters Index (SPI). The most common entries in an SA are:

- T*he type and operating mode of the transform*, for example DES in block chaining mode. This is a required parameter. Remember that IPSec was designed to be transform independent so this information must be synchronized between the endpoints if any meaningful exchange of data is going to take place.

- *The key or keys used by the transform algorithm*. For obvious reasons this is also a mandatory parameter. The source of the keys can vary. They can be entered manually when the SAS is defined on the host or gateway. They can be supplied via a key distribution system or — in the case of asymmetric encryption — the public key is sent across the wire during the connection setup.
- *The encryption algorithm's synchronization or initialization vector*. Some encryption algorithms, in particular those that use chaining, may need to supply the receiving system with an initial block of data to synchronize the cryptographic sequence. Usually, the first block of encrypted data serves this purpose, but this parameter allows for other implementations. This parameter is required for all ESP implementations but may be designated as "absent" if synchronization is not required.
- *The life span of the transform key(s)*. The parameter can be an expression of duration or a specific time when a key change is to occur. There is no predefined life span for cryptographic keys. The frequency with which keys are changed is entirely at the discretion of the security implementers at the endpoints. Therefore, this parameter is only recommended, not required.
- *The life span of the security association*. There is no predefined life span for a security association. The length of time a security association remains in effect is at the discretion of the endpoint implementers. Therefore, this parameter is also recommended, but not required.
- *Source address of the security association*. A security association is normally established in one direction only. A communications session between two endpoints will usually involve two security associations. When more than one sending host is using this security association, the parameter may be set to a wild-card value. Usually this address is the same as the source address in the IP header; therefore, this parameter is recommended, but not required.
- *The sensitivity level of the protected data*. This parameter is required for hosts implementing multilevel security and recommended for all other systems. The parameter provides a method of attaching security labels (e.g., Secret, Confidential, Unclassified) to ensure proper routing and handling by the endpoints.

Security associations are normally set up in one direction only. Before a secure transmission can be established, the SAs must be created on the sending and receiving hosts. These security associations can be configured manually or automatically via a key management protocol. When a datagram destined for a (secure) receiving host is ready to be sent, the sending system looks up the appropriate security association and passes the resulting index value to the receiving host. The receiving host uses the SPI and the destination address to look up the corresponding SA on its system. In the case of multilevel security, the security label also becomes part of the SA selection process. The receiving system then uses those SA parameters to process all subsequent packets from the sending host. To establish a fully authenticated communications session, the sending and receiving hosts would reverse roles and establish a second SA in the reverse direction.

One advantage to this unidirectional SA selection scheme is support for broadcast types of traffic. Security associations can still be established even in this receive-only scenario by having the receiving host select the SPI. Unicast packets can be assigned a single SPI value, and multicast packets can be assigned an SPI for each multicast group. However, the use of IPSec for broadcast traffic does have some serious limitations. The key management and distribution is difficult, and the value of cryptography is diminished because the source of the packet cannot be positively established.

Security Parameters Index (SPI)

The Security Parameters Index is a 32-bit pseudo-random number used to uniquely identify a security association (SA). The source of an SPI can vary. They can be entered manually when the SA is defined on the host or gateway, or they can be supplied via an SA distribution system. Obviously for the security function to work properly, the SPIs must be synchronized between the endpoints. SPI values 1 through 255 have been reserved by the IANA for use with openly specified (i.e., standard) implementations. SPIs require minimal management but some precautions should be observed to ensure that previously assigned SPIs are not reused too quickly after their associated SA has been deleted. An SPI value of zero (0) specifies that no security association exists for this transaction. On host-to-host connections, the SPI is used by the receiving host to look up the security association. On a gateway-to-gateway, unicast, or multicast transaction, the receiving system combines the SPI with the destination address (and in an MLS system, with the security label) to determine the appropriate SA. Now we will look at how IPSec authentication and privacy functions utilize SAs and SPIs.

Authentication Function

IPSec authentication uses a cryptographic hashing function to provide strong integrity and authentication for IP datagrams. The default algorithm is keyed Message Digest version 5 (MD5), which does not provide non-repudiation. Non-repudiation can be provided by using a cryptographic algorithm that supports it (e.g., RSA). The IPSec authentication function does not provide confidentiality or traffic analysis protection.

The function is computed over the entire datagram using the algorithm and keys(s) specified in the security association (SA). The calculation takes place prior to fragmentation, and fields that change during transit (e.g., ttl or hop count) are excluded. The resulting authentication data is placed into the Authentication Header (AH) along with the Security Parameter Index (SPI) assigned to that SA. Placing the authentication data in its own payload structure (the AH) rather than appending it to the original datagram means the user datagram maintains its original format and can be read and processed by systems not participating in the authentication. Obviously there is no confidentiality, but there is also no need to change the Internet infrastructure to support the IPSec authentication function. Systems not participating in the authentication can still process the datagrams normally.

The Authentication Header (AH) is inserted into the datagram immediately following the IP header (IPv4) or the Hop-by-Hop Header (IPv6) and prior to the ESP header when used with the confidentiality function, as seen in Exhibit 39.1.

The header type is IANA assigned number 51 and is identified in the next header or the protocol field of the preceding header structure. There are five parameter fields in an authentication header, four of which are currently in use (see also Exhibit 39.2):

- The next header field — used to identify the IP protocol (IANA assigned number) used in the next header structure.
- The payload length — the number of 32-bit words contained in the authentication data field.
- The reserved field — intended for future expansion. This field is currently set to zero (0).
- The SPI field — the value that uniquely identifies the security association (SA) used for this datagram.
- The authentication data field — the data output by the cryptographic transform padded to the next 32-bit boundary.

IP version 4 systems claiming AH compliance must implement the IP Authentication Header with at least the MD5 algorithm using a 128-bit key. Implementation of AH is mandatory for all IP version 6 hosts and must also implement the MD5 algorithm with a 128-bit key. All AH implementations have an option to support other additional authentication algorithms (e.g., SHA-1). In fact, well-known weaknesses in the current MD5 hash functions (see Hans Dobbertin, Cryptanalysis of MD5 Compress) will undoubtedly lead to its replacement in the next version of the AH specification. The likely replacement is HMAC-MD5. HMAC is an enhanced method for calculating Hashed Message Authentication Codes that greatly increased the cryptographic strength of the underlying algorithm. Because HMAC is an enhancement rather than a replacement, it can be easily added to existing AH implementations with little impact upon the original algorithm's performance. Systems using MLS are required to implement AH on packets containing sensitivity labels to ensure the end-to-end integrity of those labels.

EXHIBIT 39.1 IPv4 placement example.

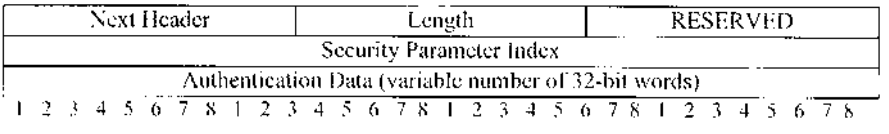

EXHIBIT 39.2 IP Authentication Header structure.

The calculation of hashed authentication data by systems using the Authentication Header does increase processing costs and communications latency; however, this impact is considerably less than that of a secret key cryptographic system. The Authentication Header function has a low implementation cost and is easily exportable because it is based on a hashing algorithm. Nevertheless , it would still represent a significant increase in security for most of the current Internet traffic.

Confidentiality Function

IPSec confidentiality uses keyed cryptography to provide strong integrity and confidentiality for IP datagrams. The default algorithm uses the Cipher Block Chaining mode of the U.S. Data Encryption Standard (DES CBC), which does not provide authentication or non-repudiation. It is possible to provide authentication by using a cryptographic transform that supports it. However, it is recommended that implementation requiring authentication or nonrepudiation use the IP Authentication Header for that purpose. The IPSec confidentiality function does not provide protection from traffic analysis attacks.

There are two modes of operation: tunnel and transport. In tunnel mode the entire contents of the original IP datagram are encapsulated into the Encapsulation Security Payload (ESP) using the algorithm and key(s) specified in the security association (SA). The resulting encrypted ESP along with the Security Parameter Index (SPI) assigned to this SA become the payload portion of a second datagram with a cleartext IP header. This cleartext header is usually a duplicate of the original header for host-to-host transfers, but in implementations involving security gateways the cleartext header usually addresses the gateway, while the encrypted header's addressing point is the endpoint host on an interior subnet. In transport mode only the transport layer (i.e., TCP, UDP) portion of the frame is encapsulated into the ESP so the cleartext portions of the IP header retain their original values. Although the term "transportmode" seems to imply a use limited to TCP and UDP protocols, this is a misnomer. Transport mode ESP supports all IP client protocols. Processing for both modes takes place prior to fragmentation on output and after reassembly on input.

The Encapsulation Security Payload (ESP) header can be inserted anywhere in the datagram after the IP Header and before the transport layer protocol. It must appear after the AH header when used with the authentication function (see Exhibit 39.3).

The header type is IANA-assigned number 50 and is identified in the next header or the protocol field of the preceding header structure. The ESP header contains three fields (Exhibit 39.4):

- The SPI field — the unique identifier for the SA used to process this datagram. This is the only mandatory ESP field.
- The opaque transform data field — additional parameters required to support the cryptographic transform used by this SA (e.g., an initialization vector). The data contained in this field is transform specific and therefore varies in length. The only IPSec requirement is that the field be padded so it ends on a 32-bit boundary.
- The encrypted data field — the data output by the cryptographic transform.

EXHIBIT 39.3 IPv4 Placement Example.

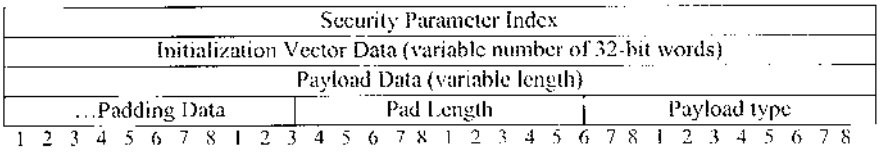

EXHIBIT 39.4 IP ESP Header Structure.

IP version 4 or version 6 systems claiming ESP compliance must implement the Encapsulation Security Protocol supporting the use of the DES CBC transform. All ESP implementations have an option to support other encryption algorithms. For example, if no valid SA exists for an arriving datagram (e.g., the receiver has no key), the receiver must discard the encrypted ESP and record the failure in a system or audit log. The recommended values to be logged are the SPI value, date/time, the sending and destination addresses, and the flow ID. The log entry may include other implementation-specific data. It is recommended that the receiving system not send immediate notification of failures to the send system because of the strong potential for easy-to-exploit denial-of-service attacks.

The calculation of the encrypted data by systems using the ESP does increase processing costs and communications latency. The overall impact depends upon the cryptographic algorithm and the implementation. Secret key algorithms require much less processing time than public key algorithms, and hardware-based implementations tend to be even faster with very little system impact.

The Encapsulation Security Payload function is more difficult to implement and subject to some international export and use restrictions, but its flexible structure, VPN capabilities, and strong confidentiality are ideal for businesses requiring secure communications across untrusted networks.

Key Management

Key management functions include the generation, authentication, and distribution of the cryptographic keys required to establish secure communications. The functions are closely tied to the cryptographic algorithms they are supporting but, in general, generation is the function that creates the keys and manages their life span and disposition; authentication is the process used to validate the hosts or gateways requesting keys services; and distribution is the process that transfers the keys to the requesting systems in a secure manner.

There are two common approaches to IP keying: host-oriented and user-oriented. Host-oriented keys have all users sharing the same key when transferring data between endpoint (i.e., hosts and gateways). User-oriented keying establishes a separate key for each user session that is transferring data between endpoints. The keys are not shared between users or applications. Users have different keys for Telnet and FTP sessions. Multilevel security (MLS) systems require user-oriented keying to maintain confidentiality between the different sensitivity levels. But it is not uncommon on non-MLS systems to have users, groups, or processes that do not trust each other. Therefore, the IETF Security Working Group strongly recommends the use of user-oriented keying for all IPSec key management implementations.

Thus far we have only mentioned traditional cryptographic key management. However, traditional key management functions are not capable of supporting a full IPSec implementation. IPSec's transform independence requires that all the elements of the security association, not just the cryptographic keys, be distributed to the participating endpoints. Without all the security association parameters, the endpoints would be unable to determine how the cryptographic key is applied. This requirement led to the development of the Internet Security Association and Key Management Protocol (ISAKMP). ISAKMP supports the standard key management functions and incorporates mechanisms to negotiate, establish, modify, and delete security associations and their attributes. For the remainder of this section we will use the term "SA management" to refer to the management of the entire SA structure (including cryptographic keys) and key management to refer to just the cryptographic key parameters of an SA. It is important to note that key management can take place separate from SA management. For example, host-oriented keying would use SA management to establish both the session parameters and the cryptographic keys, whereas user-oriented keying would use the SA management function to establish the initial session parameters and the key management function to supply the individual-use session keys.

The simplest form of SA or key management is manual management. The system security administrator manually enters the SA parameters and encryption keys for their system and the system(s) it communicates with. All IPv4 and IPv6 implementations of IPSec are required to support the manual configuration of security associations and keys. Manual configuration works well in small, static environments but is extremely difficult to scale to larger environments, especially those involving multiple administrative domains. In these environments the SA and key management functions must be automated and centralized to be effective. This is the functionality ISAKMP is designed to provide.

Internet Security Association and Key Management Protocol (ISAKMP)

ISAKMP provides a standard, flexible, and scalable methodology for distributing security associations and cryptographic keys. The protocol defines the procedures for authenticating a communicating peer, creating and managing security associations, techniques for generating and managing keys and security associations, and ways to mitigate threats like replay and denial-of-service attacks. ISAKMP was designed to support IPSec AH and ESP services, but it goes far beyond that. ISAKMP has the capability of supporting security services at the transport and applications layers for a variety of security mechanisms. This is possible because ISAKMP separates the security association management function from the key exchange mechanism. ISAKMP has key exchange protocol independence. It provides a common framework for negotiating, exchanging, modifying, and deleting SAs between dissimilar systems. Centralizing the management of the security associations with ISAKMP reduces much of the duplicated functionality within each security protocol and significantly reduces the connection setup time because ISAKMP can negotiate an entire set of services at once.

A detailed discussion of ISAKMP is beyond the scope of this chapter so only the operations and functional requirements of a security association and key management system will be covered. A security association and key management system is a service application that mediates between systems establishing secure connections. It does not actively participate in the transfer of data between these systems. It only assists in the establishment of a secure connection by generating, authenticating, and distributing the required security associations and cryptographic keys.

Two parameters must be agreed upon for the system to work properly. First, a trust relationship must be established between the endpoint systems and the SA manager. The SA manager can be a third-party system — similar to a Kerberos Key Distribution Center (KDC) — or integrated into the endpoint's IPSec implementation. Each approach requires a manually configured SA for each manager and the endpoints it communicates with. The advantage is these few manual SAs can be used to establish a multitude of secure connections. Most vendors have chosen to integrate ISAKMP into the endpoint systems and use a third-party (e.g., Certificate Authority) system to validate the initial trust relationship. The second requirement is for the endpoints to have a trusted third party in common. In other words, both endpoints must have an SA management system or Certificate Authority they both trust.

The operation is pretty straightforward. We will use systems with integrated SAs for this scenario. System A wishes to establish a secure communications session with System B and no valid security association currently exists between them. System A contacts the SA management function on System B. The process then reverses itself (remember that SAs are only established in one direction) as System B establishes a secure return path to System A. ISAKMP does have the capability of negotiating bidirectional SAs in a single transaction, so a separate return path negotiation is usually not required.

ISAKMP has four major functional components. They are:

1. Authentication of communications peers
2. Cryptographic key establishment and management
3. Security association creation and management
4. Threat mitigation

Authenticating the entity at the other end of the communication is the first step in establishing a secure communications session. Without authentication it is impossible to trust an entity's identification, and without a valid ID access control is meaningless. What value is there to secure communication with an unauthorized system?

ISAKMP mandates the use of public key digital signatures (e.g., DSS, RSA) to establish strong authentication for all ISAKMP exchanges. The standard does not specify a particular algorithm. Public key cryptography is a very effective, flexible, and scalable way to distribute shared secrets and session keys. However, to be completely effective, there must be a means of binding public keys to a specific entity. In larger implementations, this function is provided by a trusted third party (TTP) like a Certificate Authority (CA). Smaller implementations may choose to use manually configured keys. ISAKMP does not define the protocols used for communication with trusted third parties.

Key establishment encompasses the generation of the random keys and the transportation of those keys to the participating entities. In an RSA public key system, key transport is accomplished by encrypting the session

key with the recipient's public key. The encrypted session key is then sent to the recipient system, which decrypts it with its private key. In a Diffie–Hellman system, the recipient's public key would be combined with the sender's private key information to generate a shared secret key. This key can be used as the session key or for the transport of a second randomly generated session key. Under ISAKMP these key exchanges must take place using strong authentication. ISAKMP does not specify a particular key exchange protocol, but it appears that Oakley will become the standard.

Security association creation and management is spread across two phases of connection negotiation. The first phase establishes a security association between the two endpoint SA managers. The second phase establishes the security associations for the security protocols selected for that session. Phase one constitutes the trust between the managers and endpoints; the second phase constitutes the trust between the two endpoints themselves. Once phase two has been completed, the SA manager has no further involvement in the connection.

ISAKMP integrates mechanisms to counteract threats like denial of service, hijacking, and man-in-the-middle attacks. The manager service sends an anti-clogging token (cookie) to the requesting system prior to performing any CPU-intensive operation. If the manager does not receive a reply to this cookie, it assumes the request is invalid and drops it. Although this certainly is not comprehensive anti-clogging protection, it is quite effective against most common flooding attacks. The anti-clogging mechanism is also useful for detecting redirection attacks. Because multiple cookies are sent during each session setup, any attempt to redirect the data stream to a different endpoint will be detected.

ISAKMP links the authentication process and the SA/key exchange process into a single data stream. This makes attacks which rely on the interception or modification of the data stream (e.g., hijacking, man-in-the-middle) completely ineffective. Any interruption or modification of the data stream will be detected by the manager and further processing halted. ISAKMP also employs a built-in state machine to detect data deletions, thus ensuring that SAs based on partial exchanges will not be established. As a final anti-threat, ISAKMP specifies logging and notification requirements for all abnormal operations and limits the use of on-the-wire error notification.

Summary

As a standard, IPSec is quickly becoming the preferred method for secure communications on TCP/IP networks. Designed to support multiple encryption and authentication schemes and multi-vendor interoperability, IPSec can be adapted to fit the security requirements of large and small organizations alike. Industries that rely on extranet technologies to communicate with their business partners will benefit from IPSec's flexible encryption and authentication schemes; large businesses will benefit from IPSec's scalability and centralized management; and every company can benefit from IPSec's virtual private networking (VPN) capabilities to support mobile workers, telecommuters, or branch offices accessing company resources via the Internet.

The Internet Security Protocol Architecture was designed with the future in mind and is garnering the support it deserves from the security and computer communities. Recent endorsements by major manufacturing associations like the Automotive Industry Action Group, product commitments from major vendors like Cisco Systems, as well as the establishment of a compliance certification program through the International Computer Security Association are clear signs that IPSec is well on its way to becoming the industry standard for business-to-business communications in the 21st century.

Wireless Internet Security

Dennis Seymour Lee

RECALLING THE EARLY DAYS OF THE INTERNET, ONE CAN RECOUNT SEVERAL REASONS WHY THE INTERNET CAME ABOUT. Some of these include:

- providing a vast communication medium to share electronic information
- creating a multiple-path network that could survive localized outages
- providing a means for computers from different manufacturers and different networks to talk to one another

Commerce and security, at that time, were not high on the agenda (with the exception of preserving network availability). The thought of commercializing the Internet in the early days was almost unheard of. In fact, it was considered improper etiquette to use the Internet to sell products and services. Commercial activity and their security needs are a more recent development on the Internet, having come about strongly in the past few years.

Today, in contrast, the wireless Internet is being designed from the very beginning with commerce as its main driving force. Nations and organizations around the globe are spending millions, even billions of dollars to buy infrastructure, transmission frequencies, technology, and applications in the hopes of drawing business. In some ways, this has become the "land rush" of the new millennium. It stands to reason then that security must play a critical role early on as well — where money changes hands, security will need to accompany this activity.

Although the wireless industry is still in its infancy, the devices, infrastructure, and application development for the wireless Internet are rapidly growing on a worldwide scale. Those with foresight will know that security must fit in early into these designs. The aim of this chapter is to highlight some of the significant security issues in this emerging industry that need addressing. These are concerns that any business wishing to

deploy a wireless Internet service or application will need to consider to protect their own businesses and their customers, and to safeguard their investments in this new frontier.

Incidentally, the focus of this chapter is not about accessing the Internet using laptops and wireless modems. That technology, which has been around for many years, in many cases, is an extension of traditional wired Internet access. Neither will this chapter focus on wireless LANs and Bluetooth, which are not necessarily Internet based, but deserve chapters on their own. Rather, the concentration is on portable Internet devices, which inherently have far less computing resources than regular PCs, such as cell phones and PDAs (personal digital assistants). Therefore, these devices require different programming languages, protocols, encryption methods, and security perspectives to cope with the different technology. It is important to note, however, that despite their smaller sizes and limitations, these devices have a significant impact on information security, mainly because of the electronic commerce and intranet-related applications that are being designed for them.

WHO IS USING THE WIRELESS INTERNET?

Many studies and estimates are available today that suggest the number of wireless Internet users will soon surpass the millions of wired Internet users. The assumption is based on the many more millions of worldwide cell phone users who are already out there, a population that grows by the thousands every day. If every one of these mobile users chose to access the Internet through cell phones, indeed that population could easily exceed the number of wired Internet users by several times. It is this very enormous potential that has many businesses devoting substantial resources and investments in the hopes of capitalizing on this growing industry.

The wireless Internet is still very young. Many mobile phone users do not yet have access to the Internet through their cell phones. Many are taking a "wait-and-see" attitude to see what services will be available. Most who do have wireless Internet access are early adopters who are experimenting with the potential of what this service could provide. Because of the severe limitations in the wireless devices — the tiny screens, the extremely limited bandwidth, as well as other issues — most users who have both wired and wireless Internet access will admit that, for today, the wireless devices will not replace their desktop computers and notebooks anytime soon as their primary means of accessing the Internet. Many admit that "surfing the Net" using a wireless device today could become a disappointing exercise. Most of these wireless Internet users have expressed the following frustrations:

- It is too slow to connect to the Internet.
- Mobile users can be disconnected in the middle of a session when they are on the move.
- It is cumbersome to type out sentences using a numeric keypad.
- It is expensive to use the wireless Internet, especially when billed on a per-minute basis.
- There is very little or no graphics display capabilities on wireless devices.
- The screens are too small and users have to scroll constantly to read a long message.
- There are frequent errors when surfing Web sites (mainly because most Web sites today are not yet wireless Internet compatible).

At the time of this writing, the one notable exception to these disappointments is found in Japan. The telecommunications provider NTT DoCoMo has experienced phenomenal growth in the number of wireless Internet subscribers, using a wireless application environment called i-Mode (as opposed to wireless application protocol, or WAP). For many in Japan, connection using a wireless phone is their only means of accessing the Internet. In many cases, wireless access to the Internet is far cheaper than wired access, especially in areas where the wired infrastructure is expensive to set up. I-Mode users have the benefit of "always online" wireless connections to the Internet, color displays on their cell phones, and even graphics, musical tones, and animation. Perhaps Japan's success with the wireless Internet will offer an example of what can be achieved in the wireless arena, given the right elements.

WHAT TYPES OF APPLICATIONS ARE AVAILABLE?

Recognizing the frustrations and limitations of today's wireless technology, many businesses are designing their wireless devices and services, not necessarily as replacements for wired Internet access, but as specialized services that extend what the wired Internet could offer. Most of these services highlight the attractive convenience of portable informational access, anytime and anywhere, without having to sit in front of a computer — essentially, Internet services one can carry in one's pocket. Clearly, the information would have to be concise, portable, useful, and easy to access. Examples of mobile services available or being designed today include:

- shopping online using a mobile phone; comparing online prices with store prices while inside an actual store
- getting current stock prices, trading price alerts, trade confirmations, and portfolio information anywhere
- performing bank transactions and obtaining account information
- obtaining travel schedules and booking reservations

- obtaining personalized news stories and weather forecasts
- receiving the latest lottery numbers
- obtaining the current delivery status for express packages
- reading and writing e-mail "on the go"
- accessing internal corporate databases such as inventory, client lists, etc.
- getting map directions
- finding the nearest ATM machines, restaurants, theaters, and stores, based on the user's present location
- dialing 911 and having emergency services quickly triangulate the caller's location
- browsing a Web site and speaking live with the site's representative, all within the same session

Newer and more innovative services are in the works. As any new and emerging technology, wireless services and applications are often surrounded by much hope and hype, as well as some healthy skepticism. But as the technology and services mature over time, yesterday's experiments can become tomorrow's standards. The Internet is a grand example of this evolving progress. Development of the wireless Internet will probably go through the same evolutionary cycle, although probably at an even faster pace.

Like any new technology, however, security and safety issues can damage its reputation and benefits if they are not included intelligently into the design from the very beginning. It is with this purpose in mind that this chapter is written.

Because the wireless Internet covers a lot of territory, the same goes for its security as well. This chapter discusses security issues as they relate to the wireless Internet in a few select categories, starting with transmission methods to the wireless devices and ending with some of the infrastructure components themselves.

HOW SECURE ARE THE TRANSMISSION METHODS?

For many years, it was public knowledge that analog cell phone transmissions are fairly easy to intercept. It has been a known problem for as long as analog cell phones have been available. They are easily intercepted using special radio scanning equipment. For this reason, as well as many others, many cell phone service providers have been promoting digital services to their subscribers and reducing analog to a legacy service.

Digital cell phone transmissions, on the other hand, are typically more difficult to intercept. It is on these very same digital transmissions that most of the new wireless Internet services are based.

However, there is no single method for digital cellular transmission. In fact, there are several different methods for wireless transmission available today. For example, in the United States, providers such as Verizon and Sprint primarily use CDMA (Code Division Multiple Access), whereas AT&T primarily uses TDMA (Time Division Multiple Access) and Voicestream uses GSM (Global Systems for Mobile Communications). Other providers, such as Cingular, offer more than one method (TDMA and GSM), depending on the geographic location. All these methods differ in the way they use the radio frequencies and the way they allocate users on those frequencies. This chapter discusses each of these in more detail.

Cell phone users are generally not concerned with choosing a particular transmission method if they want wireless Internet access, nor do they really care to. Instead, most users select their favorite wireless service provider when they sign up for service. It is generally transparent to the user which transmission method their provider has implemented. It is an entirely different matter for the service provider, however. Whichever method they implement has significant bearing on its infrastructure. For example, the type of radio equipment they use, the location and number of transmission towers to deploy, the amount of traffic they can handle, and the type of cell phones to sell to their subscribers are all directly related to the digital transmission method chosen.

Frequency Division Multiple Access (FDMA) Technology

All cellular communications, analog or digital, are transmitted using radio frequencies that are purchased by, or allocated to, the wireless service provider. Each service provider typically purchases licenses from the respective government to operate a spectrum of radio frequencies.

Analog cellular communications typically operate on what is called Frequency Division Multiple Access (or FDMA) technology. With FDMA, each service provider divides its spectrum of radio frequencies into individual frequency channels. Each channel is a specific frequency that supports a one-way communication session; and each channel has a width of 10 to 30 kilohertz (kHz). For a regular two-way phone conversation, every cell phone caller would be assigned two frequency channels: one to send and one to receive.

Because each phone conversation occupies two channels (two frequencies), it is not too difficult for specialized radio scanning equipment to tap into a live analog phone conversation once the equipment has tuned into the right frequency channel. There is very little privacy protection in analog cellular communications if no encryption is added.

Time Division Multiple Access (TDMA) Technology

Digital cellular signals, on the other hand, can operate on a variety of encoding techniques, most of which are resistant to analog radio frequency scanning. (Note that the word "encoding" in wireless communications does not mean encryption. "Encoding" here usually refers to converting a signal from one format to another; for example, from a wired signal to a wireless signal.)

One such technique is called time division multiple access, or TDMA. Similar to FDMA, TDMA typically divides the radio spectrum into multiple 30-kHz frequency channels (sometimes called frequency carriers). Every two-way communication requires two of these frequency channels: one to send and one to receive. But in addition, TDMA further subdivides each frequency channel into three to six time slots called voice/data channels, so that now up to six digital voice or data sessions can take place using the same frequency. With TDMA, a service provider can handle more calls at the same time compared to FDMA. This is accomplished by assigning each of the six sessions a specific time slot within the same frequency. Each time slot (or voice/data channel) is approximately seven milliseconds in duration. The time slots are arranged and transmitted over and over again in rapid rotation. Voice or data for each caller is placed into the time slot assigned to that caller and then transmitted. Information from the corresponding time slot is quickly extracted and reassembled at the receiving cellular base station to piece together the conversation or session. Once that time slot (or voice/data channel) is assigned to a caller, it is dedicated to that caller for the duration of the session, until it terminates. In TDMA, a user is not assigned an entire frequency, but shares the frequency with other users, each with an assigned time slot.

As of the writing of this chapter, there have not been many publicized cases of eavesdropping of TDMA phone conversations and data streams as they travel across the wireless space. Access to special types of equipment or test equipment would probably be required to perform such a feat. It is possible that an illegally modified TDMA cell phone could also do the job.

However, this does not mean that eavesdropping is unfeasible. With regard to a wireless Internet session, consider the full path that such a session takes. For a mobile user to communicate with an Internet Web site, a wireless data signal from the cell phone will eventually be converted into a wired signal before traversing the Internet itself. As a wired signal, the information can travel across the Internet in clear text until it reaches the Web site. Although the wireless signal itself may be difficult to intercept, once it becomes a wired signal, it is subject to the same interception vulnerabilities as all unencrypted communications traversing the Internet.

Always as a precaution, if there is confidential information being transmitted over the Internet, regardless of the method, it is necessary to encrypt that session from end-to-end. Encryption is discussed in a later chapter section.

Global Systems for Mobile Communications (GSM)

Another method of digital transmission is Global Systems for Mobile Communications (GSM). GSM is actually a term that covers more than just the transmission method alone. It covers the entire cellular system, from the assortment of GSM services to the actual GSM devices themselves. GSM is primarly used in European nations.

As a digital transmission method, GSM uses a variation of TDMA. Similar to FDMA and TDMA, the GSM service provider divides the allotted radio frequency spectrum into multiple frequency channels. This time, each frequency channel has a much larger width of 200 kHz. Again, similar to FDMA and TDMA, each GSM cellular phone uses two frequency channels: one to send and one to receive.

Like TDMA, GSM further subdivides each frequency channel into time slots called voice/data channels. However, with GSM, there are eight time slots, so that now up to eight digital voice or data sessions can take place using the same frequency. As for TDMA, once that time slot (or voice/data channel) is assigned to a caller, it is dedicated to that caller for the duration of the session, until it terminates.

GSM has additional features that enhance security. Each GSM phone uses a subscriber identity module (or SIM). A SIM can look like a credit-card sized smart card or a postage-stamp sized chip. This removable SIM is inserted into the GSM phone during usage. The smart card or chip contains information pertaining to the subscriber, such as the cell phone number belonging to the subscriber, authentication information, encryption keys, directory of phone numbers, and short saved messages belonging to that subscriber. Because the SIM is removable, the subscriber can take this SIM out of one phone and insert it into another GSM phone. The new phone with the SIM will then take on the identity of the subscriber. The user's identity is not tied to a particular phone but to the removable SIM itself. This makes it possible for a subscriber to use or upgrade to different GSM phones, without changing phone numbers. It is also possible to rent a GSM phone in another country, even if that country uses phones that transmit on different GSM frequencies. This arrangement works, of course, only if the GSM service providers from the different countries have compatible arrangements with each other.

The SIM functions as an authentication tool because the GSM phones are useless without it. Once the SIM is inserted into a phone, users are

prompted to put in their personal identification numbers (PINs) associated with that SIM (if the SIM is PIN-enabled). Without the correct PIN number, the phone will not work.

In addition to authenticating the user to the phone, the SIM is also used to authenticate the phone to the phone network itself during connection. Using the authentication (or Ki) key in the SIM, the phone authenticates to the service provider's Authentication Center during each call. The process employs a challenge-response technique, similar in some respects to using a token card to remotely log a PC onto a network.

The keys in the SIM have another purpose in addition to authentication. The encryption (or Kc) key generated by the SIM can be used to encrypt communications between the mobile phone and the service provider's transmission equipment for confidentiality. This encryption prevents eavesdropping, at least between these two points.

GSM transmissions, similar to TDMA, are difficult, but not impossible, to intercept using radio frequency scanning equipment. A frequency can have up to eight users on it, making the digital signals difficult to extract. By adding encryption using the SIM card, GSM can add yet another layer of security against interception.

However, when it comes to wireless Internet sessions, this form of encryption does not provide end-to-end protection. Only part of the path is actually protected. This is similar to the problem mentioned previously with TDMA Internet sessions. A typical wireless Internet session takes both a wireless and a wired path. GSM encryption protects only the path between the cell phone and the service provider's transmission site — the wireless portion. The remainder of the session through the wired Internet — from the service provider's site to the Internet Web site — can still travel in the clear. One would need to add end-to-end encryption if one needs to keep the entire Internet session confidential.

Code Division Multiple Access (CDMA) Technology

Another digital transmission method is called code division multiple access, or CDMA. CDMA is based on spread spectrum, a transmission technology that has been used by the U.S. military for many years to make radio communications more difficult to intercept and jam. Qualcomm is one of the main pioneers incorporating CDMA spread spectrum technology into the area of cellular phones.

Instead of dividing a spectrum of radio frequencies into narrow frequency bands or time slots, CDMA uses a very large portion of that radio spectrum, also called a frequency channel. The frequency channel has a wide width of 1.25 megahertz (MHz). For duplex communication, each cell

phone uses two of these wide CDMA frequency channels: one to send and one to receive.

During communication, each voice or data session is first converted into a series of data signals. Next, the signals are marked with a unique code to indicate that they belong to a particular caller. This code is called a pseudo-random noise (PN) code. Each mobile phone is assigned a new PN code by the base station at the beginning of each session. These coded signals are then transmitted by spreading them out across a very wide radio frequency spectrum. Because the channel width is very large, it has the capacity to handle many other user sessions at the same time, each session again tagged by unique PN codes to associate them to the appropriate caller.

A CDMA phone receives transmissions using the appropriate PN code to pick out the data signals that are destined for it and ignores all other encoded signals.

With CDMA, cell phones communicating with the base stations all share the same wide frequency channels. What distinguishes each caller is not the frequency used (as in FDMA), nor the time slot within a particular frequency (as in TDMA or GSM), but the PN noise code assigned to that caller. With CDMA, a voice/data channel is a data signal marked with a unique PN code.

Intercepting a single CDMA conversation would be difficult because its digital signals are spread out across a very large spectrum of radio frequencies. The conversation does not reside on just one frequency alone, making it difficult to scan. Also, without knowledge of the PN noise code, an eavesdropper would not be able to extract the relevant session from the many frequencies used. To further complicate interception, the entire channel width is populated by many other callers at the same time, creating a vast amount of noise for anyone trying to intercept the call.

However, as seen earlier with the other digital transmission methods, Internet sessions using CDMA cell phones are not impossible to intercept. As before, although the CDMA digital signals themselves can be difficult to intercept, once these wireless signals are converted into wired signals, the latter signals can be intercepted as they travel across the Internet. Without using end-to-end encryption, wireless Internet sessions are as vulnerable as other unencrypted communications traveling over the Internet.

Other Methods

There are additional digital transmission methods, many of which are derivatives of the types already discussed, and some of which are still under development. Some of these that are under development are called

third-generation or 3G transmission methods. Second-generation (2G) technologies, such as TDMA, GSM, and CDMA, offer transmission speeds of 9.6 to 14.4 Kbps (kilobits per second), which is slower than today's typical modem speeds. 3G technologies, on the other hand, are designed to transmit much faster and carry larger amounts of data. Some will be capable of providing high-speed Internet access as well as video transmission. Below is a partial listing of other digital transmission methods, including those in the 3G category.

- *iDEN* (Integrated Digital Enhanced Network) is based on TDMA and is a 2G transmission method. In addition to sending voice and data, it can also be used for two-way radio communications between two iDEN phones, much like walkie-talkies.
- *PDC* (Personal Digital Communications) is based on TDMA and is a 2G transmission method widely used in Japan.
- *GPRS* (General Packet Radio Service) is a 2.5G (not quite 3G) technology based on GSM. It is a packet-switched data technology that provides "always online" connections, which means that the subscriber can stay logged on to the phone network all day but uses it only if there is actual data to send or receive. Maximum data rates are estimated to be 115 Kbps.
- *EDGE* (Enhanced Data rates for Global Evolution) is a 3G technology based on TDMA and GSM. Like GPRS, it features "always online" connections using packet-switched data technologies. Maximum data rates are estimated to be 384 Kbps.
- *UMTS* (Universal Mobile Telecommunications System) is a 3G technology based on GSM. Maximum data rates are estimated at 2 Mbps (megabits per second).
- *CDMA2000* and *W-CDMA* (Wideband CDMA) are two 3G technologies based on CDMA. CDMA2000 is a more North American design, whereas W-CDMA is more European and Japanese oriented. Both provide maximum data rates estimated at 384 Kbps for slow-moving mobile units, and at 2 Mbps for stationary units.

Regardless of the methods or the speeds, the need for end-to-end encryption will still be a requirement if confidentiality is needed between the mobile device and the Internet or intranet site. Because wireless Internet communications encompass both wireless and wired-based transmissions, encryption features covering just the wireless portion of the communication is clearly not enough. For end-to-end privacy protection, the applications and the protocols have a role to play, as discussed later in this chapter.

HOW SECURE ARE WIRELESS DEVICES?

Internet security, as many have seen it applied to corporate networks today, can be difficult to implement on wireless phones and PDAs for a

variety of reasons. Most of these devices have limited CPUs, memory, bandwidth, and storage abilities. As a result, many have disappointingly slow and limited computing power. Robust security features that can take less than a second to process on a typical workstation can take potentially many minutes on a wireless device, making them impractical or inconvenient for the mobile user. Because many of these devices have merely a fraction of the hardware capabilities found on typical workstations, the security features on portable devices are often lightweight or even nonexistent — from an Internet security perspective. However, these same devices are now being used to log into sensitive corporate intranets, or to conduct mobile commerce and banking. Although these wireless devices are smaller in every way, their security needs are just as significant as before. It would be a mistake for corporate IT and information security departments to ignore these devices as they start to populate the corporate network. After all, these devices do not discriminate; they can be designed to tap into the same corporate assets as any other node on a network. Some of the security aspects as they relate to these devices are examined here.

Authentication

The process of authenticating wireless phone users has gone through many years of implementation and evolution. It is probably one of the most reliable security features digital cell phones have today, given the many years of experience service providers have had in trying to reduce the theft of wireless services. Because the service providers have a vested interest in knowing who to charge for the use of their services, authenticating the mobile user is of utmost importance.

As previously mentioned, GSM phones use SIM cards or chips that contain authentication information about the user. SIMs typically carry authentication and encryption keys, authentication algorithms, identification information, phone numbers belonging to the subscriber, etc. They allow users to authenticate to their own phones and to the phone network to which they are subscribed.

In North America, TDMA and CDMA phones use a similarly complex method of authentication as in GSM. Like GSM, the process incorporates keys, Authentication Centers, and challenge-response techniques. However, because TDMA and CDMA phones do not generally use removable SIM cards or chips, instead, these phones rely on the authentication information embedded into the handset. The user's identity is therefore tied to the single mobile phone itself.

The obvious drawback is that for authentication purposes, TDMA and CDMA phones offer less flexibility when compared to GSM phones. To

deploy a new authentication feature with a GSM phone, in many cases, all that is needed is to update the SIM card or chip. On the other hand, with TDMA and CDMA, deploying new authentication features would probably require users to buy new cell phones — a more expensive way to go. Because it is easier to update a removable chip than an entire cell phone, it is likely that one will find more security features and innovations being offered for GSM as a result.

One important note, however, is that this form of authentication does not necessarily apply to Internet-related transactions. It merely authenticates the mobile user to the service provider's phone network, which is only one part of the transmission if one is talking about Internet transactions. For securing end-to-end Internet transactions, mobile users still need to authenticate the Internet Web servers they are connecting to, to verify that indeed the servers are legitimate. Likewise, the Internet Web servers need to authenticate the mobile users that are connecting to it, to verify that they are legitimate users and not impostors. The wireless service providers, however, are seldom involved in providing full end-to-end authentication service, from mobile phone to Internet Web site. That responsibility usually falls to the owners of the Internet Web servers and applications.

Several methods for providing end-to-end authentication are being tried today at the application level. Most secure mobile commerce applications are using IDs and passwords, an old standby, which of course has its limitations because it provides only single-factor authentication. Other organizations are experimenting with GSM SIMs by adding additional security ingredients such as public/private key pairs, digital certificates, and other public key infrastructure (PKI) components into the SIMs. However, because the use of digital certificates can be process intensive, cell phones and hand-held devices typically use lightweight versions of these security components. To accommodate the smaller processors in wireless devices, the digital certificates and their associated public keys may be smaller or weaker than those typically deployed on desktop Web browsers, depending on the resources available on the wireless device.

Additionally, other organizations are experimenting with using elliptic-curve cryptography (ECC) for authentication, digital certificates, and public key encryption on the wireless devices. ECC is an ideal tool for mobile devices because it can offer strong encryption capabilities but requires less computing resources than other popular forms of public key encryption. Certicom is one of the main pioneers incorporating ECC for use on wireless devices.

As more and more developments take place with wireless Internet authentication, it becomes clear that, in time, these Internet mobile devices will become full-fledged authentication devices, much like tokens,

smart cards, and bank ATM cards. If users begin conducting Internet commerce using these enhanced mobile devices, securing those devices themselves from loss or theft now becomes a priority. With identity information embedded into the devices or the removable SIMs, losing these could mean that an impostor can now conduct electronic commerce transactions using that stolen identity. With a mobile device, the user, of course, plays the biggest role in maintaining its overall security. Losing a cell phone that has Internet access and an embedded public/private key pair can be potentially as disastrous as losing a bank ATM card with its associated PIN written on it, or worse. If a user loses such a device, contacting the service provider immediately about the loss and suspending its use is a must.

Confidentiality

Preserving confidentiality on wireless devices poses several interesting challenges. Typically, when one accesses a Web site with a browser and enters a password to gain entry, the password one types is masked with asterisks or some other placeholder to prevent others from seeing the actual password on one's screen. With cell phones and hand-held devices, masking the password could create problems during typing. With cell phones, letters are often entered using the numeric keypad, a method that is cumbersome and tedious for many users. For example, to type the letter "R," one must press the number 7 key three times to get to the right letter. If the result is masked, it is not clear to the user what letter was actually submitted. Because of this inconvenience, some mobile Internet applications do away with masking so that the entire password is displayed on the screen in the original letters. Other applications initially display each letter of the password for a few seconds as they are being entered, before masking each with a placeholder afterward. This gives the user some positive indication that the correct letters were indeed entered, while still preserving the need to mask the password on the device's screen for privacy. The latter approach is probably the more sensible of the two, and should be the one that application designers adopt.

Another challenge to preserving confidentiality is making sure that confidential information such as passwords and credit card numbers are purged from the mobile device's memory after they are used. Many times, such sensitive information is stored as variables by the wireless Internet application and subsequently cached in the memory of the device. There have been documented cases in which credit card numbers left in the memory of cell phones were reusable by other people who borrowed the same phones to access the same sites. Once again, the application designers are the chief architects in preserving the confidentiality here. It is important that programmers design an application to clear the mobile

device's memory of sensitive information when the user finishes using that application. Although leaving such information in the memory of the device may spare the user of having to re-enter it the next time, it is, however, as risky as writing the associated PIN or password on a bank ATM card itself.

Yet another challenge in preserving confidentiality is making sure that sensitive information is kept private as it travels from the wireless device to its destination on the Internet, and back. Traditionally, for the wired Internet, most Web sites use Secure Sockets Layer (SSL) or its successor, Transport Layer Security (TLS), to encrypt the entire path end-to-end, from the client to the Web server. However, many wireless devices, particularly cell phones, lack the computing power and bandwidth to run SSL efficiently. One of the main components of SSL is RSA public key encryption. Depending on the encryption strength applied at the Web site, this form of public key encryption can be processor and bandwidth intensive, and can tax the mobile device to the point where the communication session itself becomes too slow to be practical.

Instead, wireless Internet applications that are developed using the Wireless Application Protocol (WAP) use a combination of security protocols. Secure WAP applications use both SSL and WTLS (Wireless Transport Layer Security) to protect different segments of a secure transmission. Typically, SSL protects the wired portion of the connection and WTLS primarily protects the wireless portion. Both are needed to provide the equivalent of end-to-end encryption.

WTLS is similar to SSL in operation. However, although WTLS can support either RSA or ECC, ECC is probably preferred because it provides strong encryption capabilities but is more compact and faster than RSA.

WTLS has other differences from SSL as well. WTLS is built to provide encryption services for a slower and less resource-intensive environment, whereas SSL could tax such an environment. This is because SSL encryption requires a reliable transport protocol, particularly TCP (Transmission Control Protocol, a part of TCP/IP). TCP provides error detection, communication acknowledgments, and retransmission features to ensure reliable network connections back and forth. But because of these features, TCP requires more bandwidth and resources than what typical wireless connections and devices can provide. Most mobile connections today are low bandwidth and slow, and not designed to handle the constant, back and forth error-detection traffic that TCP creates.

Realizing these limitations, the WAP Forum, the group responsible for putting together the standards for WAP, designed a supplementary protocol stack that is more suitable for the wireless environment. Because this environment typically has low connection speeds, low reliability, and low

bandwidth, in order to compensate, the protocol stack uses compressed binary data sessions and is more tolerant of intermittent coverage. The WAP protocol stack resides in layers 4, 5, 6, and 7 of the OSI reference model. The WAP protocol stack works with UDP (User Datagram Protocol) for IP-based networks and WDP (Wireless Datagram Protocol) for non-IP networks. WTLS, which is the security protocol from the WAP protocol stack, can be used to protect UDP or WDP traffic in the wireless environment.

Because of these differences between WTLS and SSL, as well as the different underlying environments that they work within, an intermediary device such as a gateway is needed to translate the traffic going from one environment into the next. This gateway is typically called a WAP gateway. The WAP gateway is discussed in more detail in the infrastructure section below.

Malicious Code and Viruses

The number of security attacks on wireless devices has been small compared to the many attacks against workstations and servers. This is due, in part, to the very simple fact that most mobile devices, particularly cell phones, lack sufficient processors, memory, or storage that malicious code and viruses could exploit. For example, a popular method for spreading viruses today is by hiding them in file attachments to e-mail. However, many mobile devices, particularly cell phones, lack the ability to store or open e-mail attachments. This makes mobile devices relatively unattractive as targets because the damage potential is relatively small.

However, mobile devices are still vulnerable to attack and will become increasingly more so as they evolve with greater computing, memory, and storage capabilities. With greater speeds, faster downloading abilities, and better processing, mobile devices can soon become the equivalent of today's workstations, with all their exploitable vulnerabilities. As of the writing of this chapter, cell phone manufacturers were already announcing that the next generation of mobile phones will support languages such as Java so that users can download software programs such as organizers, calculators, and games onto their Web-enabled phones. However, on the negative side, this also opens up more opportunities for users to unwittingly download malicious programs (or "malware") onto their own devices. The following adage applies to mobile devices: "The more brains they have, the more attractive they become as targets."

HOW SECURE ARE THE NETWORK INFRASTRUCTURE COMPONENTS?

As many of us who have worked in the information security field know, security is usually assembled using many components, but its overall strength is only as good as its weakest link. Sometimes it does not matter

if one is using the strongest encryption available over the network and the strongest authentication at the devices. If there is a weak link anywhere along the chain, attackers will focus on this vulnerability and may eventually exploit it, choosing a path that requires the least effort and the least amount of resources.

Because the wireless Internet world is still relatively young and a work in progress, vulnerabilities abound, depending on the technology one has implemented. This chapter section focuses on some infrastructure vulnerabilities for those who are using WAP (Wireless Application Protocol).

The "Gap in WAP"

Encryption has been an invaluable tool in the world of E-commerce. Many online businesses use SSL (Secure Sockets Layer) or TLS (Transport Layer Security) to provide end-to-end encryption to protect Internet transactions between the client and the Web server.

When using WAP however, if encryption is activated for the session, there are usually two zones of encryption applied, each protecting the two different halves of the transmission. SSL or TLS is generally used to protect the first path, between the Web server and an important network device called the WAP gateway that was previously mentioned. WTLS (Wireless Transport Layer Security) is used to protect the second path, between the WAP gateway and the wireless mobile device.

The WAP gateway is an infrastructure component needed to convert wired signals into a less bandwidth-intensive and compressed binary format, compatible for wireless transmissions. If encryption such as SSL is used during a session, the WAP gateway will need to translate the SSL-protected transmission by decrypting this SSL traffic and re-encrypting it with WTLS, and vice versa in the other direction. This translation can take just a few seconds; but during this brief period, the data sits in the memory of the WAP gateway decrypted and in the clear before it is re-encrypted using the second protocol. This brief period in the WAP gateway — some have called it the "gap in WAP" — is an exploitable vulnerability. It depends on where the WAP gateway is located, how well it is secured, and who is in charge of protecting it.

Clearly, the WAP gateway should be placed in a secure environment. Otherwise, an intruder attempting to access the gateway can steal sensitive data while it transitions in clear text. The intruder can also sabotage the encryption at the gateway, or even initiate a denial-of-service or other malicious attack on this critical network component. In addition to securing the WAP gateway from unauthorized access, proper operating procedures should also be applied to enhance its security. For example, it is wise not to save any of the clear-text data onto disk storage during the

decryption and re-encryption process. Saving this data onto log files, for example, could create an unnecessarily tempting target for intruders. In addition, the decryption and re-encryption should operate in memory only and proceed as quickly as possible. Furthermore, to prevent accidental disclosure, the memory should be properly overwritten, thereby purging any sensitive data before that memory is reused.

WAP Gateway Architectures

Depending on the sensitivity of the data and the liability for its unauthorized disclosure, businesses offering secure wireless applications (as well as their customers) may have concerns about where the WAP gateway is situated, how it is protected, and who is protecting it. Three possible architectures and their security implications are examined:

WAP Gateway at the Service Provider. In most cases, the WAP gateways are owned and operated by the wireless service providers. Many businesses that deploy secure wireless applications today rely on the service provider's WAP gateway to perform the SSL-to-WTLS encryption translation. This implies that the business owners of the sensitive wireless applications, as well as their users, are entrusting the wireless service providers to keep the WAP gateway and the sensitive data that passes through it safe and secure. Exhibit 8-1 provides an example of such a setup, where the WAP gateway resides within the service provider's secure environment. If encryption is applied in a session between the user's cell phone and the application server behind the business' firewall, the path between the cell phone and the service provider's WAP gateway is typically encrypted using WTLS. The path between the WAP gateway and the business host's application server is encrypted using SSL or TLS.

A business deploying secure WAP applications using this setup should realize, however, that it cannot guarantee end-to-end security for the data because it is decrypted, exposed in clear text for a brief moment, and then re-encrypted, all at an outside gateway that is away from its control. The WAP gateway is generally housed in the wireless service provider's data center and attended by those who are not directly accountable to the businesses. Of course, it is in the best interest of the service provider to maintain the WAP gateway in a secure manner and location.

Sometimes, to help reinforce that trust, businesses may wish to conduct periodic security audits on the service provider's operation of the WAP gateways to ensure that the risks are minimized. Bear in mind, however, that by choosing this path, the business may need to inspect many WAP gateways from many different service providers. A service provider sets up the WAP gateway primarily to provide Internet access to its own wireless phone subscribers. If users are dialing into a business' secure Web

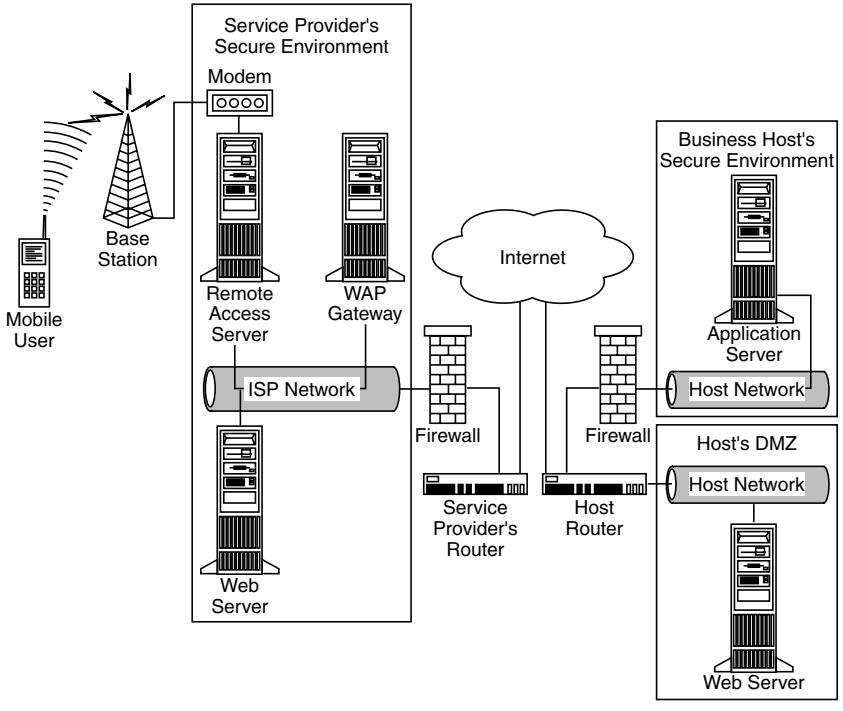

Exhibit 8-1. WAP gateway at the service provider.

site, for example, from 20 different wireless service providers around the world, then the business may need to audit the WAP gateways belonging to these 20 providers. This, unfortunately, is a formidable task and an impractical method of ensuring security. Each service provider might apply a different method for protecting its own WAP gateway — if protected at all. Furthermore, in many cases, the wireless service providers are accountable to their own cell phone subscribers, not necessarily to the countless businesses that are hosting secure Internet applications, unless there is a contractual arrangement to do so.

WAP Gateway at the Host. Some businesses and organizations, particularly in the financial, healthcare, and government sectors, may have legal requirements to keep their customers' sensitive data protected. Having such sensitive data exposed outside the organization's internal control may pose an unnecessary risk and liability. To some, the "gap in WAP" presents a broken pipeline, an obvious breach of confidentiality that is just waiting to be exploited. For those who find such a breach unacceptable, one possible solution is to place the WAP gateway at the business host's own protected network, bypassing the wireless service provider's

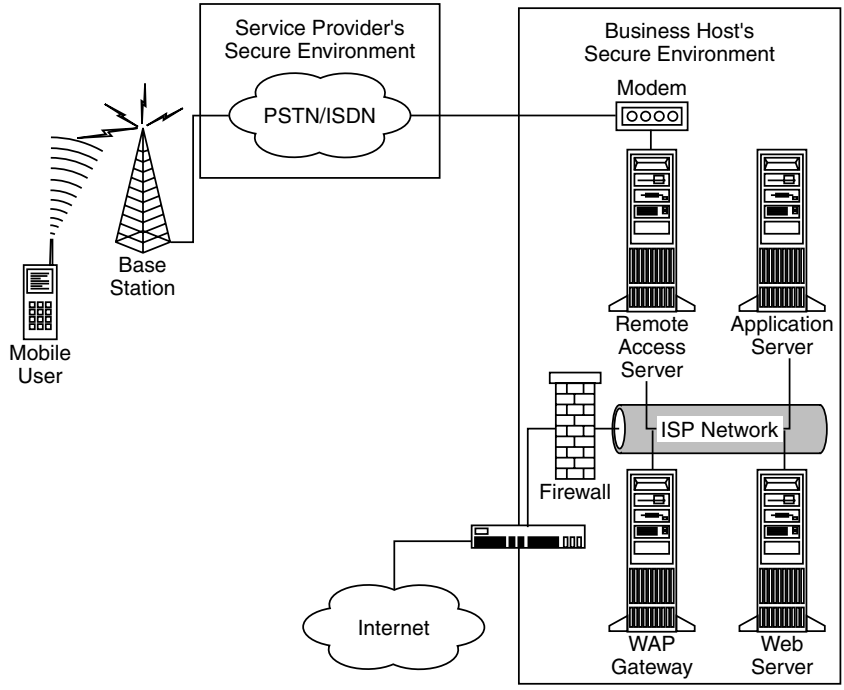

Exhibit 8-2. WAP gateway at the host.

WAP gateway entirely. Exhibit 8-2 provides an example of such a setup. Nokia, Ericsson, and Ariel Communications are just a few of the vendors offering such a solution.

This approach has the benefit of keeping the WAP gateway and its WTLS-SSL translation process in a trusted location, within the confines of the same organization that is providing the secure Web applications. Using this setup, users are typically dialing directly from their wireless devices, through their service provider's Public Switched Telephone Network (PSTN), and into the business' own Remote Access Servers (RAS). Once they reach the RAS, the transmission continues onto the WAP gateway, and then onward to the application or Web server, all of these devices within the business host's own secure environment.

Although it provides better end-to-end security, the drawback to this approach is that the business host will need to set up banks of modems and RAS so users have enough access points to dial in. The business will also need to reconfigure the users' cell phones and PDAs to point directly to the business' own WAP gateway instead of typically to the service provider's. However, not all cell phones allow this reconfiguration by the

user. Furthermore, some cell phones can point to only one WAP gateway, while others are fortunate enough to point to more than one. In either case, individually reconfiguring all those wireless devices to point to the business' own WAP gateway may take significant time and effort.

For users whose cell phones can point to only a single WAP gateway, this reconfiguration introduces yet another issue. If these users now want to access other WAP sites across the Internet, they still must go through the business host's WAP gateway first. If the host allows outgoing traffic to the Internet, the host then becomes an Internet service provider (ISP) to these users who are newly configured to point to the host's own WAP gateway. Acting as a makeshift ISP, the host will inevitably need to attend to service- and user-related issues, which to many businesses can be an unwanted burden because of the significant resources required.

Pass-Through from Service Provider's WAP Gateway to Host's WAP Proxy. For those businesses that want to provide secure end-to-end encrypted transactions, yet want to avoid the administrative headaches of setting up their own WAP gateways, there are other approaches. One such approach, as shown in Exhibit 8-3, is to keep the WTLS-encrypted data unchanged as it goes from the user's mobile device and through the service provider's WAP gateway. The WTLS-SSL encryption translation will not occur until the encrypted data reaches a second WAP gateway-like device residing within the business host's own secure network. One vendor developing such a solution is Openwave Systems (a combination of Phone.com and Software.com). Openwave calls this second WAP gateway-like device the Secure Enterprise Proxy. During an encrypted session, the service provider's WAP gateway and the business' Secure Enterprise Proxy negotiate with each other, so that the service provider essentially passes the encrypted data unchanged onto the business that is using this Proxy. This solution utilizes the service provider's WAP gateway because it is still needed to provide proper Internet access for the mobile users, but it does not perform the WTLS-SSL encryption translation there and thus is not exposing confidential data. The decryption is passed on and occurs, instead, within the confines of the business' own secure network, either at the Secure Enterprise Proxy or at the application server.

One drawback to this approach, however, is its proprietary nature. At the time of this writing, to make the Openwave solution work, three parties would need to implement components exclusively from Openwave. The wireless service providers would need to use Openwave's latest WAP gateway. Likewise, the business hosting the secure applications would need to use Openwave's Secure Enterprise Proxy to negotiate the encryption pass-through with that gateway. In addition, the mobile devices themselves would need to use Openwave's latest Web browser,

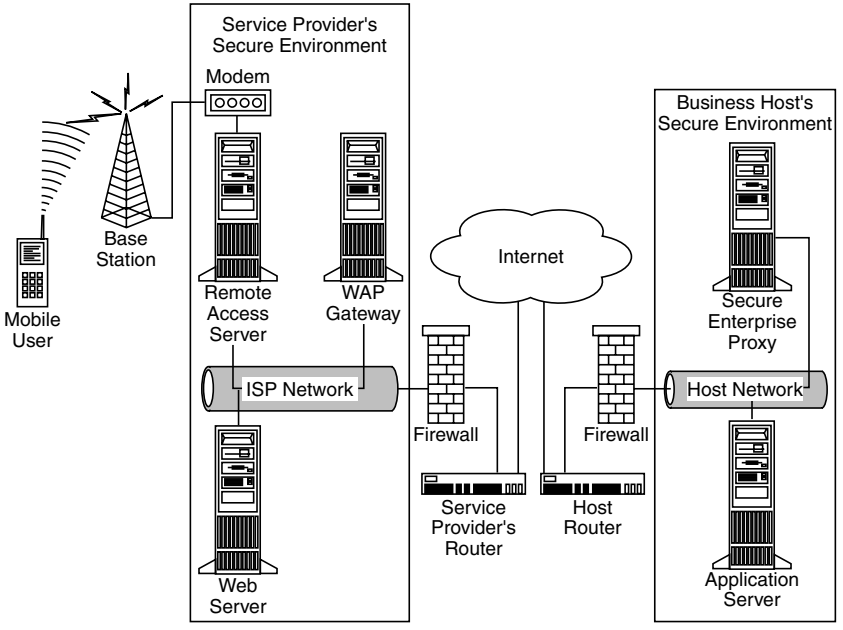

Exhibit 8-3. Pass-through from service provider's WAP gateway to host's WAP proxy.

at least Micro-browser version 5. Although approximately 70 percent of WAP-enabled phones throughout the world are using some version of Openwave Micro-browser, most of these phones are using either version 3 or 4. Unfortunately, most of these existing browsers are not upgradable by the user, so most users may need to buy new cell phones to incorporate this solution. It may take some time before this solution comes to fruition and becomes popular.

These are not the only solutions for providing end-to-end encryption for wireless Internet devices. Other methods in the works include applying encryption at the applications level, adding encryption keys and algorithms to cell phone SIM cards, and adding stronger encryption techniques to the next revisions of the WAP specifications, perhaps eliminating the "gap in WAP" entirely.

CONCLUSION

Two sound recommendations for the many practitioners in the information security profession are:

- Stay abreast of the wireless security issues and solutions.
- Do not ignore the wireless devices.

Many in the IT and information security professions regard the new wireless Internet devices diminutively as personal gadgets or executive toys. Many are so busy grappling with the issues of protecting their corporate PCs, servers, and networks that they cannot imagine worrying about yet another class of devices. Many corporate security policies make no mention about securing mobile hand-held devices and cell phones, although some of these same corporations are already using these devices to access their own internal e-mail. The common fallacy heard is: because these devices are so small, what harm can such a tiny device create?

Security departments have had to wrestle with the migration of information assets from the mainframe world to distributed PC computing. Many corporate attitudes have had to change during that evolution regarding where to apply security. With no exaggeration, corporate computing is undergoing yet another significant phase of migration. It is not so much that corporate information assets can be accessed through wireless means, because wireless notebook computers have been doing that for years; rather, the means of access will become ever cheaper and, hence, greater in volume. Instead of using a $3000 notebook computer, users (or intruders) can now tap into a sensitive corporate network from anywhere, using just a $40 Internet-enabled cell phone. Over time, these mobile devices will have increasing processing power, memory, bandwidth, storage, ease of use, and finally, popularity. It is this last item that will inevitably draw upon the corporate resources.

Small as these devices may be, once they access the sensitive assets of an organization, they can do as much good or harm as any other computer. Ignoring or disallowing these devices from an information security perspective has two probable consequences. First, the business units or executives within the organization will push, and often successfully, to deploy wireless devices and services anyway, but shutting out any involvement or guidance from the information security department. Inevitably, information security will be involved at a much later date, but reactively and often too late to have any significant impact on proper design and planning.

Second, by ignoring the wireless devices and their capabilities, the information security department will give attackers just what they need — a neglected and unprotected window into an otherwise fortified environment. Such an organization will be caught unprepared when an attack using wireless devices surfaces.

Wireless devices should not be treated as mere gadgets or annoyances. Once they tap into the valued assets of an organization, they are indiscriminate and equal to any other node on the network. To stay truly informed and prepared, information security practitioners should stay

abreast of the news developments and security issues regarding wireless technology. In addition, they need to work with the application designers as an alliance to ensure that applications designed for wireless take into consideration the many points discussed in this chapter. And finally, organizations need to expand the categories of devices protected under their information security policies to include wireless devices because they are, effectively, yet another infrastructure component of the organization.

VPN Deployment and Evaluation Strategy

Keith Pasley, CISSP

VPN technology has rapidly improved in recent years in the areas of performance, ease of use, deployment, and management tool effectiveness. The market demand for virtual private network (VPN) technology is also rapidly growing. Similarly, the number of different VPN products is increasing. The promise of cost savings is being met. However, there is a new promise that approaches VPNs from both a technical and business perspective. In today's fast-paced business environment, the promises of ease of management, deployability, and scalability of VPN systems are the critical success factors when it comes to selecting and implementing the right VPN system. From a business perspective, the realized benefits include:

- Competitive advantage due to closer relationships with business partners and customers
- New channels of service delivery
- Reaching new markets with less cost
- Offering higher-value information with removal of security concerns that have hampered this effort in the past

With so many choices, how does one determine the best fit? Objective criteria are needed to make a fair assessment of vendor product claims. What should one look for when evaluating a vendor's performance claims? What else can add value to VPN systems? In some cases, outsourcing to a managed security service provider is an option. Managed security service providers are service outsourcers that typically host security applications and offer transaction-based use of the hosted security application. Many businesses are now seriously considering outsourcing VPNs to managed security service providers that can provide deployment and management. The perception is that managed service providers have the expertise and management infrastructure to operate large-scale VPNs better than in-house staff.

VPN performance has consistently improved in newer versions of VPN products. Although performance is important, is it the most important criterion in selecting a VPN solution? No. A fast but exploitable VPN implementation will not improve security. Performance is also difficult to evaluate, and many performance tests do a poor job of mimicking real-world situations. Vendor performance claims should be evaluated very closely due to overly optimistic marketing-oriented performance claims that do not pan out in real-world implementations. It is important to understand the test methodologies used by vendors as the basis for such performance claims.

This chapter provides answers to a number of issues that information security professionals face when selecting products and implementing VPNs.

What is a VPN?

VPNs allow private information to be transferred across a public network such as the Internet. A VPN is an extension of the network perimeter, and therefore must have the ability to uniformly enforce the network security policy across all VPN entry points. Through the use of encapsulation and encryption, the confiden-

tiality of the data is protected as it traverses a public network. Technical benefits of proper use of this technology include reduced business operational costs, increased security of network access, in-transit data integrity, user and data authentication, and data confidentiality. However, some of the financial benefits can be negated by the real costs of a VPN system, which are incurred after the purchase of a VPN solution, during deployment, ongoing management, and support. The new promise of manageability, deployability, and scalability offers vendors an opportunity to differentiate their products from their competitors'. This type of product differentiation is increasingly important because most vendors' VPN products use the same VPN protocol — IPSec — and other underlying technologies. IPSec is an international standard that defines security extensions to the Internet Protocol. Although there are other secure tunneling protocols used to implement VPNs, IPSec has taken the leadership position as the protocol of choice. This standard specifies mandatory features that provide for a minimal level of vendor interoperability. This chapter will help information security professionals sort out a set of criteria that can be used when evaluating IPSec VPN solutions. The discussion begins with an examination of VPN applications.

IPSec VPN Applications

Enterprises have typically looked to virtual private networks (VPNs) to satisfy four application requirements: remote access, site-to-site intranet, secure extranet, and secured internal network. The technical objective, in most cases, is to provide authorized users with controlled access to protected network data resources (i.e., server files, disk shares, etc.). A companion business objective is to manage down network infrastructure costs and increase the efficiency of internal and external business information flow, increasing user productivity, competitive advantage, or strength of business partner relationships.

It is a good idea to define the tasks involved in a VPN evaluation project. A task list will help keep the evaluation focused and help anticipate the resources needed to complete the evaluation. Exhibit 40.1 gives an example list of VPN evaluation project tasks.

Remote Access VPN

There are two parts to a remote access VPN: the server and the client. They have two different roles and therefore two different evaluation criteria.

- B*usiness goal:* lower telecom costs, increased employee productivity
- T*echnical goal:* provide secured same-as-on-the-LAN access to remote workers

Both roles and criteria are discussed in this chapter section.

Remote access IPSec VPNs enable users to access corporate resources whenever, wherever, and however they require. Remote access VPNs encompass analog, dial, ISDN, digital subscriber line (DSL), mobile IP, and cable Internet access technologies, combined with security protocols such as IPSec to securely connect mobile users and telecommuters.

EXHIBIT 40.1 VPN evaluation project tasks

Assess data security requirements.
Classify users.
Assess user locations.
Determine the networking connectivity and access requirements.
Choose product or a service provider.
Assess hardware/software needs.
Set up a test lab.
Obtain evaluation devices.
Test products based on feature requirements.
Implement a pilot program.

The Client Software

Remote access users include telecommuters, mobile workers, traveling employees, and any other person who is an employee of the company whose data is being accessed. The most frequently used operating systems are MS Windows based, due to its market acceptance as a corporate desktop standard. IPSec VPN system requirements may indicate support for other operating systems, such as Macintosh, UNIX, PalmOS, or Microsoft Pocket PC/Windows CE. Preferably, the IPSec VPN vendor offers a mix of client types required by company. Mobile workers sometimes require access to high-value/high-risk corporate data such as sales forecasts, confidential patient or legal information, customer lists, and sensitive but unclassified DoD or law enforcement information. Remote access can also mean peer-to-peer access for information collaboration across the Internet (e.g., Microsoft NetMeeting) and can also be used for remote technical support.

The client hardware platforms for this application include PDAs, laptops, home desktop PC, pagers, data-ready cell phones, and other wired and wireless networked devices. As hardware platform technology evolves, there are sure to be other devices that can be used to remotely access company data. An interesting phenomenon that is increasing in popularity is the use of wireless devices such as personal digital assistants, cell phones, and other highly portable network-capable devices as access platforms for remote access IPSec VPN applications. The issues facing wireless devices include the same basic issues that wired IPSec VPN platforms face, such as physical security and data security, with the added issue of implementing encryption in computationally challenged devices.

Another issue with wireless IPSec VPN platforms, such as PDAs, is compatibility with wired-world security protocols. The Wireless Application Protocol (WAP) Forum, a standards body for wireless protocols, is working to improve compatibility between the WAP-defined security protocol — Wireless Transport Layer Security (WTLS) — and wired-world security protocols, such as SSL. Industry observers estimate that wireless devices such as PDAs and data-ready cell phones will be the platform of choice for applications that require remote, transactional data access. However, these devices are small and can easily be stolen or lost. This emphasizes the need to include hardware-platform physical security as part of the evaluation criteria when analyzing the features of IPSec VPN client software. Physical security controls for these platforms can include cables and locks, serial number tracking, motion sensors, location-based tracking (via the use of Global Positioning Systems), and biometric authentication such as finger scan with voice verification.

The communications transport for remote access continues to be predominately via dial-up. Wireless and broadband access continue to grow in usage. However, early complexities in broadband implementations and certain geographic constraints have recently been mitigated, and it is likely that broadband and wireless may grow in usage beyond dial-up use.

One issue with broadband (DSL, cable modem) usage is that as it becomes a commodity, broadband providers may try to segment allowable services on their networks. One tactic that is being used by cable services that provide Internet access is to prohibit the use of IPSec VPNs by residential users. According to one cable company, based on the U.S. West Coast, the network overhead generated by residential IPSec VPN users was affecting its available bandwidth to other home-based users. Therefore, this cable company had prohibited all VPNs from being used by its residential service customers through the use of port and protocol packet filter rules in the cable modem. Obviously, this benefits the cable company because it can then charge higher business-class fees to route VPNs from home users through the Internet. Some vendors of proprietary VPN solutions have responded by using encapsulation of VPN payloads into allowed protocols, within HTTP packets for example, to bypass this cable company constraint. How this issue will be resolved remains to be seen, but it does identify another criterion when selecting a VPN: will it work over the end user's ISP or network access provider network? Will the remote end users use their own residential class ISP? Or will the company purchase business-class access to ensure consistent and reliable connectivity?

End users are focused on getting done the work they are paid to do. Users, in general, are not incentived to really care about the security of their remote access connection. Users are primarily concerned with ease of use, reliability, and compatibility with existing applications on their computers.

Therefore, a part of a comprehensive evaluation strategy is that the VPN client should be fully tested on the same remote platform configuration as will be used by the users in real life. For example, some vendors' personal firewall may cause a conflict with another vendor's IPSec VPN client. This type of incompatibility may or may not be resolvable by working with the vendor and may result in disqualification from a list of potential solutions. Another example of IPSec VPN client incompatibility is the case in which one vendor's

IPSec VPN client does not support the same parameters as, say, the IPSec VPN server or another IPSec VPN client. The thing to keep in mind here is that standards usually define a minimum level of mandatory characteristics. Vendors, in an effort to differentiate their products, may add more advanced features, features not explicitly defined by a standard. Also, vendors may optimize their IPSec VPN client to work most effectively with their own IPSec VPN server. This leaves a mixed vendor approach to use a "lowest common denominator" configuration that may decrease the level of security and performance of the overall IPSec VPN system. For example, some IPSec VPN server vendors support authentication protocols that are not explicitly defined as mandatory in the standard. Obviously, if the IPSec VPN client that is selected is not from the same vendor as the IPSec VPN server and acceptable interoperability cannot be attained, then a compromise in criteria or vendor disqualification would be the decision that would have to be made.

As Internet access becomes more pervasive and subscribers stay connected longer or "always," there are resultant increases in attack opportunity against the remote VPN user's computer. Therefore, if there is valuable data stored on the remote user's computer, it may make sense to use some form of file or disk encryption. Because encryption is a processor-intensive activity, the computing resources available to the remote computer may need to be increased. The goal here is to also protect the valuable data from unauthorized viewing, even if it is stored on a portable computing device. Some VPN client software includes virus protection, distributed desktop firewall, desktop intrusion protection, and file/disk encryption. This type of solution may be more than is required for certain applications, but it does illustrate the principle of defense in depth, even at a desktop level. Add to this mix strong authentication and digital signing and the security risk decreases, assuming the application of a well-thought-out policy along with proper implementation of the policy. The aforementioned applies to dialup users as well; any time one connects via dialup, one receives a publicly reachable and hence attackable IP address.

VPN client integrity issues must also be considered. For example, does the VPN client have the ability to authenticate a security policy update or configuration update from the VPN server? Does the user have to cooperate in some way for the update to be successfully completed? Users can be a weak link in the chain if they have to be involved in the VPN client update process. Consider VPN clients that allow secured auto-updates of VPN client configuration without user participation. Antivirus protection is a must due to the potential of a Trojan horse or virus, for example, to perform unauthorized manipulation of VPN system. Is the VPN client compatible with (or does it include) desktop antivirus programs? We are witnessing an increase in targeted attacks, that is, where the attacker select targets for a particular reason rather than blindly probing for a vulnerable host. These kinds of attacks include the ability of attackers to coordinate and attack through VPN entry points. This is plausible for a determined attacker who systematically subverts remote VPN user connections into the central site. Therefore, one may have a requirement to protect the VPN client from subversion through the use of distributed desktop firewalls and desktop intrusion-detection systems.

The key differentiator of a distributed desktop firewall is that firewall policy for all desktops within an organization are managed from a central console. Personal firewalls, as the name implies, are marketed to individual consumers. The individual user is responsible for policy maintenance on personal firewalls. A distributed firewall is marketed to businesses that need to centrally enforce a consistent network security policy at all entry points to the internal network, including the remote VPN user connection. By deploying an IPSec VPN client in conjunction with a distributed firewall and an intrusion-detection system that reports back to a central management console, ongoing network attacks can be coalesced and correlated to provide an enterprise view of the security posture. Ideally, an IPSec vendor could provide a VPN client that includes anti-virus, desktop intrusion detection, and a distributed firewall along with the IPSec VPN client. A product that provides that level of integration would certainly enhance the efficiency of desktop security policy management.

Deploying the Client

Remote access VPN client software deployment issues are primarily operational issues that occur with any distributed software, such SQL client software. There is a wide body of software administration knowledge and methodologies that can be adapted to deploying remote access VPN client software.

Several issues must be sorted out when examining the deployability of a VPN client. One such issue is the VPN client software file size. This becomes an important issue if the selected mode of client software distribution is via low-speed dial-up, currently the most widely used remote access method. If the file takes too long to download, say, from a distribution FTP server, it is possible that affected users will be resistant to downloading the file or future updates. Resistant users may increase the likelihood of protracted implementation of the VPN, thus increasing total implementation cost. However, promise of pervasive high-speed access is on

the horizon. A deployment strategy that could resolve this issue is to distribute the VPN client initially by portable media, such as diskette or CD-ROM. Data compression can also help shrink VPN client distribution size. Most vendors supply some sort of client configuration utility that allows an administrator to preconfigure some initial settings, then distribute the installation file to each remote user. Possible VPN client distribution methods include posting to a Web or FTP site. If using Web, FTP, or other online file transfer method, it is important that the security professional anticipate possible scenarios that include the case of unauthorized access to the VPN client installation file. Some companies may decide that they will only distribute the installation files in person. Others are prepared to accept the risk of distribution via postal or electronic mail. Others may elect to set up a secured file transfer site, granting access via a PIN or special passphrase. When it comes to the initial distribution of the VPN client, the possibilities are limited only by the level of risk that is acceptable based on the value of loss if breached. This is especially the case if the initial VPN client software contains is preconfigured with information that could be used as reconnaissance information by an attacker.

Client Management Issues

VPN client management pertains to operational maintenance of the client configuration, VPN client policy update process, and upgrading of the VPN client software. Again, there are many approaches that can be adapted from the general body of knowledge and software management methodologies used to manage other types of software deployed by enterprises today. The additional factors are user authentication of updates, VPN availability, update file integrity, and confidentiality. The ability to manage user credentials is discussed in the chapter section on VPN server management issues.

Because the VPN client represents another access point into the internal network, such access requires rigorous user authentication and stringently controlled VPN configuration information. Many would argue that the highest practical level of strong authentication is biometrics based. If a PIN is used in conjunction with biometrics, it can be considered two-factor authentication. The next choice by many security professionals is the digital certificate stored on a smart card with PIN combination. The use of time-based calculator cards (tokens) and simple passwords is falling into legacy usage. However, many IPSec vendors are implementing the XAUTH extension to the IKE/IPSec standard. The XAUTH extension allows the use of legacy user authentication methods such as RADIUS, currently the most widely used authentication method in use, when validating user identity during IPSec tunnel setup. An added benefit is that XAUTH allows a company to leverage existing legacy authentication infrastructure, thus extending the investment in the older technology. The result: less changes to the network and a potential for decreased implementation time and costs due to reuse of existing user accounts. Another result of XAUTH use is relatively weaker authentication, given the increased vulnerability of passwords and token use.

A question that bears consideration due to the possibility of spoofing the VPN update server is "How does the client software confirm the sender of its receipt of the configuration update file?" With many forms of configuration distribution, an opportunity exists for an attacker to send an unauthorized update file to users. One control against this threat is the use of cryptography and digital signatures to digitally sign the update file, which can then be verified by the VPN client before acceptance. An additional protection would be to encrypt the actual configuration file as it resides on the remote user computer. One common method is to use a secured path to transfer updates, for example, LDAP over SSL (LDAPs).

Exhibit 40.2 shows a sample evaluation profile for remote access VPN client software. This is a list of items that may be considered when developing evaluation criteria for a VPN client.

The Remote Access Server

The major processing of encryption tunnel traffic is done at the remote access (VPN) server. The VPN server becomes a point of tunnel aggregation: the remote access client uses the server as a tunnel endpoint. There are basically two ways to verify that the VPN server has the capacity to efficiently process the VPN traffic. The first is to use bigger, faster hardware devices to overcome processing limitations; solutions based on monolithic hardware are tied directly to performance advances in hardware. If performance enhancements are slow to arrive, so will the ability to scale upward. This approach is commonly referred to as vertical scalability. The second alternative is load balancing, or distributing, the VPN connections across a VPN server farm. Load balancing requires special processors and software, either through dedicated load balancing hardware or via policy and state replication among multiple VPN servers. In terms of connections and economies, a load balanced VPN server farm will always offer better scalability because more servers can be added as needed. Load balancing will also offer redundancy; if any VPN server fails, the load will be distributed among the remaining VPN servers. (Some HA solutions can do this without disrupting sessions; other are more disrup-

EXHIBIT 40.2 Evaluation Criteria for Remote Access VPN Client

Assumption: VPN client is subject to the management of the central site
File/disk encryption may be needed for security of mobile user desktop
High-performance laptops/notebooks may be needed if using extensive disk/file encryption
Desktop intrusion detection with alerting integrated into centralized VPN manager
Distributed desktop firewall with alerting integrated into centralized VPN manager
Ability to lock down VPN client configuration
Transparent-to-user VPN client update
Authenticated VPN client update over an encrypted link
Adherence to current industry VPN standards if interoperability is a requirement

tive.) Encryption accelerators — hardware-based encryption cards — can be added to a VPN server to increase the speed of tunnel processing at the server. Encryption acceleration is now being implemented at the chip level of network interface cards as well. Encryption acceleration is more important for the VPN server than on the individual VPN client computer, again due to the aggregation of tunnels.

When evaluating the VPN server's capability, consider ease of management. Specifically, how easy is it for an administrator to perform and automate operational tasks? For example, how easy is it to add new tunnels? Can additional tunnel configurations be automatically "pushed" or "pulled" down to the VPN client? Logging, reporting, and alerting is an essential capability that should be integrated into the VPN server management interface. Can the VPN logs be exported to existing databases and network management systems? Does the VPN server provide real-time logging and alerting? Can filters be immediately applied to the server logs to visually highlight user-selectable events? If using digital certificates, what certificate authorities are supported? Is the certificate request and acquisition process an automated online procedure? Or does it require manual intervention? Repetitive tasks such as certificate request and acquisition are natural candidates for automation. Does the VPN server automatically request certificate revocation lists to check the validity of user certificates?

Exhibit 40.3 shows a sample evaluation profile for remote access VPN servers.

Intranet VPN

An intranet VPN connects fixed locations and branch and home offices within an enterprise WAN. An intranet VPN uses a site-to-site, or VPN gateway-to-VPN gateway, topology. The business benefits of an intranet VPN include reduced network infrastructure costs and increased information flow within an organization. Because the nature of an intranet is site to site, there is little impact on end-user desktops. The key criteria in evaluating VPN solutions for an intranet application are performance, interoperability with preexisting network infrastructure, and manageability. The technical benefits of an intranet VPN include reduced WAN bandwidth costs, more flexible topologies (e.g., fully meshed), and quick and easy connection of new sites.

EXHIBIT 40.3 Evaluation Profile for Remote Access VPN Server

Scalability (can the server meet connectivity requirements?)
Supports high-availability options
Integrates with preexisting user authentication systems
Hardware-based tunnel processing, encryption/decryption acceleration
Automated management of user authentication process
Supports industry VPN standards for interoperability
What authentication types are supported?
Does the VPN server run on a hardened operating system?
Is firewall integration on both the VPN client and server side possible?
Centralized client management features
Broad client support for desktop operating systems

The use of remotely configurable VPN appliances, a vendor-provided VPN hardware/software system, is indicated when there will be a lack of on-site administration and quick implementation timeframe. The value of VPN appliances becomes clear when comparing the time and effort needed to integrate hardware, operating system, and VPN server software using the more traditional "build-it-yourself" approach.

Class-of-service controls can be useful when performing traffic engineering to prioritize certain protocols over others. This becomes an issue, for example, when business requirements mandate that certain types of VPN traffic must have less latency than others. For example, streaming video or voice traffic requires a more continuous bit rate than a file transfer or HTTP traffic due to the expectations of the end user or the characteristics of the type of application.

Two limiting factors for general use of intranet VPNs that tunnel through the Internet are latency and lack of guaranteed bandwidth. Although these factors can also affect internationally deployed private WAN-based intranet VPNs, most companies cannot afford enough international private WAN bandwidth to compete against the low cost of VPN across the Internet. Performing a cost/benefit analysis may help in deciding whether to use a private WAN, an Internet-based intranet VPN, or an outsourced VPN service. Multi-Protocol Label Switching (MPLS) is a protocol that provides a standard way to prioritize data traffic. MPLS could be used to mitigate latency and guaranteed bandwidth issues. With MPLS, traffic can be segregated and prioritized so as to allow certain data to traverse across faster links than other data traffic. The benefit of using MPLS-enabled network components in IPSec VPN applications is that VPN traffic could be given priority over other data traffic, thereby increasing throughput and decreasing latency.

The topology of the VPN is an important consideration in the case of the intranet VPN. Many intranet VPNs require a mesh topology, due to the decentralized nature of an organization's information flow. In other cases, a hub-and-spoke topology may be indicated, in the case of centralized information flow, or in the case of a "central office" concept that needs to be implemented. If it is anticipated that network changes will be frequent, VPN solutions that support dynamic routing and dynamic VPN configuration are indicated. Dynamic routing is useful in the case where network addressing updates need to be propagated across the VPN quickly, with little to no human intervention required. Routing services ensure cost-effective migration to VPN infrastructures that provide robust bandwidth management without impacting existing network configurations. Dynamic VPN technology is useful where it is anticipated that spontaneous, short-lived VPN connectivity is a requirement. There is much ongoing research in the area of dynamic VPNs that promise to ease the administrative burden of setting up VPN tunnels in large-scale deployments.

Building an intranet VPN using the Internet is, in general, the most cost-effective means of implementing VPN technology. Service levels, however, as mentioned before, are generally not guaranteed on the Internet. While the lack of service level guarantees is true for general IP traffic, it is not universally so for intranet VPNs. While some ISPs and private-label IP providers (e.g., Digital Island) offer service level guarantees, this technology is only now maturing; and to get the most benefit from such service offerings, customers will typically build their intranets on top of a single ISP's IP network. When implementing an intranet VPN, businesses need to assess which trade-off they are willing to make between guaranteed service levels, pervasiveness of network access, and transport cost. Enterprises requiring guaranteed throughput levels should consider deploying their VPNs over a network service provider's private end-to-end IP network, or, potentially, Frame Relay, or build one's own private backbone.

Exhibit 40.4 provides a list of items that can be used when developing a set of evaluation criteria for an intranet VPN.

EXHIBIT 40.4 Evaluation Profile for a Site-to-Site Intranet VPN

Assumption: none
Support for automatic policy distribution and configuration
Mesh topology automatic configuration, support for hub-and-spoke topology
Network and service monitoring capability
Adherence to VPN standards if used in heterogeneous network
Class-of-service controls
Dynamic routing and tunnel setup capability
Scalability and high availability

Extranet VPN

Extranet VPNs allows for selective flow of information between business partners and customers, with an emphasis on highly granular access control and strong authentication. For example, security administrators may grant user-specific access privileges to individual applications using multiple parameters, including source and destination addresses, authenticated user ID, user group, type of authentication, type of application (e.g., FTP, Telnet), type of encryption, the day/time window, and even by domain.

An extranet VPN might use a user-to-central site model, in which a single company shares information with supply-chain and business partners, or a site-to-site model, such as the Automotive Network Exchange. If using the user-to-site model, then evaluation criteria are similar to remote access VPNs with the exception that the user desktop will not be under the control of the central site. Because the extranet user's computer is under the control of its own company security policy, there may be a conflict in security policy, implemented on the users' computer. In general, extranet partners in the user-to-site model will need to work together to reach an agreement as to security policy implementation at the user desktop, VPN client installation issues, help desk, ongoing maintenance if one partner is mandating the use of a particular VPN client, and liability issues should one partner's negligence lead to the compromise of the other partner's network. The hardware platforms supported by a vendor's VPN client will also be an issue that will require a survey of possible platforms that remote extranet partners will be using. For the most part, Web-based access is often used as the software client of choice in extranet environments, and SSL is often chosen as the security protocol. This greatly simplifies the configuration and maintenance issues that will need to be confronted. With an extranet VPN, it really does not matter whether all the participants use the same ISP, assuming acceptable quality of service is provided by whichever ISP is chosen. All that is required is for each member of the group to have some type of access to the Internet. The VPN software or equipment in each site must be configured with the IP address of the VPN equipment in the main site of the extranet.

Because the appeal of an extranet VPN is largely one of the ability to expand markets and increased strength of business relationships, from a marketing perspective it may be desirable to brand the extranet client software. This can be done, with some extranet VPN software and service providers, either at the Web page that is the extranet entry point (if using a Web browser as the software platform) or within the VPN client (if using the traditional client/server software model). In the consumer market, extranet VPNs can be used as an alternative to Web browser-based SSL. A situation in which IPSec VPNs would be preferable to Web browser-based SSL is when the customer is known and is likely to come back to the site many times. In other words, an extranet VPN would not necessarily work well in a consumer catalog environment where people might come once to make a purchase with a credit card.

A Web browser-based SSL is fine for spontaneous, simple transactional relationships, but an IPSec VPN client/server solution using digital certificates-based mutual authentication may be more appropriate for persistent business relationships that entail access to high-value data. Browser-based SSL could be appropriate for this kind of application if client-side certificates are used. The main idea is that once the user is known by virtue of a digital certificate, the access control features of a VPN can then be used to give this person access to different resources on the company's network. This level of control and knowledge of who the user is has led many companies to use digital certificates. Obviously, this is a concern in large-scale extranet VPN implementations. The issues related to the PKI within the extranet VPN are beyond the scope of this chapter.

Should an existing intranet VPN be used as the basis for implementing an extranet VPN? It depends on the level of risk acceptance and additional costs involved. Enabling an intranet to support extranet connections is a fairly simple undertaking that can be as basic as defining a new class of users with limited rights on a network. There are, however, several nuances to designing an extranet VPN that can directly impact the security of the data. One approach to enabling an extranet, for example, is to set up a demilitarized zone (for example, on a third interface of a perimeter firewall) to support outside users. This solution provides firewall protection for the intranet and the extranet resources, as well as data integrity and confidentiality via the VPN server.

Exhibit 40.5 shows a sample evaluation profile for an extranet VPN application. Below is a list of items that can be used when developing a set of evaluation criteria for an extranet VPN.

Securing the Internal Network

Due to constant insider threat to data confidentiality, companies now realize that internal network compartmentalization through the use of VPNs and firewalls is not just a sales pitch by security vendors trying to sell

EXHIBIT 40.5 Evaluation Profile for an Extranet VPN

Prefer strong mutual authentication over simple username/passwords
Access control and logging are very important
Prefer solutions that allow client customization for branding
Minimal desktop footprint (because the desktop is not under the control of the partner)
Minimal intrusiveness to normal application use
Silent installation of preconfigured VPN client and policy
Ease-of-use of the VPN client is key
Service level monitoring and enforcement support

more products. Although external threat is growing, the internal threat to data security remains constant. Therefore, an emerging VPN application is to secure the internal network.

There are many ways that a network can be partitioned from a network security perspective. One approach is to logically divide the internal network. Another approach is to physically partition the network. VPN technology can be used in both approaches. For example, physical compartmentalization can be accomplished by placing a target server directly behind a VPN server. Here, the only way the target server can be accessed is by satisfying the access control policy of the VPN server. The benefits here include simplicity of management, clearly defined boundaries, and a single point of access. An example of logical compartmentalization would be the case in which users who need access to a target server are given VPN client software. The users can be physically located anywhere on the internal network, locally or remote. The VPN client software automatically establishes an encrypted session with the target server, either directly or through an internal VPN gateway. The internal network is thereby logically "partitioned" via access control. Another logical partitioning scenario would be the case in which peer-to-peer VPN sessions need to be established on the internal network. In this case, two or more VPN clients would establish VPN connectivity, as needed, on an ad hoc basis. The benefit of this configuration is that dynamic VPNs could be set up with little user configuration needed, along with data privacy. The downside of this approach would be decreased user authentication strength if the VPN clients do not support robust user authentication in the peer-to-peer VPN.

There appears to be a shift in placement emphasis regarding where VPN functionality is implemented within the network hierarchy. With the introduction of Microsoft Windows 2000, VPN technology is being built into the actual operating system as opposed to being added later using specialized hardware and software. With this advent, the level of VPN integration that can be used to secure the internal network becomes much deeper, if implemented properly. VPN technology is being implemented at the server level as well in Microsoft Windows and with various versions of UNIX. Although this does not mean that this level of VPN integration is all that is needed to secure the internal network, it does encourage the concept of building in security from the beginning, and using it end-to-end. Implementation of a VPN directly on the target application server, to date, has a considerable impact on performance; thus, hardware acceleration for cryptographic functions is typically required.

The requirement to provide data confidentiality within the internal network can be met using the same deployment and management approaches used in implementing remote access VPN. The user community is generally the same. The hardware platform could be the same, especially with so many companies issuing laptop and other portable computers to their employees. One difference that must be considered is the security policy to be implemented on the VPN client while physically inside the internal network versus the policy needed when using the same hardware platform to remotely access the internal network via remote access VPN. The case might exist where it is prudent to have a tighter security policy when users are remotely logging in due to increased risk of unauthorized access to company data as it traverses a public transport such as the Internet. Although the risks are the same on internal or external access, the opportunity for attack is much greater when using the remote access VPN. There is another application of VPN technology on internal networks, which is to provide data confidentiality for communications across LANs. Due to the operational complexity of managing potentially *n*-squared VPN connections in a Microsoft File Sharing/SMB environment, however, some companies are investigating whether a single "group" or LAN key is sufficient — in such deployments, data confidentiality in transport is more important than authentication.

A sample evaluation profile for securing the internal network VPN application in Exhibit 9-6.

EXHIBIT 40.6 Evaluation Profile for Securing the Internal Network VPN Application

Strong user authentication
Strong access control
Policy-based encryption for confidentiality
In-transit data integrity
Low impact to internal network performance
Low impact on the internal network infrastructure
Low impact to user desktop
Ease of management
Integration with preexisting network components
Operational costs (may not be a big issue when weighed against the business objective)
VPN client issues:
User transparency (does the user have to do anything different?)
Automatic differentiation between remote access and internal VPN policy (can the VPN client auto adapt to internal/external security policy changes?)

VPN Deployment Models

There are four VPN server deployment models discussed in this chapter section: dedicated hardware/appliance, software based, router based, and firewall based. The type of VPN platform used depends on the level of security needed, performance requirements, network infrastructure integration effort, and implementation and operational costs. This discussion now concentrates on VPN server deployment considerations, as VPN client deployment was discussed in earlier chapter sections.

Dedicated Hardware VPN Appliance

An emerging VPN server platform of choice is that of a dedicated hardware appliance, or purpose-built VPN appliance. Dedicated hardware appliance usage has become popular due to fact that its single-purpose, highly optimized design is shown to be (in some respects) easier to deploy, easier to manage, easier to understand, and in many cases cost effective. The idea behind this type of platform is similar to the example of common household appliances. For example, very few people buy a toaster and then attempt to modify it after bringing it home. The concept to grasp here is turnkey.

These units are typically sold in standard hardware configurations that are not meant to be modified by the purchaser. Purpose-built VPN appliances often have the advantage over other platforms when it comes to high performance due to the speed efficiency of performing encryption in hardware. Most purpose-built VPN appliances are integrated into a specialized real-time operating system optimized to efficiently run on specially designed hardware. Many low-end VPN appliances use a modified Linux or BSD operating system running on an Intel platform. Many VPN appliances can be preconfigured, shipped to a remote site, and easily installed and remotely managed. The advantage here is quick implementation in large-scale deployments. This deployment model is used by large enterprises with many remote offices, major telecom carriers, ISPs, and managed security service providers. If an enterprise is short of field IT personnel, VPN appliances can greatly reduce the human resource requirement for implementing a highly distributed VPN.

One approach to rolling out a large-scale, highly distributed VPN using hardware VPN devices is to: (1) preconfigure the basic networking parameters that will be used by the appliance, (2) pre-install the VPN appliance's digital certificate, (3) ship the appliance to its remote location, and (4) then have someone at the remote location perform the rudimentary physical installation of the appliance. After the unit is plugged into the power receptacle and turned on, the network cables can be connected and the unit should then be ready for remote management to complete the configuration tasks as needed. Drawbacks to the use of the VPN appliances approach include the one-size-fits-all design concept of VPN appliance products, which does not always allow for vendor support of modifications of the hardware in a VPN appliance. Additionally, VPN appliances that use proprietary operating systems may mean learning yet another operating system and may

not cleanly interoperate with existing systems management tools. The bottom line is: if planning to modify the hardware of a VPN appliance oneself, then VPN appliances may not be the way to go.

Many carrier-class VPN switches — VPN gateways that are capable of maintaining tens of thousands of separate connections — are another class of VPN component that fits the requirements of large-scale telecommunications networks such as telcos, ISPs, or large enterprise business networks. Features of carrier-class VPN gateways include quick and easy setup and configuration, allowing less-experienced personnel to perform installations. High throughput, which means it can meet the needs of a growing business, and easy-to-deploy client software are also differentiators for carrier-class VPN gateways.

Software-Based VPNs

Software-based VPN servers usually require installation of VPN software onto a general-purpose computer running on a general-purpose operating system. Typical operating systems that are supported tend to be whatever operating system is the market leader at the time. This has included both Microsoft Windows-based and UNIX-based operating systems. Some software-based VPNs will manipulate the operating system during installation to provide security hardening, some level of performance optimization, or fine-tuning of network interface cards. Software-based VPNs may be indicated if the VPN strategy is to upgrade or "tweak" major components of the VPN hardware in some way due to the turnkey concept of the appliance approach. Also, the software VPN approach is indicated if one plans to minimize costs by utilizing existing general-purpose computing hardware.

Disadvantages of software-based VPN servers are typically performance degradation when compared to purpose-built VPN appliances, the server hardware and operating system must be acquired if not available, the additional cost for hardware encryption cards, and the additional effort required to harden the operating system. Applying appropriate scalability techniques such as load balancing and using hardware encryption add-on cards can mitigate these disadvantages. Also, the VPN software-only approach has a generally less-expensive upfront purchase price. Sometimes, the software is built into the operating system; for example, Microsoft Windows 2000 Server includes an IPSec VPN server.

Some vendors' software VPN products are supported on multiple platforms that cannot be managed using a central management console or have a different look and feel on each platform. To ensure consistent implementation and manageability, it makes sense to standardize on hardware platforms and operating systems. By standardizing on platforms, the learning curve can be minimized and platform-based idiosyncrasies can be eliminated.

Router-Based VPNs

One low-cost entry point into deploying a VPN is to use existing routers that have VPN functionality. By leveraging existing network resources, implementation costs can be lowered, and integration into network management infrastructure can more easily be accomplished. Many routers today support VPN protocols and newer routers have been enhanced to more efficiently process VPN traffic. However, a router's primary function is to direct network packets from one network to another network; therefore, a trade-off decision may have to be made between routing performance and VPN functionality. Some router models support hardware upgrades to add additional VPN processing capability. The ability to upgrade existing routers provides a migration path as the VPN user community grows. Many router-based VPNs include support for digital certificates. In some cases, the digital certificates must be manually requested and acquired through the use of cutting and pasting of text files. Depending on the number of VPN nodes, this may affect scalability. VPN-enabled routers require strong security management tools — the same kinds of tools normally supplied with hardware appliance and software VPNs.

Where should the router-based VPN tunnel terminate? The tunnel can be terminated in either of two places: outside the network perimeter when adding VPN to an access router, or terminating tunneled traffic behind the firewall when adding VPN to an interior router.

Firewall-Based VPNs

Firewalls are designed to make permit/deny decisions on traffic entering a network. Many companies are have already implemented firewalls at the perimeter of their networks. Many firewalls have the ability to be upgraded

for use as VPN endpoints. If this is the case, for some organizations it may make sense to investigate the VPN capability of their existing firewall. This is another example of leveraging existing network infrastructure to reduce upfront costs. A concern with using firewalls as a VPN endpoint would be performance. Because all traffic entering or leaving a network goes through a firewall, the firewall may already be overloaded. Some firewall vendors, however, offer hardware encryption add-ons. As with any configurable security device, any changes made to a firewall can compromise its security. VPN management is enhanced through use of a common management interface provided by the firewall. As the perimeter firewall, this is an ideal location for the VPN because it isolates the ingress/egress to a single point. Adding the VPN server to the firewall eliminates the placement issues associated with hardware, software, and router VPNs; for example, should encrypted packets be poked through a hole in the firewall, what happens if the firewall performs NAT, etc.?

The firewall/VPN approach also allows for termination of VPN tunnels at the firewall, decryption, and inspection of the data. A scenario in which this capability is advantageous is when firewall-based anti-virus software needs to be run against data traversing the VPN tunnel.

General Management Issues for Any VPN

The question arises as to who should manage the software-based VPN. Management can be divided between a network operations group, a security group, and the data owner. The network operations will need to be included in making implementation and design decisions, as this group is usually charged with maintaining the availability of a company's data and data integrity. The security group would need to analyze the overall system design and capability to ensure conformance to security policy. The data owner, in this case, refers to the operational group that is using the VPN to limit access. The data owner could be in charge of access control and user account setup. In an ideal situation, this division of labor would provide a distributed management approach to VPN operations. In practice, there is rarely the level of cooperation required for this approach to be practical.

Evaluating VPN Performance

To this point, we have discussed the criteria for evaluating VPNs from end-user and administrator perspectives. However, it is also insightful to understand how VPN vendors establish benchmarks for performance as a marketing tool. Many vendors offer VPN products that they classify by the number of concurrent VPN connections, by the maximum number of sessions, or by throughput. Most security professionals are interested in how secure the implementation is; most network operations staff, especially ISP staff, are interested in how many clients or remote user tunnels are supported by a VPN gateway. An IPSec remote user tunnel can be defined as the completion of IKE phase 1 and phase 2 key exchanges. These phases must be completed to create a secure tunnel for each remote communications session, resulting in four security associations. This is a subjective definition because vendors typically establish various definitions to put their performance claims in the best possible light.

Although many vendors provide a single number to characterize VPN throughput, in real-world deployments, performance will vary depending on many conditions. This chapter section provides a summary of the factors that affect throughput in real-world deployments.

Packet Size

Most VPN operations, such as data encryption and authentication, are performed on a per-packet basis. CPU overhead is largely independent of packet size. Therefore, larger packet sizes typically result in higher data throughput figures. The average size of IP packets on the Internet is roughly 300 bytes. Unfortunately, most vendors state VPN throughput specifications based on relatively large average packet sizes of 1000 bytes or more. Consequently, organizations should ask vendors for throughput specifications over a range of average packet sizes to better gauge expected performance.

Encryption and Authentication Algorithms

Stronger encryption algorithms require greater system resources to complete mathematical operations, resulting in lower data throughput. For example, VPN throughput based on DES (56-bit strength) encryption may

be greater than that based on 3DES (168-bit strength) encryption. Stream ciphers are typically faster than block ciphers.

Data authentication algorithms can have a similar effect on data throughput. For example, using MD5 authentication may result in a slightly greater throughput when compared with SHA1.

Host CPU

Software-based VPN solutions provide customers with a choice of central processors, varying in class and clock speed. Host processing power is especially critical with VPN products not offering optional hardware-based acceleration. VPN testing has shown that performance does not linearly increase by adding additional general-purpose CPUs to VPN servers. One vendor claims that on a Windows NT server, if one processor is 100 percent loaded, adding a second processor frees CPU resources by only 5 percent. The vendor claims a sevenfold increase in throughput when using encryption acceleration hardware instead of adding general-purpose CPUs to the server. In other cases, the price/performance of adding general-purpose CPUs compared to adding hardware acceleration weighs against the former. In one case, the cost of adding the general-purpose CPU was approximately twice the price of a hardware acceleration card, with substantially less performance increase. Speed is not just a factor of CPU, but also a factor of I/O bus, RAM, and cache. Reduced Instruction Set CPUs, RISC processors, are faster than general-purpose CPUs, and Application-Specific Integrated Circuits, ASICs, are typically faster at what they are designed to do than RISC processors.

Operating System and Patch Levels

Many software-based VPN solutions provide customers with a choice of commercial operating systems. Although apples-to-apples comparisons of operating systems are difficult, customers should make sure that performance benchmarks are specific to their target operating system. Also, operating system patch levels can have a significant throughput impact. Usually, the most current operating system patch levels deliver better performance. If the VPN requirement is to use operating system-based VPN technology, consider software products that perform necessary "hardening" of operating systems, as most software firewalls do. Consider subscribing to ongoing service plans that offer software updates, security alerts, and patch updates.

Network Interface Card Drivers

Network interface card (NIC) version levels can affect throughput. Usually, the most updated network interface card drivers deliver the best performance. A number of network interface card manufacturers now offer products that perform complementary functions to IPSec-based VPNs. NICs can be installed in user computers or IPSec VPN gateways that perform encryption/decryption, thereby increasing system performance while decreasing CPU utilization. This is achieved by installing a processor directly on the NIC, which allows the NIC to share a greater load of network traffic processing so the host system can focus on servicing applications.

Memory

The ability of a VPN to scale on a remote user tunnel basis depends on the amount of system memory installed in the gateway server. Unlike many VPN appliance solutions (which are limited by a fixed amount of memory), a software-based VPN is limited in its support of concurrent connections and remote user tunnels by maximum number of concurrent connections established by the kernel. In some cases, concurrent connections are limited by VPN application proxy connection limits, which are independent of the host's kernel limits. However, it is important to understand that most VPN deployments are likely to run into throughput limitations before reaching connection limitations. Only by combining the memory extensibility of software-based VPN platforms and throughput benefits of dedicated hardware can the best of both worlds be achieved. Consider the following hypothetical example. An organization has a 30-Mbps Internet link connected to a software-based VPN with a hardware accelerator installed. For this organization, the required average data rate for a single remote user is approximately 40K. In this scenario, the VPN will support approximately 750 concurrent remote users (30 Mb/40K.) Once the number of users increases beyond 750 users, average data rates and the corresponding user experience will begin to decline. It is clear from this example that reliable, concurrent user support is more likely to be limited by software-based VPN gateway throughput than by limitations in the number of

connections established. From this perspective, the encryption accelerator card is a key enabler in scaling a software-based VPN deployment to support thousands of users.

A single number does not effectively characterize the throughput performance of a VPN. The size of packets being transferred by the system, for example, has a major impact on throughput. System performance degrades with smaller packet sizes. The smaller the packet size, the greater the number of packets processed per second, the higher the overhead, and thus the lower the effective throughput. An encryption accelerator card can be tuned for both large and small packets to ensure performance is optimized for all packet sizes. Other factors that can affect performance include system configuration (CPU, memory, cache, etc.), encryption algorithms, authentication algorithms, operating system, and traffic types. Most of these factors apply to all VPN products. Therefore, do not assume that performance specifications of competitive VPN products mean that those numbers can be directly compared or achieved in all environments.

Data Compression Helps

To boost performance and improve satisfaction among end users, a goal to reach for is to minimize delay across the VPN. One way to minimize delay is to send less traffic. This goal can be achieved by compressing data before it is put on the VPN. Performance gains from compression vary, depending on what kind of data is being sent; but, in general, once data is encrypted, it just does not compress as well as it would have unencrypted. Data compression is an important performance enhancer, especially when optimizing low-bandwidth analog dialup VPN access, where MTU size and fragmentation can be factors.

Is Raw Performance the Most Important Criteria?

According to a recent VPN user survey whose goal was to discover which features users think are most important in evaluating VPNs and what they want to see in future offerings, performance was rated higher than security as a priority when evaluating VPNs. This marks a shift in thinking from the early days of VPN when few were convinced of the security of the underlying technology of VPN.

This is particularly true among security professionals who rate their familiarity with VPN technologies and products as "high." Those who understand VPNs are gaining confidence in security products and realize that performance and management are the next big battles. According to the survey results, many users feel that while the underlying security components are a concern, VPN performance must not be sacrificed. According to the survey, users are much more concerned about high-level attributes, such as performance, security of implementation, and usability, and less concerned about the underlying technologies and protocols of the VPN.

Outsourcing the VPN

Outsourcing to a knowledgeable service provider can offer a sense of security that comes from having an expert available for troubleshooting. Outsourcing saves in-house security managers from the problems associated with physically upgrading their VPNs every time branch offices are setting and testing remote users who need to be added to the network. Unless a company happens to have its own geographically dispersed backbone, then at least the transit portion of the VPN will have to be outsourced to an Internet access service provider or private IP network provider. However, a generic Internet access account does not provide much assurance that the VPN traffic will not get bogged down with the rest of the traffic on the Internet during peak hours. The ISP or VPN service provider can select and install the necessary hardware and software, as well as assume the duties of technical support and ongoing maintenance.

Exhibit 40.7 lists some factors to consider when evaluating a VPN service provider.

Reliability

If users are not able to get on to the network and have an efficient connection, then security is irrelevant. If the goal of the VPN is to provide remote access for mobile workers, then a key aspect of performance is going to be the number of points of presence the service provider has in the geographic regions that will require service, as well as guarantees the service provider can make in terms of its success rates for dialup access. For example, one VPN service provider (provides transport and security services) offers 97 percent busy-free dialing

EXHIBIT 40.7 Evaluating a VPN service provider

Factors to consider when evaluating a VPN service provider include:
Quality of service
Reliability
Security
Manageability
Securities of the provider's own networks and network operations centers
Investigate the hiring practices of the provider (expertise, background checks)
What pre- and post-deployment services does the provider offer (vulnerability assessment, forensics)

for remote access, with initial modem connect speeds of 26.4 KBps or higher, 99 percent of the time. Another VPN service provider (provides transport and security services) promotes 100 percent network availability and a 95 percent connection success rate for dialup service. When such guarantees are not met, the service provider typically promises some sort of financial compensation or service credit. VPN transport and security services can be outsourced independently.

However, if the main goal is to provide a wide area network for a company, overall network availability and speed should be a primary concern. Providers currently measure this by guaranteeing a certain level of performance, such as throughput, latency, and availability, based on overall network averages. Providers that build their own backbones use them to support many customer VPNs. Some VPN service providers provide private WAN service via Asynchronous Transfer Mode or Frame Relay transport for customer VPNs. This way, VPN traffic does not have to compete for bandwidth with general Internet traffic, and the VPN service provider can do a better job of managing the network's end-to-end performance.

Quality of Service

VPN service providers are beginning to offer guarantees for performance-sensitive traffic such as voice data and multimedia. For example, a network might give higher priority to a streaming video transmission than to a file download because the video requires speedy transmission for it to be usable. The current challenge is to be able to offer this guarantee across network boundaries. While it is currently possible with traffic traveling over a single network, it is almost impossible to do for traffic that must traverse several networks. This is because, although standards like MPLS are evolving, there is no current single standard for prioritizing traffic over a network, much less the Internet.

To ensure better performance, many VPN service providers offer service level agreements. For an extra charge, commensurate with the quality of service, a VPN service provider can offer its customers guarantees on throughput, dial-in access, and network availability. Some VPN service providers have their own private Frame Relay or Asynchronous Ttransfer mode networks over which much of the VPN traffic is routed, enhancing performance.

Security

A VPN provides security through a combination of encryption, tunneling, and authentication/authorization. A firewall provides a perimeter security defense by allowing only trusted, authorized packets or users access to the corporate network. Companies can opt to have their VPN service provider choose the security method for their VPN and can either manage it in-house or allow the service provider to manage this function. Another option is for the customer to handle the security policy definition of the VPN entirely. Most security managers prefer to retain some control over their network's security, mainly in the areas of end-user administration, policy, and authentication. A company might opt to do its own encryption, for example, or administer its own security server, but use the VPN service provider for other aspects of VPN management, such as monitoring and responding to alerts. The decision of whether or not to outsource security, for some, has to do with the size and IT resources of a company. For others, outsource decisions have more to do with the critical nature of the corporate data and the confidence the IT manager has in outsourcing in general.

Exhibit 40.7 enumerates factors to be considered when evaluating outsourced VPNs.

Manageability

Another issue to consider is the sort of management and reporting capabilities that are needed from the VPN service provider. Many VPN service providers offer subscribers some sort of Web-based access to network performance data and customer usage reports. Web-based tools allow users to perform tasks such as conducting updates of remote configurations, adding/deleting users, controlling the issuance of digital certificates, and monitoring performance-level data. Check if the VPN service provider offers products that allow split administration so that customers can add and delete users and submit policy changes at a high level.

Summary

Establishing a VPN evaluation strategy will allow security professionals to sort out vendor hype from actual features that meet a company's own VPN system requirements. The key is to develop a strategy and set of criteria that match the VPN application type that is needed. The evaluation criteria should define exactly what is needed. A hands-on lab evaluation will help the security professional understand exactly what will be delivered. Pay particular attention to the details of the VPN setup and be vigilant with any VPN service provider or product vendor that is selected.

Similarly, a well-thought-out VPN deployment strategy will help keep implementation costs down, increase user acceptance, and accelerate the return on investment. The deployment strategy will vary, depending on the type of VPN application and deployment model chosen.

Vendors traditionally want to streamline the sales cycle by presenting as few decision points as possible to customers. One way this is done is to oversimplify VPN product performance characteristics. Do you want a size small, medium, or large? Do you want a 10-user VPN server, 100-user VPN server, or mega-user VPN server? Do you want the 100-MHz or 1-Gigabit model? Insist that VPN vendors provide the parameters used to validate their claims. It is important that security professionals understand the metrics and validation methodologies used by vendors. Armed with this knowledge, security professionals can make informed decisions when selecting products.

There are many options available for implementing VPNs. Managed security service providers can ease some of the burden and help implement VPNs quickly. However, security professionals will do well to exercise due diligence when selecting a service provider.

Glossary

ATM (Asynchronous Transfer Mode) A means of digital communications that is capable of very high speeds; suitable for transmission of images or voice or video as well as data. Commonly deployed in backbone networks.

DSL (Digital Subscriber Line) A generic name for a family of high-speed digital lines being provided by competitive local exchange carriers and local phone companies to provide broadband access to their subscribers.

FTP (File Transfer Protocol) A protocol that allows users to copy files between their local system and any system they can reach on a network. Consists of FTP client and FTP server.

IKE (Internet Key Exchange) A protocol used in IPSec VPNs to establish security parameters for use during an IPSec VPN session (referred to as a security association).

IPSec (IP Security protocol) A standard suite of protocols used in VPNs which defines encryption and data integrity algorithms and rules determining the format and transmission of secure IP packets.

Kbps Kilobits per second.

Mbps Megabits per second.

MSP (Managed Security Service Provider) A class of network infrastructure provider that offers to assume various network security tasks on behalf of its customers. VPN service providers provide VPN server/client deployment assistance and operational management of VPNs.

SSL (Secure Socket Layer) A security protocol that was originally developed by Netscape. SSL has been universally accepted on the World Wide Web for authenticated and encrypted communication between clients and servers. SSL is usually associated with browsers, although it can be used to secure other TCP/IP protocols, such as FTP. SSL has evolved into TLS.

TLS (Transport Layer Security protocol) An IETF draft standard protocol that provides communications privacy over the Internet. The protocol allows client/server applications to communicate in a way that is designed to prevent eavesdropping, tampering, and message forgery.

VPN client Software that resides on individual users computer that establishes a VPN tunnel to a VPN server.

VPN server A device (IPSec security gateway) that resides at a central location and terminates a VPN tunnel. Communicates with VPN clients and other VPN servers. Can be hardware or software based.

VPN (Virtual Private Network) A network that provides the ability to transmit data that ensures confidentiality, authentication, and data integrity.

41

HOW TO PERFORM A SECURITY REVIEW OF A CHECKPOINT FIREWALL

Ben Rothke, CISSP

Altered States was not just a science fiction movie about a research scientist who experimented with altered states of human consciousness; it is also a metaphor for many firewalls in corporate enterprises.

In general, when a firewall is initially installed, it is tightly coupled to an organization's security requirements. After use in a corporate environment, the firewall rule base, configuration, and underlying operating system often gets transformed into a radically different arrangement. This altered firewall state is what necessitates a firewall review.

A firewall is only effective to the degree that it is properly configured. And in today's corporate environments, it is easy for a firewall to become misconfigured. By reviewing the firewall setup, management can ensure that its firewall is enforcing what it expects, and in a secure manner.

This chapter focuses on performing a firewall review for a Checkpoint Firewall-1.[1] Most of the information is sufficiently generic to be germane to any firewall, including Cisco PIX, NAI Gauntlet, Axent Raptor, etc. One caveat: it is important to note that a firewall review is not a penetration test. The function of a firewall review is not to find exploits and gain access into the firewall; rather, it is to identify risks that are inadvertently opened by the firewall.

Finally, it must be understood that a firewall review is also not a certification or guarantee that the firewall operating system or underlying network operating system is completely secure.

The Need for a Firewall Review

Firewalls, like people, need to be reviewed. In the workplace, this is called a performance review. In the medical arena, it is called a physical. The need for periodic firewall reviews is crucial, as a misconfigured firewall is often worse than no firewall. When organizations lack a firewall, they understand the risks involved and are cognizant of the fact that they lack a fundamental security mechanism. However, a misconfigured firewall gives an organization a false sense of security.

In addition, because the firewall is often the primary information security mechanism deployed, any mistake or misconfiguration on the firewall trickles into the entire enterprise. If a firewall is never reviewed, any of these mistakes will be left unchecked.

Review, Audit, Assessment

Firewall reviews are often called audits. An audit is defined as "a methodical examination and review." As well, the terms "review," "assessment," and "audit" are often synonymous. It is interesting to note that when security groups from the Big Five[2] accounting firms perform a security review, they are specifically prohibited from using the term "audit." This is due to the fact that the American Institute of Certified Public Accounts (www.aicpa.org), which oversees the Big Five, prohibits the use of the term "audit" because there is no set of official information security standards in which to audit the designated environment.

On the other hand, financial audits are performed against the Generally Accepted Accounting Principles (GAAP). While not a fixed set of rules, GAAP is a widely accepted set of conventions, standards, and procedures for reporting financial information. The Financial Accounting Standards Board (www.fasb.org) established GAAP in 1973. The mission of the Financial Accounting Standards Board is to establish and improve standards of financial accounting and reporting for the guidance and education of the public, including issuers, auditors, and users of financial information.

As of January 2001, the Generally Accepted System Security Principles (GASSP) Committee was in the early stages of drafting a business plan that reflects their plans for establishing and funding the International Information Security Foundation (IISF).[3] While there is currently no set of geerally accepted security principles (in which a firewall could truly be *audited* against), work is underway to create such a standard. Working groups for the GASSP are in place. Work is currently being done to research and complete the Authoritative Foundation and develop and approve the framework for GASSP. The committee has developed a detailed plan for completing the GASSP Detailed Principles and plans to implement that plan upon securing IISF funding.

The lack of a GASSP means that there is no authoritative reference on which to maintain a protected infrastructure. If there were a GAASP, there would be a way to enforce a level of compliance and provide a vehicle for the authoritative approval of reasonably founded exceptions or departures from GASSP.

Similar in theory to GASSP is the Common Criteria Project (http://csrc. nist.gov/cc). The Common Criteria is an international effort that is being developed as a way to evaluate the security properties of information technology (IT) products and systems. By establishing such a common criteria base, the results of an IT security evaluation will be meaningful to a wider audience.

The Common Criteria will permit comparability between the results of independent security evaluations. It facilitates this by providing a common set of requirements for the security functions of IT products and systems and for assurance measures applied to them during a security evaluation. The evaluation process establishes a level of confidence that the security functions of such products and systems, and the assurance measures applied to them, meet these requirements. The evaluation results help determine whether the information technology product or system is secure enough for its intended application and whether the security risks implicit in its use are tolerable.

Steps in Reviewing a Firewall

A comprehensive review of the firewall architecture, security plans, and processes should include:

- Procedures governing infrastructure access for employees and business partners accessing the infrastructure
- Physical and logical architecture of the infrastructure
- Hardware and software versions of the infrastructure and underlying network operating systems
- Infrastructure controls over access control information
- Review of log event selection and notification criteria
- All access paths, including those provided for maintenance and administration

- Security policies and administrative procedures (i.e., addition or deletion of users and services, review of device and system audit logs, system backup and retention of media, etc.)
- Access controls over the network operating system, including user accounts, file system permissions, attributes of executable files, privileged programs, and network software
- Emergency Response Plans for the infrastructure in the event of an intrusion, denia-of-service attack, etc.
- Access to and utilization of published security alert bulletins

There are many methodologies with which to perform a firewall review. Most center around the following six steps:

1. Analyze the infrastructure and architecture.
2. Review corporate firewall policy.
3. Run hosts and network assessment scans.
4. Review Firewall-1 configuration.
5. Review Firewall-1 Rule Base.
6. Put it all together in a report.

The following discussion expands on each step.

Step 1: Analyze the Infrastructure and Architecture

An understanding of the network infrastructure is necessary to ensure that the firewall is adequately protecting the network. Items to review include:

- Internet access requirements
- Understanding the business justifications for Internet/extranet access
- Validating inbound and outbound services that are allowed
- Reviewing firewall design (i.e., dual-homed, multi-homed, proxy)
- Analyzing connectivity to internal/external networks:
  - Perimeter network and external connections
  - Electronic commerce gateways
  - Inter- or intra-company LAN-WAN connectivity
  - Overall corporate security architecture
  - The entire computing installation at a given site or location
- Interviewing network and firewall administrators

If there is a fault in the information security architecture that does not reflect what is corporate policy, then the firewall can in no way substitute for that deficiency.

From a firewall perspective, to achieve a scalable and distributable firewall system, Checkpoint has divided the functionality of its Firewall-1 product into two components: a Firewall Module and a Management Module. The interaction of these components makes up the whole of the standard Checkpoint Firewall architecture.

The management module is a centralized controller for the other firewall modules and is where the objects and rules that define firewall functionality exist. The rules and objects can be applied to one or all of the firewall modules. All logs and alerts generated by other firewall modules are sent to this management system for storage, querying, and review.

The firewall module itself is the actual gateway system in which all traffic between separate zones must pass. The firewall module is the system that inspects packets, applies the rules, and generates logs and alerts. It relies on one or more management modules for its rule base and log storage, but may continue to function independently with its current rule base if the management module is not functioning.

An excellent reference to use in the design of firewall architectures is *Building Internet Firewalls* by Elizabeth Zwicky (O'Reilly & Assoc. ISBN: 1565928717).[4]

Step 2: Review Corporate Information System Security Polices

Policy is a critical element of the effective and successful operation of a firewall. A firewall cannot be effective unless deployed in the context of working policies that govern use and administration.

Marcus Ranum defines a firewall as "the implementation of your Internet security policy. If you haven't got a security policy, you haven't got a firewall. Instead, you've got a thing that's sort of doing something, but you don't know what it's trying to do because no one has told you what it should do." Given that, if an organization expects to have a meaningful firewall review in the absence of a set of firewall policies, the organization is in for a rude awakening.

Some policy-based questions to ask during the firewall review include:

- Is there a published firewall policy for the organization?
- Has top management reviewed and approved policies that are relevant to the firewall infrastructure?
- Who has responsibility for controlling the organization's information security?
- Are there procedures to change the firewall policies? If so, what is the process?
- How are these policies communicated throughout the organization?

As to the management of the firewall, some of the issues that must be addressed include:

- Who owns the firewalls, and is this defined?
- Who is responsible for implementing the stated policies for each of the firewalls?
- Who is responsible for the day-to-day management of the firewall?
- Who monitors the firewall for compliance with stated policies?
- How are security-related incidents reported to the appropriate information security staff?
- Are CERT, CIAC, vendor-specific, and similar advisories for the existence of new vulnerabilities monitored?
- Are there written procedures that specify how to react to different events, including containment and reporting procedures?

Change control is critically important for a firewall. Some change controls issues are:

- Ensure that change control procedures documents exist.
- Ensure that test plans are reviewed.
- Review procedures for updating fixes.
- Review the management approval process.
- Process should ensure that changes to the following components are documented:
  - — Any upgrades or patches require notification and scheduling of downtime
  - — Electronic copies of all changes
  - — Hard-copy form filled out for any changes

Finally, backup and contingency planning is crucial when disasters occur. Some issues are:

- *Maintain a golden copy of Firewall-1.* A golden copy is full backup made before the host is connected to the network. This copy can be used for recovery and also as a reference in case the firewall is somehow compromised.
- *Review backup procedures and documentation.* Part of the backup procedures must also include restoration procedures. A backup should only be considered complete if one is able to recover from the backups made. Also, the backups must be stored in a secure location.[5] Should the firewall need to be rebuilt or replaced, there are several files that will need to be restored (see Exhibit 41.1). These files can be backed up via a complete system backup, utilizing an external device such as a

tape drive or other large storage device. The most critical files for firewall functionality should be able to fit on a floppy disk.

- *Review backup schedule.*
- *Determine if procedures are in place to recover the firewall system should a disruption of service occur.*
- *Review contingency plan.*
- *Contingency plan documentation.*

Information Security Policies and Procedures (Thomas Peltier, Auerbach Publications) is a good place to start a policy roll-out. While not a panacea for the lack of a comprehensive set of policies, *Information Security Policies and Procedures* enables an organization to quickly roll-out policies without getting bogged down in its composition.

It must be noted that all of this analysis and investigation should be done in the context of the business goals of the organization. While information systems security is about risk management, if it is not implemented within the framework of the corporate strategy, security is bound to fail.

Step 3: Perform Hosts Software Assessment Scan

A firewall misconfiguration can allow unauthorized parties, outsiders, to break into the network despite the firewall's presence. By performing software scans against the individual firewall hosts, specific vulnerabilities can be detected. These scanning tools can identify security holes, detail system weaknesses, validate policies, and enforce corporate security strategies. Such tools are essential for checking system vulnerabilities.

Some of the myriad checks that scanners can identify include:

- Operating system misconfiguration
- Inappropriate security and password settings
- Buffer overflow
- Detection of SANS Top 10 Internet Security Threats

- Segmentation fault affecting FreeBSD
- Detection of unpassworded NT guest and administrator accounts

Some popular scanning tools[6] include:

- NAI Cybercop, http://www.pgp.com/products/cybercop-scanner
- ISS Internet Scanner, http://www.iss.net/internet_scanner/index.php
- SAINT, http://www.wwdsi.com/saint
- Symantec (formerly Axent) NetRecon, http://enterprisesecurity.symantec.
- com/products
- Netcat, http://www.l0pht.com/~weld/netcat/
- nmap, http://www.insecure.org/nmap/index.html

It must be noted that running a host software assessment scan on a firewall is just one aspect of a firewall review. Tools such as Cybercop are extremely easy to run; as such, there is no need to bring in a professional services firm to run the tools. The value added by security professional service firms is in the areas of comprehensive architecture design, analysis, and fault amelioration. Any firm that would run these tools and simply hand the client the output is doing the client a serious injustice.

This only serves to reiterate the point that a security infrastructure must be architected from the onset. This architecture must take into consideration items such as security, capacity, redundancy, and management. Without a good architecture, system redesign will be a constant endeavor.

Step 4: Review Firewall-1 Configuration

While Firewall-1 affords significant security, that security can be compromised if Firewall-1 is misconfigured. Some of the more crucial items to review are listed below (not in any specific order).

IP Forwarding.

Set to *Control IP Forwarding*. IP Forwarding should be disabled in the operating system kernel. This ensures that IP Forwarding will be never be enabled unless Firewall-1 is operating.

Firewall Administrators.

Ensure that the number of Firewall-1 administrators is limited only to those who truly need it. The purpose of every account on the firewall (both for the operating system and the firewall operating system) must be justified. Exhibit 41.2 provides a list of firewall administrators and their permissions.

Trained Staff.

A firewall cannot be effective unless the staff managing the firewall infrastructure is experienced with security and trained in Firewall-1 operations. If a person is made responsible for a firewall simply because he or she has experience with networking, the firewall should be expected to be filled with misconfigurations, which in turn will make it much easier for adversaries to compromise the firewall.

SYN Flood Protection.

Denial-of-service (DoS) attacks enable an attacker to consume resources on a remote host to the degree it cannot function properly. SYN flood attacks are one of the most common types of DoS attacks.

Ensure that SYN flood protection is activated at the appropriate level: None, SYN Gateway, or Passive SYN Gateway (see Exhibit 41.3).

Operating System Version Control.

For both the Checkpoint software and network operating system, ensure that the firewall is running a current and supported version of Firewall-1. While the latest version does not specifically have to be loaded, ensure that current patches are installed.

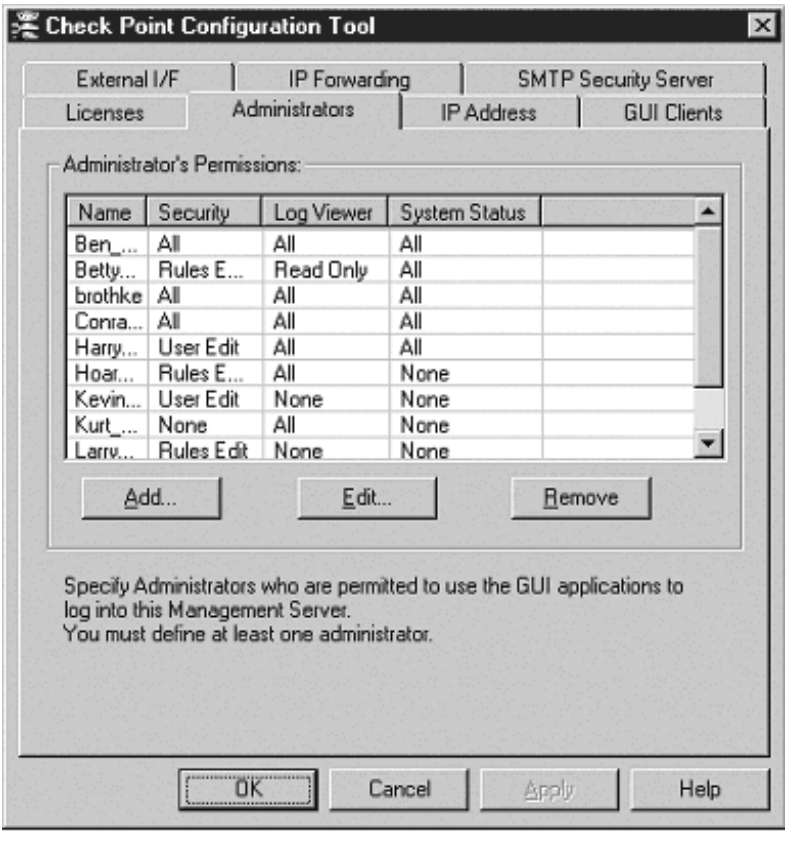

EXHIBIT 41.2 Firewall administrators and their permissions.

Physical Security.

The firewall must be physically secured. It should be noted that all network operating systems base their security models on a secure physical infrastructure. A firewall must be located in areas where access is restricted only to authorized personnel; specifically:

- The local console must be secure.
- The management console should not be open to the external network.
- The firewall configuration should be fully protected and tamper-proof (except from an authorized management station).
- Full authentication should be required for the administrator for local administration.
- Full authentication and an encrypted link are required for remote administration.

Remove Unneeded System Components.

Software such as compilers, debuggers, security tools, etc. should be removed from the firewall.

Adequate Backup Power Supplies.

If the firewall lacks a UPS, security will not be completely enforced in the event of a power disruption.

Log Review.

The logs of both the firewall and network operating system need to be reviewed and analyzed. All events can be traced to the logs, which can be used for debugging and forensic analysis.

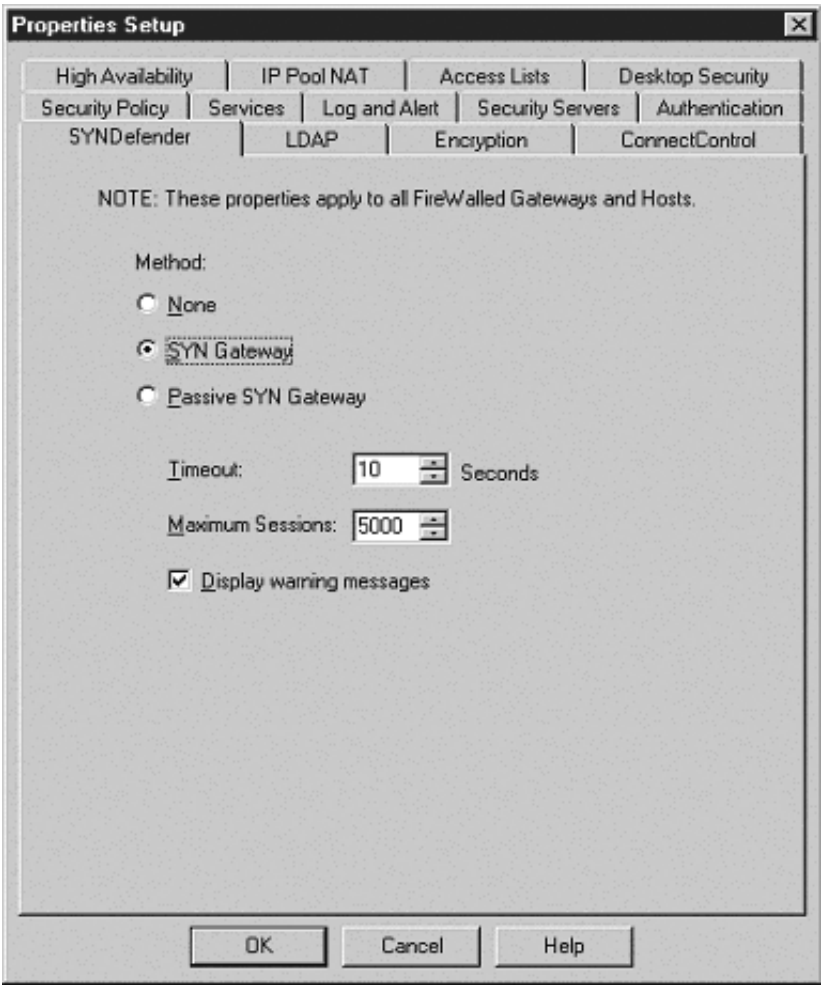

EXHIBIT 41.3 Setting the SYN flood protection.

Ideally, logs should be written to a remote log host or separate disk partition. In the event of an attack, logs can provide critical documentation for tracking several aspects of the incident. This information can be used to uncover exploited holes, discover the extent of the attack, provide documented proof of an attack, and even trace the attack's origin. The first thing an attacker will do is cover his or her tracks by modifying or destroying the log files. In the event that these log files are destroyed, backups will be required to track the incident. Thus, frequent backups are mandatory.

Time Synchronization.

Time synchronization serves two purposes: to ensure that time-sensitive events are executed at the correct time and that different log files can be correlated. Logs that reference an incorrect time can potentially be excluded as evidence in court and this might thwart any effort to prosecute an attacker.

The Network Time Protocol (NTP) RFC 1305 is commonly used to synchronize hosts. For environments requiring a higher grade and auditable method of time synchronization, the time synchronization offerings from Certified Time (www.certifiedtime.com) should be investigated.

Integrity Checking.

Integrity checking is a method to notify a system administrator when something on the file system has changed to a critical file. The most widely known and deployed integrity checking application is Tripwire (www.tripwire.com).

Limit the Amount of Services and Protocols.

A firewall should have nothing installed or running that is not absolutely required by the firewall. Unnecessary protocols open needless communication links. A port scan can be used to see what services are open. Too many services can hinder the efficacy of the firewall, but each service should be authorized; if not, it should be disabled.

Dangerous components and services include:

- X or GUI related packages
- NIS/NFS/RPC related software
- Compilers, Perl, TCL
- Web server, administration software
- Desktop applications software (i.e., Microsoft Office, Lotus Notes, browsers, etc.)

On an NT firewall, only the following services and protocols should be enabled:

- TCP/IP
- Firewall-1
- Protected Storage
- UPS
- RPC
- Scheduler
- Event log
- Plug-and-Play
- NTLM Security Support provider

If other functionality is needed, add them only on an as-needed basis.

Harden the Operating System.

Any weakness or misconfiguration in the underlying network operating system will trickle down to Firewall-1. The firewall must be protected as a bastion host to be the security stronghold. A firewall should never be treated as a general-purpose computing device.

The following are excellent documents on how to harden an operating system:

- *Armoring Solaris*, www.enteract.com/~lspitz/armoring.html
- *Armoring Linux*, www.enteract.com/~lspitz/linux.html
- *Armoring NT*, www.enteract.com/~lspitz/nt.html

Those needing a pre-hardened device should consider the Nokia firewall appliance (www.nokia.com/securitysolutions/network/firewall.html). The Nokia firewall is a hardware solution bundled with Firewall-1. It runs on the IPSO operating system that has been hardened and optimized for firewall functionality.

Firewall-1 Properties.

Exhibit 41.4 shows the Security Policies tab. One should uncheck the Accept boxes that are not necessary:

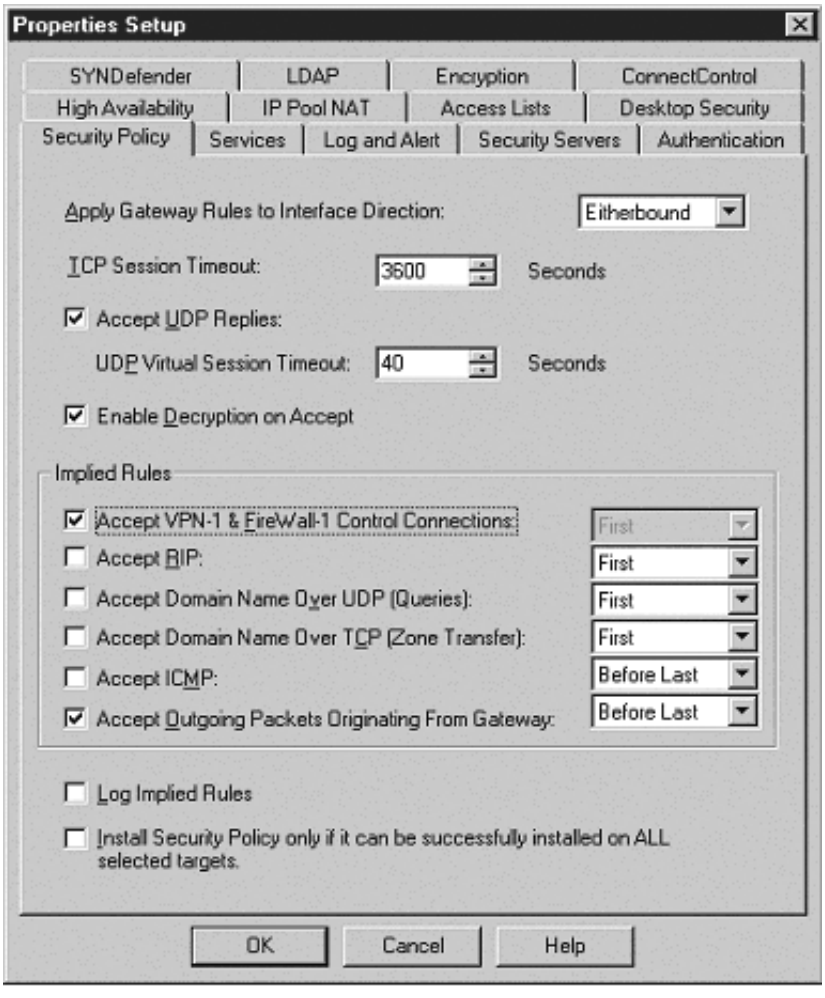

EXHIBIT 41.4 The Security Policy tab.

- *ICMP.* In general, one can disable this property, although one will need to leave it enabled to take advantage of Checkpoint's Stateful Inspection for ICMP in 4.0.
- *Zone transfer.* Most sites do not allow users to perform DNS downloads. The same is true for RIP and DNS lookup options.

Firewall-1 Network Objects.

A central aspect of a Firewall-1 review includes the analysis of all of the defined network objects. Firewall-1 network objects are logical entities that are grouped together as part of the security policy. For example, a group of Web servers could be a simple network object to which a rule is applied. Every network object has a set of attributes, such as network address, subnet mask, etc. Examples of entities that can be part of a network object include:

- Networks and sub-networks
- Servers
- Routers
- Switches
- Hosts and gateway

- Internet domains
- Groups of the above

Firewall-1 allows for the creation of network objects within the source and destination fields. These network objects can contain and referenceanywhere from a single device to entire networks containing thousands of devices. The latter creates a significant obstacle when attempting to evaluate the security configuration and security level of a Firewall-1 firewall. The critical issue is how to determine the underlying security of the network object when it contains numerous objects.

This object-oriented approach to managing devices on Firewall-1 allows the firewall administrator to define routers or any other device as network objects, and then to use those objects within the rules of the firewall security policy. The main uses of network objects are for efficiency in referencing a large amount of network devices. This obviates the need to remember such things as the host name, IP address, location, etc. While network objects provide a significant level of ease of use and time-saving by utilizing such objects, an organization needs to determine if it inherently trusts all of the devices contained within the object. Exhibit 41.5 shows the Network Objects box that shows some of the existing objects. Exhibit 41.6 shows an example of a Network Object with a number of workstations in the group.

As stated, such use of network objects is time-saving from an administrative perspective; but from a security perspective, there is a problem in that any built-in trust that is associated with the network object is automatically created for every entity within that network object. This is due to the fact that in large networks, it is time-consuming to inspect every individual entity defined in the network object. The difficulty posed by such a configuration means that in order to inspect with precision and accuracy the protection that the firewall rule offers, it is essential to inspect every device within the network object.

Step 5: Review Firewall-1 Rule Base

The purpose of a rule base review is to actually see what services and data the firewall permits. An analysis of the rule base is also meant to identify any unneeded, repetitive, or unauthorized rules. The rule base should be made as simple as possible. One way to reduce the number of rules is by combining rules, because sometimes repetitive rules can be merged.

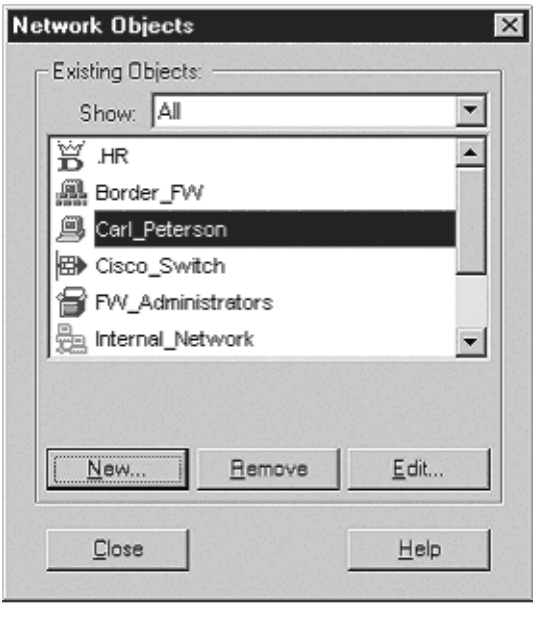

EXHIBIT 41.5 Existing objects.

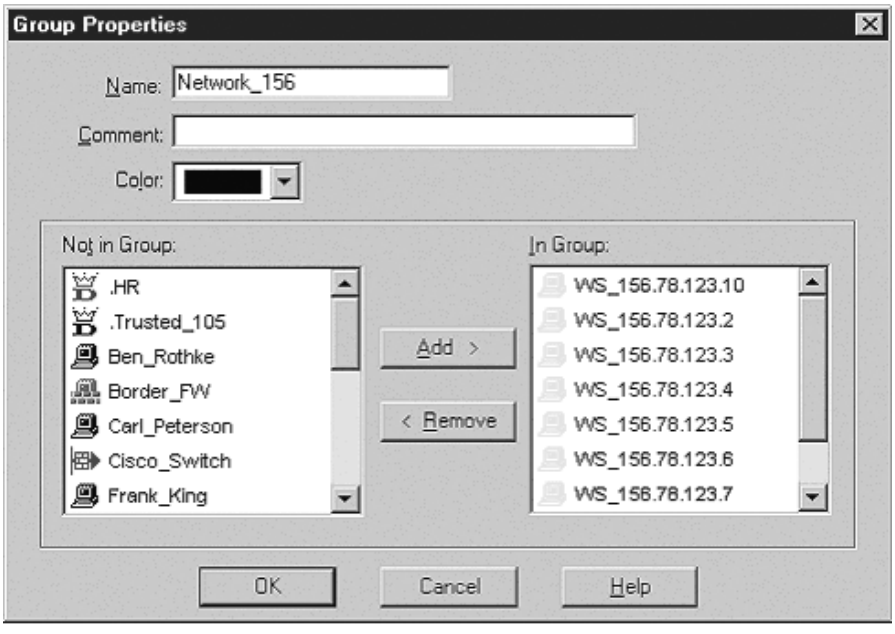

EXHIBIT 41.6 A network object with a number of workstations in the group.

The function of a rule base review is to ensure that the firewall is enforcing what it is expected to. Lance Spitzner writes in *Building Your Firewall Rule Base*[7] that "building a solid rule base is a critical, if not the most critical, step in implementing a successful and secure firewall. Security administrators and experts all often argue what platforms and applications make the best firewalls. However, all of this is meaningless if the firewall rule base is misconfigured."

The rule base is the heart and soul of a Checkpoint firewall. A rule base is a file stored on the firewall that contains an ordered set of rules that defines a distinct security policy for each particular firewall. Access to the rule base file is restricted to those that are either physically at the firewall or a member of the GUI client list specified in the configuration settings.

A rule describes a communication in terms of its source, destination, and service. The rule also specifies whether the communication should be accepted or rejected and whether a log entry is created.

The Firewall-1 inspection engine is a "first-fit" as opposed to a "best-fit" device. This means that if one has a rule base containing 20 rules, and the incoming packet matches rule #4, the inspection engine stops immediately (because rules are examined sequentially for each packet) and does not go through the remainder of the rule base.

As for the rule base review, security expert Lance Spitzer recommends that the goal is to have no more than 30 rules. Once there are more then 30 rules, things exponentially grow in complexity and mistakes then happen.

Each rule base has a separate name. It is useful to standardize on a common naming convention. A suggested format is: firewall-name_administrators-initials_date-of-change; for example, fw1_am_071298.

The result of this naming convention is that the firewall administrator knows exactly which firewall the rule base belongs to; when the rule base was last changed; and who last modified the current configuration. For the rule base review, each and every rule must be examined.

An example of a simple rule base with six rules is as shown in Exhibit 41.7:

- **Rules 1 and 2** enforce the concept of the stealth rule, in that nothing should be able to connect directly to the firewall, other than administrators that are GUI authorized. Rule 1 tells Firewall-1 to drop any packet unless it is from a member of the FW_Administrators group. The Firewall-1 service is predefined and defines all the Firewall-1 administrative ports. For the stealth rule, one

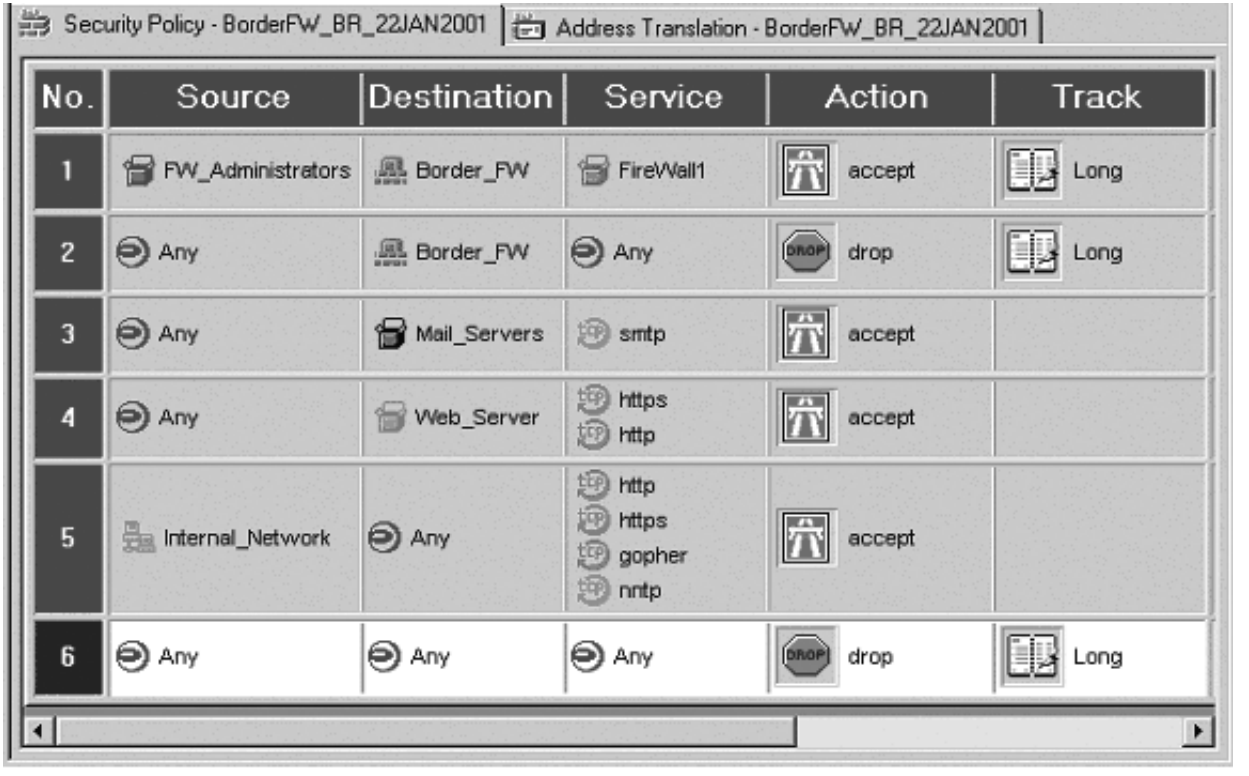

EXHIBIT 41.7 A simple rule base.

specifically wants to drop the packet, as opposed to rejecting it. A rejected packet tells the sender that there is something on the remote side, while a dropped packet does not necessarily indicate a remote host. In addition, this rule is logged; thus, detailed information can be gleaned about who is attempting to make direct connections to the firewall.

- **Rule 3** allows any host e-mail connectivity to the internal mail servers.
- **Rule 4** allows any host HTTP and HTTPS connectivity to internal Web servers.
- **Rule 5** allows internal host connectivity to the Internet for the four specified protocols.
- **Rule 6** is the cleanup rule. Any packet not handled by the firewall at this point will be dropped and logged. The truth is that any packet not handled by the firewall at that point would be dropped anyway. The advantage to this cleanup rule is that these packets will be logged. In this way, one can see which packets are not being handled by the firewall. This can be of assistance in designing a more scalable firewall architecture.

The above rule base example had only six rules and was rather simple. Most corporate rule bases are more detailed and complex. Going through a rule base containing 50 rules and thousands of network objects could take a while to complete.

Exhibit 41.8 displays a rule base that is a little more involved:

- **Rule 1** enforces the stealth rule.
- **Rules 2–4** allow mail traffic between the mail servers and clients.
- **Rule 5** allows any host HTTP connectivity to internal Web servers.
- **Rule 6** stops traffic between the DMZ and an intranet.
- **Rules 7–8** stop incoming and outgoing traffic between the DMZ and an intranet.
- **Rule 9** drop protocols that cause a lot of traffic — in this case, nbdatagram, nbname, and nbsession.
- **Rule 10** is the cleanup rule.

When performing a review and there is doubt that a specific rule is needed, it can be disabled. As a general rule, if a rule is disabled and no one complains, then the rule can be deleted. Exhibit 41.9 shows an example of a disabled rule.

Implied Pseudo-Rules

Implied pseudo-rules are rules that do not appear in the normal rule base, but are automatically created by Firewall-1 based on settings in the Properties Setup of the Security Policy.[8] These rules can be viewed along with the rule base in the Security Policy GUI application. Exhibit 41.10 displays an example of the implied pseudo-rules from a rule base with a single rule.

Although the single and only rule implicitly drops all traffic, there is a lot of traffic that can still pass through the firewall. As seen from these implied pseudo-rules, most of the connectivity deals with the internal operations of the firewall.

Step 6: Put It All Together in a Report

After all the work has been completed, the firewall review needs to be documented. The value in a post-review report is that it can be used as a resource to correct the anomalies found.

As previously stated, the ease of use afforded by scanning tools makes the creation of a huge report effortless. But for a firewall review to have value for a client, it should contain the following:

- Current security state: detail the baseline of the current networking environment and current security posture; this must reference the corporate risk assessment to ensure synchronization with the overall security goals of the organization
- Identification of all security vulnerabilities

Security Policy - DMZ2_BR_12JAN2001 | Address Translation - DMZ2_BR_12JAN2001

No.	Source	Destination	Service	Action	Track
1	Any	Main_FW	Any	drop	Alert

3	Any	Mail_Server	smtp	accept	Long
4	Mail_Server	Any	smtp	accept	Long
5	Any	Web_Servers	http	accept	Long
6	DMZ_Net	Intranet_NY	Any	reject	Alert
7	Intranet_NY	DMZ_Net	Any	reject	Alert
8	Intranet_NY	Any	Permitted_Internet_Services	accept	Long
9	Any	Any	Chatty_Protocols	drop	
10	Any	Any	Any	drop	Alert

EXHIBIT 41.8 Complex rule base.

EXHIBIT 41.9 Disabled rule.

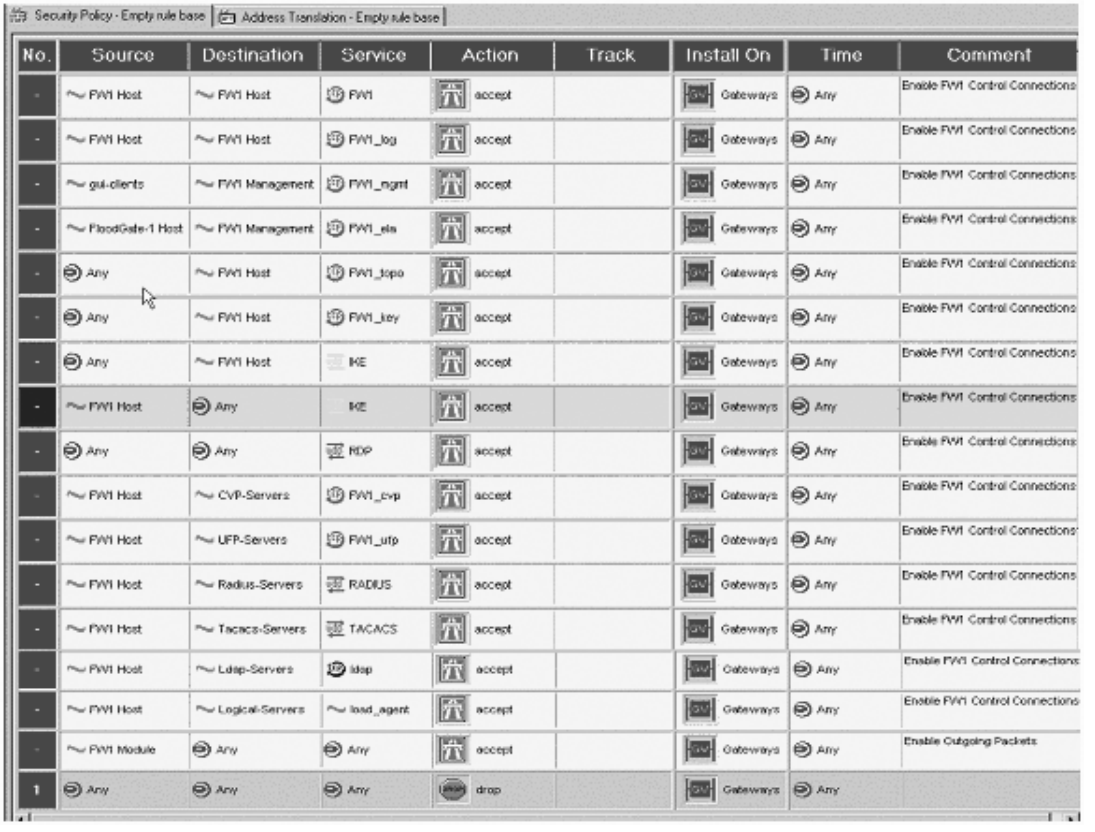

EXHIBIT 41.10 Implied pseudo-rules.

- Recommend corrections, solutions, and implementation priorities; a detailed implementation plan must be provided, showing how all of the solutions and fixes will coalesce
- Detailed analysis of security trade-offs, relating the risks to cost, ease of use, business requirements, and acceptable levels of risk
- Provide baseline data for future reference and comparison to ensure that systems are rolled out in a secure manner

Conclusion

A firewall is effective to the degree that it is properly implemented. And in today's corporate environments, it is easy for a firewall to become misconfigured. By reviewing the firewall setup, firewall administrators can ensure that their firewall is enforcing what they expect it to, in a secure manner. This makes for good sense and good security.

Notes

1. Screen shots in this chapter are from Firewall-1 v4.1 for Windows NT, but are germane for all platforms and versions. See www.phoneboy.com/fw1/docs/4.0-summary.html for the new features and up-grades in Firewall-1 version 4.x.

Comparing Firewall Technologies

Per Thorsheim

In early January 2001, a new Web page was launched. It was named Netscan,[1] and the creators had done quite a bit of work prior to launching their Web site. Actually, the work was quite simple, but time-consuming. They had pinged the entire routed IPv4 address space; or to be more exact, they pinged every IP address ending with .0 or .255. For each PING sent, they expected one PING REPLY in return. And for each network that replied with more than one packet, they counted the number of replies and put the data into a database. All networks that did reply with more than one packet for each packet sent were considered to be an amplifier network. After pinging the entire Internet (more or less), they published on their Web site a list of the 1024 worst networks, including the e-mail address for the person responsible for the IP address and its associated network. The worst networks were those networks that gave them the highest number of replies to a single PING, or the best amplification effect.

The security problem here is that it is rather easy to send a PING request to a network, using a spoofed source IP address. And when the recipient network replies, all those replies will be sent to the source address as given in the initial PING. As shown in Exhibit 42.1, the attacker can flood the Internet connection of the final recipient by repeating this procedure continuously.

In fact, the attacker can use an ISDN connection to create enough traffic to jam a T3 (45-Mbit) connection, using several SMURF amplifier networks to launch the attack. And as long as there are networks that allow such amplification, a network can be the target of the attack even if the network does not have the amplification problem itself, and there is not much security systems such as firewalls can do to prevent the attack.

This type of attack has been used over and over again to attack some of the biggest sites on the Internet, including the February 2000 attacks against Yahoo, CNN, Ebay, and Amazon.

Today, there are several Web sites that search for SMURF amplifier networks and publish their results publicly. In a presentation given in March 2001, this author pointed out the fact that the number of networks not protected from being used as such amplifiers had increased more than 1000 percent since January 2001.

One of the interesting findings from these attacks was that routers got blamed for the problems — not firewalls. And they were correct; badly configured Internet routers were a major part of the problem in these cases. Even worse is the fact that the only requirement for blocking this specific PING-based attack was to set one parameter in all routers connecting networks to the Internet. This has now become the recommended default in RFC 2644/BCP 34, "Changing the Default for Directed Broadcast in Routers." Security professionals should also read RFC 2827/BCP 0038, "Network Ingress Filtering: Defeating Denial-of-Service Attacks Which Employ IP Source Address Spoofing," to further understand spoofing attacks.

Another interesting observation after these attacks was President Clinton's announcement of a National Plan for Information Systems Protection, with valuable help from some of the top security experts in the United States. In this author's opinion, this serves as the perfect example of who should be at the top and responsible for security — the board of directors and the CEO of a company.

Finally, Web sites such as CNN, Yahoo, and Amazon all had firewalls in place, yet that did not prevent these attacks. Thus, a discussion of firewall technologies and what kind of security they can actually provide is in order.

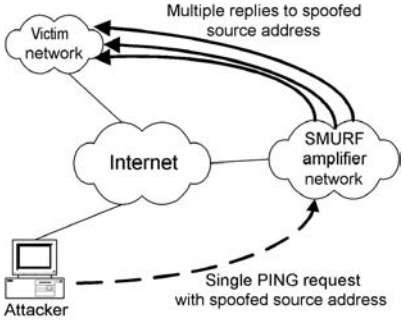

EXHIBIT 42.1 Attacker using spoofed PING packets to flood a network by using a vulnerable intermediary network.

Firewall Technologies Explained

The Internet Firewalls FAQ[2] defines two basic types of firewalls: network-layer firewalls and application-layer firewalls (also referred to as application proxy firewalls, or just proxies). For this chapter, stateful inspection firewalls are defined as a mix of the first two firewall types, in order to make it easier to understand the similarities and differences between them.

The reader may already be familiar with the OSI layer model, in which the network layer is layer 3 and the application layer is at layer 7, as shown in Exhibit 42.2.

A firewall can simply be illustrated as a router that transmits packets back and forth between two or more networks, with some kind of security filtering applied on top.

Network-Level Firewalls: Packet Filters

Packet filter firewalls are very often just a router with access lists. In its most basic form, a packet filter firewall controls traffic based on the source and destination IP address of each IP packet and the destination port. Many packet filter firewalls also allow checking the packets based on the incoming interface (is it coming from the Internet, or the internal network?). They may also allow control of the IP packet based on the source port, day and time, protocol type (TCP, UDP, or ICMP), and other IP options as well, depending on the product.

The first thing to remember about packet filter firewalls is that they inspect every IP packet by itself; they do not see IP packets as part of a session. The second thing to remember about packet filter firewalls is that many of them, by default, have a fail-open configuration, meaning that, by default, they will let packets through unless specifically instructed not to. And finally, packet filters only check the HEADER of a packet, and not the DATA part of the packet. This means that techniques such as tunneling a service within another service will easily bypass a packet filter (e.g., running Telnet on port 80 through a firewall where the standard Telnet port 23 is blocked, but HTTP port 80 is open. Because the packet filter only sees source/destination and port number, it will allow it to pass).

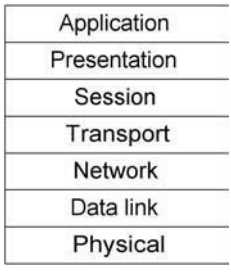

EXHIBIT 42.2 The OSI seven-layer model.

Why Use Packet Filter Firewalls?

Some security managers may not be aware of it, but most probably there are lots of devices already in their network that can do packet filtering. The best examples are various routers. Most (if not all) routers today can be equipped with access lists, controlling IP traffic flowing through the router with various degrees of security. In many networks, it will just be a matter of properly configuring them for the purpose of acting as a packet filter firewall. In fact, the author usually recommends that all routers be equipped with at least a minimum of access lists, in order to maintain security for the router itself and its surroundings at a minimal level. Using packet filtering usually has little or no impact on throughput, which is another plus over the other technologies. Finally, packet filter firewalls support most (if not all) TCP/IP-based services.

Why Not Use Packet Filter Firewalls?

Well, they only work at OSI layer 3, or the network layer as it is usually called. Packet filter firewalls only check single IP packets; they do not care whether or not the packet is part of a session. Furthermore, they do not do any checking of the actual contents of the packet, as long as the basic header information is okay (such as source and destination IP address). It can be frustrating and difficult to create rules for packet filter firewalls, and maintaining consistent rules among many different packet filter firewalls is usually considered very difficult. As previously mentioned, the typical fail-open defaults should be considered dangerous in most cases.

Stateful Inspection Firewalls

Basically, stateful inspection firewalls are the same thing as packet filter firewalls, but with the ability to keep track of the state of connections in addition to the packet filtering abilities. By dynamically keeping track of whether a session is being initiated, currently transmitting data (in either direction), or being closed, the firewall can apply stronger security to the transmission of data. In addition, stateful inspection firewalls have various ways of handling popular services such as HTTP, FTP, and SMTP. These last options (of which there are many variants of from product to product) enable the firewall to actually check whether or not it is HTTP traffic going to TCP port 80 on a host in a network by "analyzing" the traffic. A packet filter will only assume that it is HTTP traffic because it is going to TCP port 80 on a host system; it has no way of actually checking the DATA part of the packet, while stateful inspection can partially do this.

A stateful inspection firewall is capable of understanding the opening, communication, and closing of sessions. Stateful inspection firewalls usually have a fail-close default configuration, meaning that they will not allow a packet to pass if they do not know how to handle the packet. In addition to this, they can also provide an extra level of security by "understanding" the actual contents (the data itself) within packets and sessions, compared to packet filters. This last part only applies to specific services, which may be different from product to product.

Why Use Stateful Inspection Firewalls?

Stateful inspection firewalls give high performance and provide more security features than packet filtering. Such features can provide extra control of common and popular services. Stateful inspection firewalls support most (if not all) services transparently, just like packet filters, and there is no need to modify client configurations or add any extra software for them to work.

Why Not Use Stateful Inspection Firewalls?

Stateful inspection firewalls may not provide the same level of security as application-level firewalls. They let the server and the client talk "directly" to each other, just like packet filters. This may be a security risk if the firewall does not know how to interpret the DATA contents of the packets flowing through the firewall. Even more disturbing is the fact that many people consider stateful inspection firewalls to be easier to configure wrongly, compared to application-level firewalls. This is due to the fact that packet filters and stateful inspection firewalls support most, if not all, services transparently, while application-level firewalls usually support only a very limited number of services and require modification to client software in order to work with non-supported services.

In a white paper from Network Associates,[3] the Computer Security Institute (CSI) was quoted as saying, "It is quite possible, in fact trivial, to configure stateful inspection firewalls to permit dangerous services through the firewall…. Application proxy firewalls, by design, make it far more difficult to make mistakes during configuration."

Of course, it should be unnecessary to say that no system is secure if it is not configured correctly. And human faults and errors are the number one, two, and three reasons for security problems, right?

Application-Level Firewalls

Application-level firewalls (or just proxies) work as a "man-in-the-middle," where the client asks the proxy to perform a task on behalf of the client. This could include tasks such as fetching Web pages, sending mail, retrieving files using FTP, etc. Proxies are application specific, meaning that they need to support the specific application (or, more exactly, the application-level protocol) that will be used. There are also standards for generic proxy functionality, with the most popular being SOCKS. SOCKS was originally authored by David Koblas and further developed by NEC. Applications that support SOCKS will be able to communicate through firewalls that also support the SOCKS standard.[4]

Similar to a stateful inspection firewall, the usual default of an application-level firewall is fail-close, meaning that it will block packets/sessions that it does not understand how to handle.

Why Use Application-Level Firewalls?

First of all, they provide a high level of security, primarily based on the simple fact that they only support a very limited number of services; however, they do support most, if not all, of the usual services that are needed on a day-to-day basis. They understand the protocols at the application layer and, as such, they may block parts of a protocol (allow receiving files using FTP, but denying sending files using FTP as an example). They can also detect and block vulnerabilities, depending on the firewall vendor and version.

Furthermore, there is no direct contact being made between the client and the server; the firewall will handle all requests and responses for the client and the server. With a proxy server, it is also easy to perform user authentication, and many security practitioners will appreciate the extensive level of logging available in application-level firewalls.

For performance reasons, many application-level firewalls can also cache data, providing faster response times and higher throughput for access to commonly accessed Web pages, for example. The author usually does not recommend that a firewall do this because a firewall should handle the inspection of traffic and provide a high level of security. Instead, security practitioners should consider using a stand-alone caching proxy server for increasing performance while accessing common Web sites. Such a stand-alone caching proxy server may, of course, also be equipped with additional content security, thus controlling access to Web sites based on content and other issues.

Why Not Use Application-Level Firewalls?

By design, application-level firewalls only support a limited number of services. If support for other applications/services/protocols is desired, applications may have to be changed in order to work through an application-level firewall. Given the high level of security such a firewall may provide (depending on its configuration, of course), it may have a very negative impact on performance compared to packet filtering and stateful inspection firewalls.

What the Market Wants versus What the Market Really Needs

Many firewalls today seem to mix these technologies together into a simple and easy-to-use product. Firewalls try to be a "turnkey" or "all-in-one" solution. Security in a firewall that can be configured by more or less plugging it in and turning it on is something in which this author has little faith. And, the all-in-one solution that integrates VPN, anti-virus, content security/filtering, traffic shaping, and similar functionality is also something in which this author has little trust. In fact, firewalls seem to get increasingly complex in order to make them easier to configure, use, and understand for the end users. This seems a little bit wrong; by increasing the amount of code in a product, the chances of security vulnerabilities in the product increase, and most probably exponentially.

In the author's opinion, a firewall is a "black box" in a network, which most regular users will not see or notice. Users should not even know that it is there.

The market decides what it wants, and the vendors provide exactly that. But does the market always know what is good for it? This is a problem that security professionals should always give priority to — teaching security understanding and security awareness.

Firewall Technologies: Quick Summary

As a rule of thumb, packet filters provide the lowest level of security, but the highest throughput. They have limited security options and features and can be difficult to administrate, especially if there is a large number of them in a network.

Stateful inspection firewalls provide a higher level of security, but may not give the same throughput as packet filters. The leading firewalls on the market today are stateful inspection firewalls, often considered the best mix of security, manageability, throughput, and transparent integration into most environments.

Application-level firewalls are considered by many to give the highest level of security, but will usually give less throughput compared to the two other firewall technologies.

In any case, security professionals should never trust a firewall by itself to provide good security. And no matter what firewall a company deploys, it will not provide much security if it is not configured correctly. And that usually requires quite a lot of work.

Perimeter Defense and How Firewalls Fit In

Many people seem to believe that all the bad hackers are "out there" on the Internet, while none of their colleagues in a firm would ever even think of doing anything illegal, internally or externally. Sadly, however, there are statistics showing that internal employees carry out maybe 50 percent of all computer-related crime.

This is why it is necessary to explain that security in a firewall and its surrounding environment works two ways. Hackers on the Internet are not allowed access to the internal network, and people (or hostile code such as viruses and Trojans) on the internal network should be prevented from sending sensitive data to the external network. The former is much easier to configure than the latter. As a practical example of this, here is what happened during an Internet penetration test performed by the author some time ago.

Practical Example of Missing Egress (Outbound) Filtering

The client was an industrial client with a rather simple firewall environment connecting them to the Internet. They wanted a high level of security and had used external resources to help configure their Internet router act as a packet filter firewall, in addition to a stateful inspection firewall on the inside of the Internet router, with a connection to the internal network. They had configured their router and firewall to only allow e-mail (SMTP, TCP port 25) back and forth between the Internet and their anti-virus (AV) e-mail gateway placed in a demilitarized zone (DMZ) on the stateful inspection firewall. The anti-virus e-mail gateway would check all in- and outgoing e-mail before sending it to the final recipient, be it on the internal network or on the Internet. The router was incredibly well configured; inbound access lists were extremely strict, only allowing inbound SMTP to TCP port 25. The same thing was the case for the stateful inspection firewall.

While testing the anti-virus e-mail gateway for SMTP vulnerabilities, the author suddenly noticed that each time he connected to the SMTP connector of the anti-virus e-mail gateway, it also sent a Windows NetBIOS request in return, in addition to the SMTP login banner.

This simple fact reveals a lot of information to an unauthorized person (see Exhibit 42.3). First of all, there is an obvious lack of egress (outbound) filtering in both the Internet router and the firewall. This tells us that internal systems (at least this one in the DMZ) can probably do NetBIOS communication over TCP/IP with external systems. This is highly dangerous for many reasons. Second, the anti-virus e-mail gateway in the DMZ is installed with NetBIOS, which may indicate that recommended good practices have not been followed for installing a Windows server in a high-security environment. Third, it may be possible to use this system to access other systems in the DMZ or on other networks (including the internal network) because NetBIOS is being used for communication among windows computers in a workgroup or domain. At least this is the author's usual experience when doing Internet penetration testing. Of course, an unauthorized person must break into the server in the DMZ first, but that also proves to be easier than most people want to believe.

How Can One Prevent Such Information Leakage?

Security managers should check that all firewalls and routers connecting them to external networks have been properly configured to block services that are considered "dangerous," as well as all services that are never supposed to be used against hosts on external networks, especially the Internet.

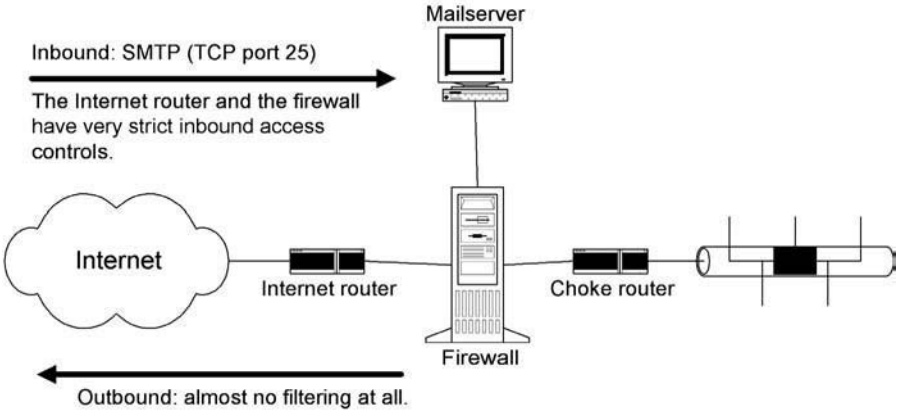

EXHIBIT 42.3 Missing egress filtering in the router and the firewall may disclose useful information to unauthorized people.

As a general rule, security managers should never allow servers and systems that are not being used at the local console to access the Internet in any way whatsoever. This will greatly enhance security, in such a way that hostile code such as viruses and Trojans will not be able to directly establish contact with and turn over control of the system to unauthorized persons on any external network.

This also applies to systems placed in a firewall DMZ, where there are systems that can be accessed by external people, even without any kind of user authentication. The important thing to remember here is: who makes the initial request to connect to a system?

If it is an external system making a connection to a mail server in a DMZ on TCP port 25 (SMTP), it is okay because it is (probably) incoming e-mail. If the mail server in the DMZ makes a connection to an external system on TCP port 25, that is also okay because it does this to send outgoing e-mail. However, if the only purpose of the mail server is to send and receive mail to and from the Internet, the firewalls and even the routers should be configured in accordance with this.

For the sake of easy administration, many people choose to update their servers directly from the Internet; some even have a tendency to sit directly on production servers and surf the World Wide Web without any restrictions or boundaries whatsoever. This poses a high security risk for the server, and also the rest of the surrounding environment, given the fact that (1) Trojans may get into the system, and (2) servers tend to have the same usernames and passwords even if they do not have anything in common except for being in the same physical/logical network.

To quote Anthony C. Zboralski Gaius[5] and his article "Things to Do in Cisco Land when You're Dead" in *Phrack Magazine*[6]:

> It's been a long time since I stopped believing in security. The core of the security problem is really because we are trusting trust (read Ken Thomson's article, Reflections on Trusting Trust). If I did believe in security then I wouldn't be selling penetration tests.

It can never be said that there is a logical link between high security and easy administration, nor will there ever be. Security is difficult, and it will always be difficult.

Common Mistakes that Lead to System and Network Compromises

Many security professionals say that "networks are hard on the outside, and soft on the inside," a phrase this author fully agrees with. The listing that follows shows some of the common weaknesses encountered over and over again.

- Remote access servers (RAS) are connected to the internal network, allowing intruders access to the network just like internal users, as soon as they have a username and password.
- Access lists and other security measures are not implemented in WAN routers and networks. Because small regional offices usually have a lower level of physical security, it may be easier to get access to the office, representing a serious risk to the entire network.

- Many services have default installations, making them vulnerable. They have known weaknesses, such as standard installation paths; default file and directory permissions that give all uses full control of the system, etc.
- Employees do not follow written password policies, and password policies are usually written with users (real people) in mind, and not generic system accounts.
- Many unnecessary services are running on various systems without being used. Many of these services can easily be used for denial-of-service (DoS) attacks against the system and across the network.
- Service applications run with administrator privileges, and their passwords are rarely changed from the default value. As an example, there are backup programs in which the program's username and password are the same as the name of the program, and the account has administrative privileges by default. Take a look at some of the default usernames/passwords lists that exist on the Internet; they list hundreds of default usernames and passwords for many, many different systems.[7]
- Companies have trust in authentication mechanisms and use them as their only defense against unauthorized people trying to get access to the various systems in the network. Many companies and people do not seem to understand that hackers do not need a username or password to get access to different systems; there are many vulnerabilities that give them full control within seconds.

Most, if not all, security professionals will recognize many of these as problems that will never go away. At the same time, it is very important to understand these problems, and professionals should work continuously to reduce or remove these problems.

When performing penetration testing, common questions and comments include: "How are you going to break into our firewall?" and "You are not allowed to do this and this and that." First of all, penetration testing does not involve breaking into firewalls, just trying to bypass them. Breaking into a firewall by itself may show good technical skills, but it does not really do much harm to the company that owns it. Second, hackers do not have to follow any rules, either given by the company they attack or the laws of the country. (Or the laws of the many countries they are passing through in order to do the attack over the Internet, which opens up lots more problems for tracking down and punishing the hackers, a problem that many security professionals are trying to deal with already.)

What about Security at the Management Workstations?

Many companies are deploying extremely tight security into their Internet connection environment and their internal servers. What many of them do wrong is that they forget to secure the workstations that are being used to administrate those highly secured systems. During a recent security audit of an Internet bank, the author was given an impressive presentation with firewalls, intrusion detection systems, proxies, and lots of other stuff thrown in. When checking a bit deeper, it was discovered that all the high-security systems were managed from specific workstations located on their internal network. All those workstations ("owned" by network administrators) were running various operating systems (network administrators tend to do this…) with more or less default configurations, including default usernames and passwords, SNMP,[8] and various services. All those workstations were in a network mixed with normal users; there were no access restrictions deployed except username/password to get access to those management stations. They even used a naming convention for their internal computers that immediately revealed which ones were being used for "critical system administration." By breaking into those workstations first (Trojans, physical access, other methods), it did not take long to get access to the critical systems.

Intrusion Detection Systems and Firewalls

Lately, more and more companies have been deploying intrusion detection systems (IDSs) in their networks. Here is another area in which it is easy to make mistakes. First of all, an IDS does not really help a company improve its security against hackers. An IDS will help a company to better detect and document an attack, but in most cases it will not be able to stop the attack. It is tempting to say that an IDS is just a new term for extensive logging and automated/manual analysis, which have been around for quite some time now.

Some time ago, someone came up with the bright idea of creating an IDS that could automatically block various attacks, or reconfigure other systems like firewalls to block the attacks. By doing a spoofing attack (very easy these days), hackers could create a false attack that originated from a trusted source (third party), making the IDS block all communications between the company and the trusted source. And suddenly everybody understood that the idea of such automated systems was probably a bad idea.

Some IDSs are signature based, while others are anomaly based. Some IDSs have both options, and maybe host and network based agents as well. And, of course, there are central consoles for logging and administrating the IDS agents deployed in the network. (How good is the security at those central consoles?)

- *Problem 1.* Signature-based detection more or less depends on specific data patterns to detect an attack. Circumventing this is becoming easier every day as hackers learn how to circumvent the patterns known by the IDS, while still making patterns that work against the target systems.
- *Problem 2.* Most IDSs do not understand how the receiving system reacts to the data sent to it, meaning that the IDSs can see an attack, but it does not know whether or not the attack was successful. So, how should the IDS classify the attack and assess the probability of the attack being successful?
- *Problem 3.* IDSs tend to create incredible amounts of false alerts, so who will check them all to see if they are legitimate or not? Some companies receive so many alerts that they just "tune" the system so that it does not create that many alerts. Sometimes this means that they do not check properly to see if there is something misconfigured in their network, but instead just turn off some of the detection signatures, thus crippling the IDS of its functions.
- *Problem 4.* Anomaly-based detection relies on a pattern of "normal" traffic and then generates alerts based on unusual activity that does not match the "normal" pattern. What is a "normal" pattern? The author has seen IDS deployments in which an IDS was placed into a network that was configured with all sorts of protocols, unnecessary services, and cleartext authentication flying over the wire. The "normal" template became a template for which almost everything was allowed, more or less disabling the anomaly detection capability of the IDS. (This is also very typical for "personal firewalls," which people are installing on their home systems these days.)

An IDS can be a very effective addition to a firewall because it is usually better at logging the contents of the attack compared to a firewall, which only logs information such as source/destination, date/time, and other information from the various IP/TCP/UDP headers. Using an IDS, it is also easier to create statistics over longer periods of time of hacker activity compared to just having a firewall and its logs. Such statistics may also aid in showing management what the reality is when it comes to hacking attempts and illegal access against the company's systems, as well as raising general security awareness among its users.

On the other hand, an IDS requires even more human attention than a firewall, and a company should have very clearly defined goals with such a system before buying and deploying it. Just for keeping hackers out of your network is not a good enough reason.

General Recommendations and Conclusions

A firewall should be configured to protect itself, in addition to the various networks and systems that it moves data to and from. In fact, a firewall should also "protect" the Internet, meaning that it should prevent internal "hackers" from attacking other parties connected to the Internet, wherever and whoever they are. Surrounding network equipment such as routers, switches, and servers should also be configured to protect the firewall environment in addition to the system itself.

Security professionals should consider using user authentication before allowing access to the Internet. This will, in many situations, block viruses and Trojans from establishing contact with hosts on the Internet using protocols such as HTTP, FTP, and Telnet, for example.

It may be unnecessary to say, but personal use of the Internet from a company network should, in general, be forbidden. Of course, the level of control here can be discussed, but the point is to prevent users from downloading dangerous content (viruses, Trojans) and sending out files from the internal network using protocols such as POP3, SMTP, FTP, HTTP, and other protocols that allow sending files in ASCII or binary formats.

Finally, other tools should be deployed as well to bring the security to a level that actually matches the level required (or wanted) in the company security policy. In the author's experience, probably less than 50 percent of all firewall installations are doing extensive logging, and less than 5 percent of the firewall owners are actually doing anything that even resembles useful log analysis, reporting, and statistics. To some, it seems like the attitude is "we've got a firewall, so we're safe." Such an attitude is both stupid and wrong.

Firewalls and firewall technologies by themselves cannot be trusted, at least not in our present Internet age of communications with hackers hiding in every corner. Hackers tunneling data through allowed protocols and ports can easily bypass today's firewalls, using encryption schemes to hide their tracks. Security professionals should, nonetheless, understand that a firewall, as part of a consistent overall security architecture, is still an important part of the network security in a company.

The best security tool available is still the human brain. Use it wisely and security will improve.

The (In)Security of Virtual Private Networks

James S. Tiller, CISA, CISSP

It is no surprise that virtual private networks (VPN) have become tremendously popular among many dissimilar business disciplines. Regardless of the vertical market or trade, VPNs can play a crucial role in communication requirements, providing flexibility and prompt return on investment when implemented and utilized properly. The adoption of VPNs has been vast and swift; and as technology advances, this trend will only increase. Some of the popularity of VPNs is due to the perceived relative ease of implementing the technology. This perceived simplicity and the promise of cheap, limitless access has created a mad rush to leverage this newfound communication type. Unfortunately, these predominant characteristics of VPNs have overshadowed fundamental security flaws that seem to remain obscure and hidden from the sales glossies and product presentations. This chapter is dedicated to shedding light on the security risks associated with VPNs and the misunderstanding that VPNs are synonymous with security.

It is crucial that the reader understands the security limitations detailed herein have almost nothing to do with VPN technology itself. There are several types of VPN technologies available — for example, IPSec, SSL, and PPTP, to mention a few — and each has advantages and disadvantages depending on the requirements and implementation. In addition, each has various levels of security that can be leveraged to accommodate a mixture of conditions. The insecurity of VPNs as a medium and a process is being discussed, and not the technical aspects or standards.

What is being addressed is the evaluation of VPNs by the general consumer arrived at from the sales paraphernalia flooding the market and the industry's products claiming to fill consumers' needs. Unfortunately, the demand is overwhelming, and the development of sufficient controls that could be integrated to increase the security lags behind what is being currently experienced. The word "security" appears frequently when VPNs are being discussed, which typically applies when defining the VPN itself — the protection of data in transit. Unfortunately, the communication's security stops at the termination point of the VPN, a point where security is paramount.

The goal of this chapter is to introduce VPNs, and explain their recent surge in popularity as well as the link to current advances in Internet connectivity, such as broadband. Then, the security experienced with legacy remote access solutions is compared with the realized security the industry has more recently adopted. This is an opportunity to look beyond the obvious and discuss the huge impact this technology is having on the total security posture of organizations. The problem is so enormous that it is difficult to comprehend — a "can't see the forest for the trees" syndrome.

One Thing Leads to Another

The popularity of VPNs seems to have blossomed overnight. The ability to remove the responsibility of maintaining a dedicated line for each contiguous remote user at the corporate site and leverage the existing

Internet connection to multiplex a greater number of connections previously unobtainable has catapulted VPN technology.

As with many technological combinations, one type may tend to feed from another and reap the benefits of its companion's advances. These can materialize as improvements or options in the technologies and the merger of implementation concepts — a marriage of symbiotic utilities that culminate to equal more than attainable alone. Cell phones are an example of this phenomenon. Cell phones support digital certificates, encryption, e-mail, and browsing, among other combinations and improvements. The wireless community has leveraged technologies normally seen in networking that are now gaining attention from their use in another environment. Cell phone use is more robust and the technology used is employed in ways not originally considered. It is typically a win–win situation.

The recent universal embracement of VPNs can be attributed to two primary changes in the communication industry: global adoption of Internet connectivity, and inexpensive broadband Internet access. These contemporary transformations and the ever-present need to support an increasing roaming user community have propelled VPN technologies to the forefront of popularity.

Roaming Users

Roaming is characterized by the natural progression from early networks providing services to a captive population and allowing those same services to be accessible from outside the normal boundaries of the network. Seemingly overnight, providing remote access to users was paramount and enormous resources were allocated to providing it.

Initially, as shown in Exhibit 43.1, modems were collected and connected into a common device that provided access to the internal network, and, of course, the modems were connected to phone lines that ultimately provided the access. As application requirements grew exponentially, the transmission speed of modems increased modestly and change was on the horizon. The first wave of change came in the form of remote desktops, or in some cases, entire systems. As detailed in Exhibit 43.2, a user would dial in and connect

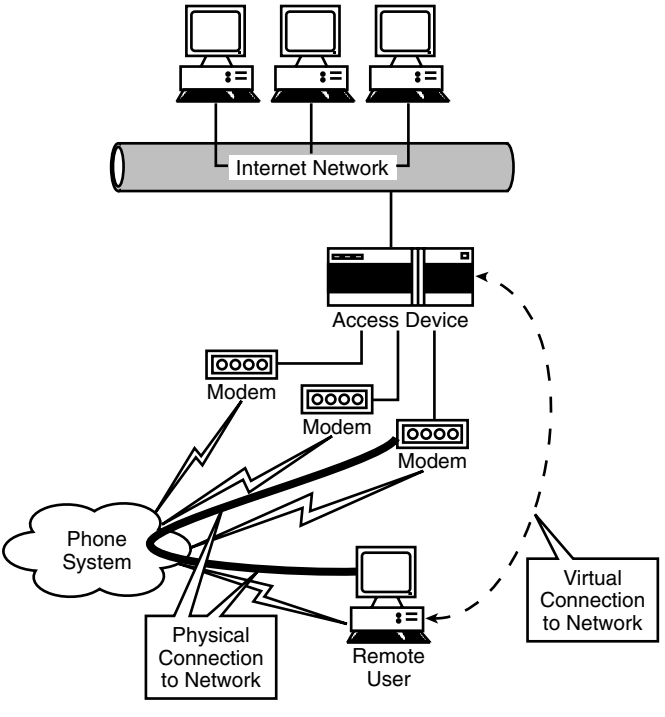

EXHIBIT 43.1 Standard remote access via modems.

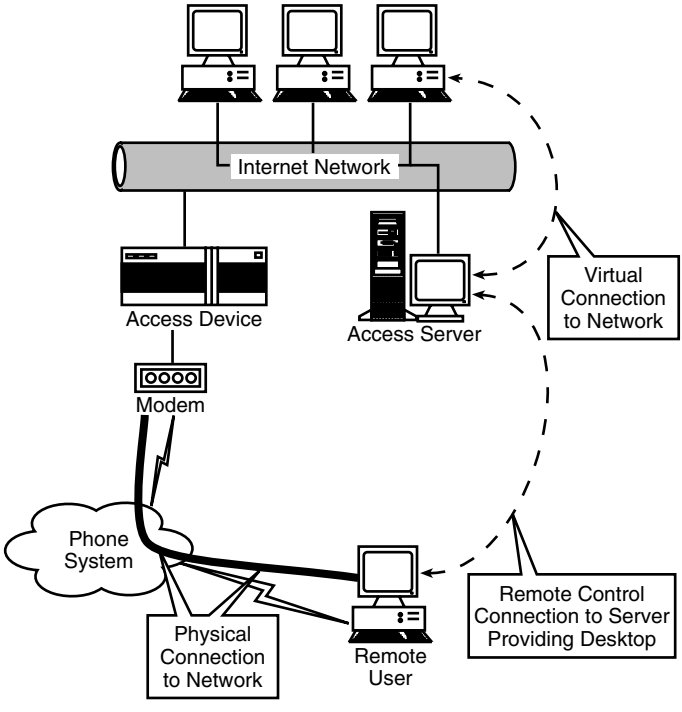

EXHIBIT 43.2 Standard remote access via modems using remote control or remote desktop.

to a system that could be either remotely controlled or export the desktop environment to the remote user. In both cases, the bandwidth required between the remote user and the core system was actually reduced and the functionality was amplified. Cubix, Citrix, and PC Anywhere became the dominant players in providing the increased capabilities, each with its own requirements, advantages, and cost.

Performance was realized by the fact that the remote access server on the internal network had very high access speeds to the other network resources. By using a lightweight protocol to control the access server, or to obtain desktop imagery, the modem connection had virtually the same feel as if on the actual network. It was at this point in the progression of remote access that having the same look and feel of the internal network had become the gauge to which all remote access solutions would be measured. From this point forward, any differences or added inconveniences would diminish the acceptance of a remote access solution.

Internet Adoption

The Internet's growth has been phenomenal. From the number of people taking their first steps on the Net, to the leaps in communication technologies, Internet utilization has become increasingly dense and more populated. The Internet has become a requirement for business and personal communications rather than a novelty or for simple amusement. Businesses that were not associated in some way with the Internet are now attempting to leverage it for expansion and increase client satisfaction while reducing costs. It is not uncommon for an organization to include an Internet connection for a new or existing office as a default install.

In contrast, early adopters of dedicated Internet connections, as a rule, had a single access point for the entire organization. As depicted in Exhibit 43.3, remote offices could get access by traversing the wide area network (WAN) to the central location at which the Internet was accessible. This very common design scenario was satisfactory when Internet traffic and requirements were limited in scope and frequency. As the requirements for Internet access grew, the number of connections grew in direct proportion, until the WAN began to suffer. Shortly thereafter, as the costs for direct connectivity declined and the Internet became more and more a part of business life, it became an essential tool and greater access was needed.

Presently, the Internet has become an indispensable utility for successful businesses, and the volume of Internet traffic coursing through internal networks is astounding. The need for information now greatly

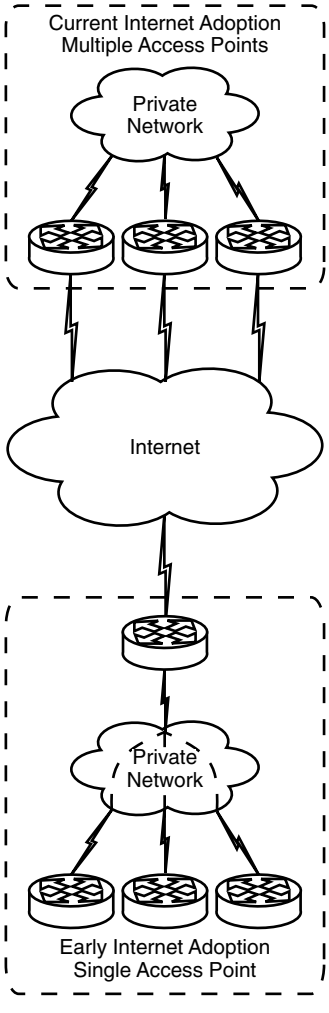

EXHIBIT 43.3 Internet access through one central point compared to the several typically seen now.

outweighs the cost of Internet connectivity. In the past, Internet connections had to be validated and carefully considered prior to implementation. Today, the first question is typically, "How big a pipe do we need?" not "Where should we put it?"

The vast adoption of the Internet and acceptance of it as a fundamental requirement has resulted in the increased density and diversity of the Internet. Today, organizations have several access points and leverage them to reduce load on other internal networks and provide increased performance for internal users as well as providing service redundancy. By leveraging the numerous existing connections, an organization can implement VPN technology to enhance communication, while using a service that was cost-justified long before the inclusion of VPNs.

Broadband

Before the existence of high-speed access to the Internet that is standard today, there were typically only modems and phone lines that provided painfully slow access. There were, of course, the few privileged users who had ISDN available to them that provided some relief. However, access was still based on modems and could be a nightmare to get to work properly. The early adopters of remote access used modems to obtain data or services. As the Internet became popular, modems were used to connect to an Internet service provider (ISP) that

provided the means for accessing the Internet. In either case, the limited speed capabilities were a troubling constant.

Today's personal and home access to the Internet can reach speeds historically realized only with expensive lines that only the largest companies could afford or obtain. At present, a simple device can be installed that provides a connection to the ISP and leverages Ethernet to connect to the host PC in the home or small office. Today, access is provided and controlled separately from the PC and rarely requires user intervention. The physical connection and communication medium are transparent to the user environment. Typically, the user turns on the computer and the Internet is immediately available. This is in stark contrast to the physical connection associated with the user's system and the modem, each working together to become the signal termination point and assuming all the responsibilities that are associated with providing the connection.

As with many communication technologies (especially with regard to modem-based remote access), a termination point must be supplied to provide the connection to the remote devices or modems. With dial-up solutions, a modem (virtual or physical) is supplied for the remote system to dial into and establish communications. A similar requirement exists for broadband, whether for cable modems or xDSL technologies: a termination point must be supplied to create a connection for the remote devices at the home or office.

The termination point at the core — with regard to the adoption of VPNs — has become one of the differentiating factors between broadband and modems. To provide remote dial-up access for employees, a single modem could be installed in a server — or workstation for that matter — and a phone line attached. The remote user could be supplied with a modem, the phone number, and the use of some basic software; a connection could be established to provide ample access to the system and services.

In contrast, broadband implementations are more complicated and considerably more expensive; thus, today, only service providers implement this type of technology. An example is Internet cable service; not too many companies have access to the cable infrastructure to build their own internal remote access solution. Currently, broadband is not being used for point-to-point remote access solutions. Therein lies the fundamental appeal of VPNs: a way to leverage this advanced communication technology to access company resources.

Not only is the huge increase in speed attractive because some of the application requirements may be too great for the limited bandwidth provided by modems, but the separation of the technology from the computer allows for a simplified and scalable integration. Under these circumstances, broadband is extremely attractive for accessing corporate resources. It is one thing to have broadband for high-speed Internet browsing and personal excursions, but it is another to have those same capabilities for business purposes. Unfortunately, as described earlier, broadband technologies are complex and infeasible for a nonservice provider organization to implement for internal use. The result is a high-speed communication solution that currently only provides Internet access — that is, until that advent of VPNs.

Extended Access

As communication capabilities increased and companies continued to integrate Internet activities into everyday procedures, the creation of VPN technology to merge the two was critical. Dial-up access to the Internet and broadband provide access to the Internet from nearly anywhere and with high speeds. Both allow global access to the Internet, but there is no feasible or cost-effective way to terminate the connection to the company headquarters. Since broadband access was intimately associated with the Internet and direct-dial solutions were ineffective and expensive, the only foreseeable solution was to leverage the Internet to provide private communications. This ultimately allowed organizations to utilize their existing investment in Internet connectivity to multiplex remote connections. The final hurdle was to afford security to the communication in the form of confidentiality, information integrity, access control, authentication, auditing, and, in some cases, nonrepudiation.

The global adoption of the Internet, its availability, and the increased speeds available have exceeded the limitless access enjoyed with dial-up. With dial-up, the telephone system was used for establishing communications — and telephones are everywhere. The serial communication itself was carried over a dedicated circuit that would be difficult to intercept for the everyday hacker and therefore relatively secure. Now that the Internet is everywhere, it can be used to duplicate the availability that exists with the telephone network while taking advantage of the increased speeds. Granted, if a modem is used to connect to the Internet, the speed is not realized and the phone system is being used to connect, but locally; the Internet is still being used for the common connection medium. Even with dial-up remote access, this was a huge leap in service because

many corporate-provided remote access solutions could be difficult to connect to from overseas. If not restricted by policy, cost became an issue because phone equipment and systems were not of the quality they are today, and long-distance transmissions would hinder the connection. In contrast, there are tens of thousands of ISPs worldwide that can provide access to the Internet, not including the very large ISPs that provide phone numbers globally. Finally, in addition to the seemingly endless supply of access points, there are companies that act as a central point for billing and management for hundreds of ISPs worldwide. From the point of view of the user, there is one large ISP everywhere on the globe.

The final hurdle was to provide the communication protection from in-transit influence or exposure as had occurred with old remote access over the phone network. VPN technology was immediately used to fill this gap. With the advent of expanded communication capabilities and the availability of the Internet, the ever-expanding corporate existence could be easily supported and protected during transit.

Connected All the Time

In the past, a remote user could dial into a modem bank at headquarters and access services remotely with little concern for eavesdropping, transmission interception, or impersonation. From the perspective of the hosting site, layers of security could be implemented to reduce exposure. Authentication, dial-back, time limitations, and access restrictions were employed to increase control over the communication and decrease exposure to threats. These protection suites were made possible primarily because of the one-on-one aspect of the communication; once the connection was established, it could be easily identified and controlled. As far as the communication itself, it was relatively protected while traversing the public phone system over dedicated circuits.

Because broadband technology can utilize Ethernet to allow connectivity to the access device, the computer simply has to be "on" for Internet communications (see Exhibit 43.4). This represents a huge change from traditional modem access, where the computer was responsible for establishing and maintaining the connection. Currently, with typical broadband the connection is sustained at the access device, allowing Internet connectivity, regardless of the state of other systems on the Ethernet interface. The Ethernet interface on the computer does not require a user to initialize it, know a phone number, or be concerned about the connection. All these options are controlled by the operating system; even the IP address is automatically assigned by the ISP, reducing the interaction with the user even further. Now the responsibility for Internet connectivity rests

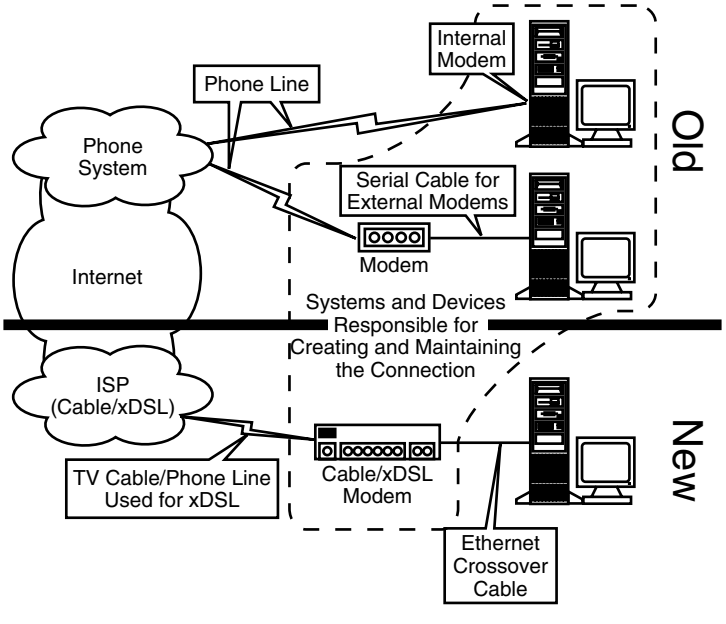

EXHIBIT 43.4 Broadband removed the user and system from the establishment of the connection.

solely on the access device, freeing the user and the user's computer from the need to maintain the connection. The end system is simply a node on a network.

Computers that are connected to the access device are connected to the Internet with little or no protection. It is very common for a broadband provider to install the cable or line and an Ethernet interface in the computer and directly connect the system with no security modifications. This results in basic end-systems with no security control being connected directly to the Internet for extended periods of time. The difference is tremendous. Instead of a fleeting instance of a roaming user on the Internet dialing up an ISP, the IP address, type of traffic, and even the location of the computer are exposed to the Internet for extended periods of time. When compared with the direct remote user dial-up support for corporations, the exposure is staggering. The obvious difference is that the user is connected to the Internet whereas the dial-up service provided by the company was point-to-point.

It is widely accepted that when a system is connected to the Internet, regardless of type, it is exposed to a colossal number of threats. It is also accepted that the greater the length of continuous time the connection is established, the greater the exposure or the risk of being found and targeted. Firewalls are usually placed on networks that have dedicated Internet connections, but they are not usually seen on hosts that have intermittent connections to the Internet. One of the reasons can be the nature of the connection — it is much more difficult to hit a moving target. But the reality is that this can be misleading, and roaming systems can be accosted in the same way as a system with a dedicated connection. In short, dial-up access to the Internet exposes the system to threats, and dedicated connections are exposed to the same threats as well, but with increased risk that can typically be attributed to duration. Whether connected all the time or some of the time, by broadband or modem, if you are on the Internet you are exposed to attack; it just so happens that when connected all the time, you are a sitting duck, not a flying one.

Accessing Corporate Networks

VPN technology is the final catalyst for allowing remote users to gain access to corporate resources by utilizing the Internet. This was a natural progression; the Internet is everywhere. Like the phone system, the higher bandwidth connections are becoming the norm, and VPN technology is securing the transmission with encryption techniques and authentication.

Much of VPN's success has been attributed to the advent and availability of broadband technologies, because high-speed access was great for browsing and getting bigger things off the Internet faster, but that is about all. Almost overnight the bandwidth typically associated with personal access, such as 32K or even 56K modems, to the Internet was increased 100 times. The greater access speeds attained by moving away from the public phone system and modems to dedicated broadband connectivity were quickly followed by rash of excitement; however, at the same time, many wanted the service to access corporate resources. As the excitement wore off from the huge leap in access speeds, many turned their eyes on ways to use this for remote access. It is at this point that VPN technology took off and absorbed the technical community.

Remote client software was the first on the scene. A product package included a device that was connected to the Internet at the corporate site and the client software that was loaded on the roaming system, resulting in remote access to corporate resources over the Internet. A great deal of time and money was invested in remote access solutions, and that continues today. In concert with remote client-based access, the rush to VPNs was joined by DSL and cable modem replacements that provided the VPN termination, once again relieving the client system from the responsibility of the communication. VPNs are now a wildfire being pushed across the technical landscape by a gale-force wind of broadband access.

Once unbridled access to the corporate network was available, it was not uncommon for remote sites or users to copy or open data normally maintained under the protection of elaborate firewalls and other protection suites provided at the corporate site. For many implementations, VPNs are used to run applications that would normally not be available on remote systems or require expensive resources and support to provide to employees at remote offices. In short, VPNs are being used for nearly everything that is typically available to a system residing on the internal network. This is to be expected, considering that vendors are selling the technology to do just that — operate as if on the internal network. Some solutions even incorporate Microsoft's Windows Internet Naming Service (WINS) and NetBIOS capabilities into their products to allow Domain browsing for systems and resources as if at the corporate site.

In essence, VPNs are being implemented as the panacea to integrate remote activities into internal operations as seamlessly as possible. The end product is data and applications being run from systems well outside the confines of a controlled environment.

Open Ended

Fundamentally, the service afforded by a VPN is quite simple: protect the information in transit, period. In doing so, various communications perks can be realized. A good example is *tunneling*. To accommodate protected communications as seamlessly as possible, the original data stream is encapsulated and then transmitted. The encapsulation procedure simplifies the protection process and transmittal of the datagram. The advantage that arises is that the systems in the VPN communicate as if there were no intermediary. An example, shown in Exhibit 43.5, is a remote system that creates a datagram that would operate normally on the internal network; instead, it is encapsulated and forwarded over the Internet to a system at the corporate office that de-encapsulates (and decrypts, if necessary) the original datagram and releases it onto the internal network. The applications and end-systems involved are typically never the wiser.

The goal for some VPN implementations is to provide communications for remote users over the Internet that emulates intranet services as closely as possible. Many VPN solutions are critiqued based on their capabilities to allow services to the client systems that are usually only available internally. With the adoption of broadband Internet access there is less stress on pure utilitarian aspects normally seen with dial-up solutions, where various limitations are assumed because of the limited bandwidth. To allow for the expanded communication requirements, many VPN solutions integrate into the environment in a manner that remains transparent not only to the user, but also to the applications that utilized the connection. Therefore, the protection realized by the VPN is extended only to the actual transport of data — exactly its purpose.

For the most part, prior to encapsulation or encryption, anything goes, and the VPN simply protects the transmission. The connection is protected but that does not equate to the communication being protected. To detail further, systems on internal networks are considered a community with common goals that are protected from the Internet by firewalls and other protection measures. Within the trusted community, data flows openly between systems, applications, and users; a VPN simply augments the process and protects it during transmission over the Internet. The process is seamless and transparent, and it accommodates the traffic and application needs. The result is that data is being shared and utilized by shadowy internal representations of the remote systems.

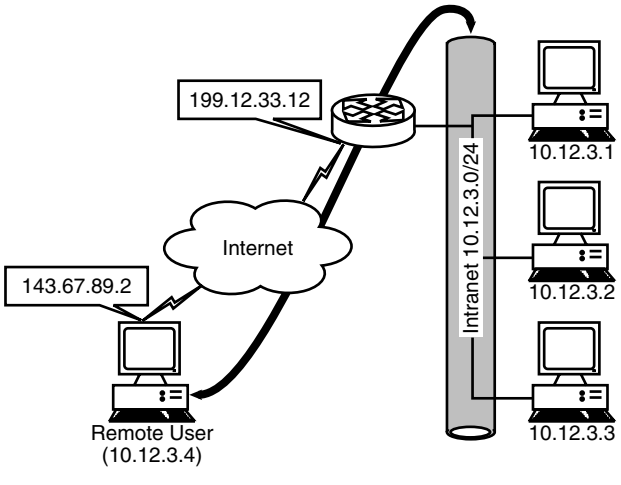

EXHIBIT 43.5 Attacker must attempt access to corporate data directly, the most difficult path.

Access Points

Having internal services wholly available to systems residing on internal networks is expected. The internal network is typically a controlled, protected, and monitored environment with security policies and procedures in place. As services and data are accessed internally, the exposure or threat to that communication is somewhat known and accepted at some level. Most organizations are aware of security threats on internal networks, but have assumed a level of risk directly proportional to the value or impact of loss if they were to be attacked. Much of this is attributed to simple population control; they assume greater risk to internal resources because there are fewer people internally than on the Internet, interaction is usually required (hence, a network), and each system can be monitored if desired. Basically, while some statistics tell us that internal networks are a growing source of attacks on corporate data, organizations feel confident that they can control what lies within their walls. Even organizations that do not have security policies and may consider themselves vulnerable will always assume that there is room to grow and implement security measures as they see fit. Nevertheless, the Internet represents a much greater threat in the eyes of many organizations, and this may be a reality for some organizations; each is different. The fundamental point is that the Internet is an unknown and will always be a threat, whereas certain measures can be taken — or the risk can be accepted — more readily on an internal network. In any case, internal networks are used to share information and collaborate to support or grow a business, and it is that open interaction people want from home over the Internet.

VPN technology is a total contradiction of the assumed posture and reach of control. The internal network, where applications, services, and data reside, is considered safe by virtue of firewalls, procedures, and processes overseen by administrators focused on maintaining security in some form or another. However, the nature of VPN negates the basic postulation of corporate security and the understood security attitude. Attackers who may have been thwarted by hardened corporate firewalls may find remote VPN clients much easier targets that may provide the same results.

On the whole, administrators are constantly applying security patches, updating processes, and performing general security maintenance on critical systems to protect them from vulnerabilities. Meanwhile, these vulnerabilities remain on end-user systems, whose users are much less likely to maintain their systems with the same integrity. In the event that an advanced user were to introduce a comprehensive protection plan, many remote systems do not run enterprise-class operating systems and are inherently insecure. Microsoft's Windows 95 and 98 platforms are currently installed on the majority of personal or end-user class systems and are well-known for limited security capabilities and overall robustness. Therefore, fundamental flaws weaken any applied security in the system.

The collision of the attributes that contribute to a common VPN implementation result in the cancellation of applied security infrastructure at the corporate site. Nearly every aspect of Internet-facing protection is invalidated the minute a user connects to corporate with a VPN. A single point of protection applies only if the protected network does not interact with the volatile environment being evaded.

Envelope of Security

To fully grasp this immense exposure, envision a corporate network segmented from the Internet by an arsenal of firewalls and intrusion detection systems, and even suppose that armed guards protect the building housing a private community of systems. Assume that the data on the network is shared and accessed in the open while on the internal network. Each system participating is protected and controlled equally by the establishment.

Now, take one of the systems to an uncontrolled remote location and build a point-to-point connection with modems. The remote computer is still isolated and not connected to any untrusted systems other than the phone system. The communication itself is relatively anonymous and its interception would be complicated, if discovered. However, as we see in VPNs, encryption can be applied to the protocol over the phone system for added protection.

Next, take the same system at the remote location and connect it to the Internet and establish a VPN to the corporate network. Now the system is exposed to influences well beyond the control realized when the computer was at the corporate office; still, the same access is being permitted.

In the three foregoing examples, degradation in security occurs as the computer is emoved from a controlled environment to a remote location and dial-up access is provided. The risks range from the system being stolen to the remote chance of the transmission being captured while communicating over the telephone network, but the overall security of the system and the information remain relatively protected. However, when the remote computer is placed on the Internet, the exposure to threats and the risk of operation are increased exponentially.

In the beginning of the example, the systems reside in an envelope of protection, isolated from unauthorized influences by layers of protection. Next, we stretch the envelope of protection out to the remote dial-in system; understandably, the envelope is weakened, but it certainly exists in nature to keep the information sheltered. The remote dial-in system loses some of the protection supplied by the fortified environment of corporate and is exposed to finite set of threats, but what is more important is that the envelope of security for the corporate site had not been dramatically affected.

In reality, the added risks of allowing remote systems to dial in directly are typically associated with unauthorized access, usually gained through the phone system. Corporate provides phone numbers to remote users to gain access and those same numbers are accessible from anywhere on the planet. Attackers can easily and quickly determine phone number ranges that have a high probability of including the target remote access numbers. Once the range is known, a phone-sweeping or "war-dialer" program can be employed to test each number with little or no intervention from the attacker. However, there are many factors that still manage to keep these risks in check. Dial-back, advanced and multi-layered authentication, extensive logging, time constraints, and access constraints can combine to make a formidable target for the attacker. With only a single point of access and the remote system in isolation, the security envelope remains intact and tangible. The degree of decay, of course, is directly related to the security of the single point of access at corporate and the level of isolation of the remote system.

In the last scenario, where the employment of a VPN provides corporate connectivity over the Internet, the security is perceived to be very high, if not greater than or equal to dial-up access solutions. Why not? They appear to have the same attributes and arguably the same security. In dial-up solutions, the communication is relatively protected, the system providing termination at corporate can be secured, and authentication measures can be put in place to reduce unauthorized access. VPNs, too, have these attributes and can be exercised to acquire an inclusive security envelope.

Unfortunately, the VPN offers a transparent envelope, a security façade that would not normally exist at such intensity if VPNs were not so accomplished as a protocol. The corporate-provided envelope is stretched to a breaking point with VPNs by the sheer fact that the remote system has gained control of the aspect of security and the employment of protection. It will become very clear that the envelope of security is no longer granted or managed by corporate but rather the remote system is now the overseer of all security — locally and into corporate.

A remote system connects to the Internet and obtains an IP address from the ISP to allow communication with the rest of the Internet community. Somewhere on the Internet is a VPN gateway on the corporate network that is providing access to the internal network. As the remote system establishes the VPN to share data, a host of vulnerabilities are introduced that can completely circumvent any security measures taken by corporate that would normally be providing the security envelope. It is at the point of connecting to the Internet where the dramatic tumbling of realized security takes place, and the remote system becomes the judge, jury, and possibly the executioner of corporate security.

The remote system may have employed a very robust VPN solution, one that does not allow the host system to act as a router or allow the forwarding of information from the Internet into the private network. To take it one step further, the VPN solution may employ limited firewalling capabilities or filtering concepts to limit access into the internal network. Nonetheless, the protection possibly supplied by the VPN client or firewall software can be turned off by users, ultimately opening them up to attack. In the event that a package can be implemented in which the user cannot turn off the protection suite, it can be assumed that a vulnerability will arise that requires a patch to remedy.

This scenario is extremely common and nearly an everyday occurrence for firewall and perimeter security administrators simply attempting to keep up with a limited number of firewalls. Given the lack of attention normally seen in many organizations toward their firewall maintenance, one can only imagine the disintegration of security when vulnerabilities are discovered in the remote system's firewall software.

Vulnerability Concepts

To fully understand the extremity of the destruction of perceived corporate security made available by ample amounts of technology and processes, it is necessary to know that the remote system is open and exposed to the Internet. In some cases, as with broadband, the exposure is constant and for long periods of time, making it predictable — an attacker's greatest asset.

The Internet is a sea of threats, if nothing else, simply because of the vast numbers of people and technologies available to them to anonymously wreak havoc on others, especially those unprepared. There are several different types of attacks that are for different uses and affect different layers in the communication. For example, denial-of-service (DoS) attacks are simply geared to eliminate the availability of a system or service — a purely destructive purpose. DoS attacks take advantage of weaknesses in low-level communication attributes, such as a protocol vulnerability, or higher-level weaknesses that may reside in the application itself. Some other attacks have very specific applications and are designed for particular situations to either gain access or obtain information. It is becoming more and more common to see these attacks taking advantage of application errors and quirks. The results are applications specifically engineered to obtain system information, or even to remotely control the host system.

Trojans have become very sophisticated and easy to use, mostly because of huge weaknesses in popular operating systems and very resourceful programmers. A typical system sitting on the Internet can have a Trojan installed that cannot only be used to gain access to the system, remotely control portions of the host system, obtain data stored locally, and collect keyboard input, but can notify the attacker when the host system is online and ready for access. In some cases, information can be collected offline and sent to the attacker when the Internet connection is reestablished by the victim. It is this vulnerability that represents the worst-case scenario and, unfortunately, it is commonplace for a typical home system to be affected.

In a case where the Trojan cannot be installed or implemented fully, an attacker could gain enough access, even if temporarily, to collect vital information about the targeted system or user, ultimately leading to more attacks with greater results. It can be argued that anti-virus programs and host-based firewall applications can assist the user in reducing the vulnerabilities and helping in discovering them — and possibly eradicating them. Unfortunately, the implementation, maintenance, and daily secure operation of such applications rests in the hands of the user. Nevertheless, it is complicated enough protecting refined, highly technical environments with dedicated personnel, much less remote systems spread all over the Internet.

A Step Back

Early in the adoption of the Internet, systems were attacked, sometimes resulting in unauthorized access and the loss of data or the disclosure of proprietary information. As the threats became greater, increasingly more sophisticated, and difficult to stop, firewalls were implemented to reduce the direct exposure to the attack. In combination, systems that were allowing certain services were hardened against known weaknesses to further the overall protection. Furthermore, these hardened specific systems were placed on isolated networks, referred to as DMZs, to protect the internal network from attacks launched from them or weaknesses in their implementation. With all these measures in place, hackers to this day continue to gain astounding access to internal systems.

Today, a firewall is a fundamental fixture in any Internet facing connection, and sometimes in huge amounts protecting vast numbers of systems and networks. It has become the norm, an accepted fact of Internet life, and an expensive one as well. Protecting the internal systems and resources from the Internet is paramount, and enormous work and finances are usually dedicated to supporting and maintaining the perimeter.

It is reasonable to state that much of the protection implemented is to protect proprietary data or information from dissemination, modification, or destruction. The data in question remains within the security envelope created by the security measures. Therefore, to get to the information, an attacker would have to penetrate, circumvent, or otherwise manipulate operational conditions to obtain the data or the means to access it more directly (see Exhibit 43.6).

With the advent of VPNs, the remote system is permitted a protected connection with the corporate data, inside the enclave of known risks and threats. It is assumed that the VPN protects the communication and

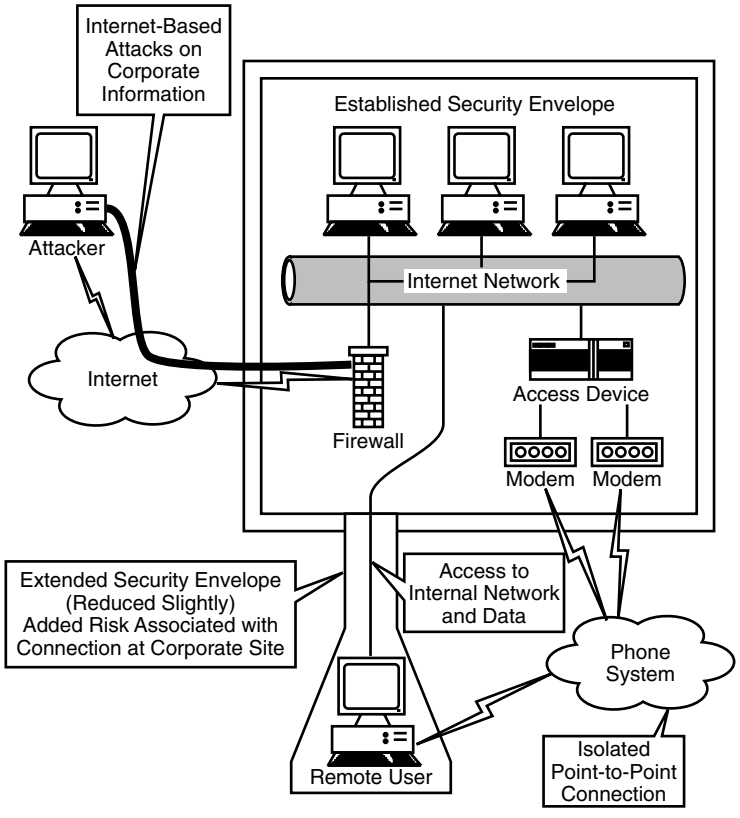

EXHIBIT 43.6 Attacker must attempt access to corporate data directly, the most difficult path.

stretches the security outward from the corporate to the remote location. Unfortunately, this assumption has overlooked an essential component of VPNs — the Internet. Now, as shown in Exhibit 43.7, an attacker can access corporate data on a system completely exposed and in control of a common user — not under the protection of technology or experience found at the corporate site.

From the point of view of the attacker, the information is simply on the Internet, as is the corporate connection; therefore, the access process and medium have not changed, just the level of security. The result is that the information is presented to the attacker, and direct access through a much more complicated path is not required. If it were not for the Internet connection, the remote hosts would have increased functionality, speed, and protection compared with legacy remote access with modems. Regrettably, the Internet is the link to the extended functionality as well as the link to ultimate insecurity.

Logically, this is a disaster for information security. We have invested monumental amounts of time, research, and money into the evolution of security and the mitigation of risk associated with connecting to a global, unrestricted network. We have built massive walls of security with bricks of technology ranging from basic router filtering, firewalls, and intrusion detection systems to system hardening, DMZs, and air-gaps. Now that we have a plethora of defense mechanisms pointed at the Internet, we are implementing an alternative route for attackers, leading them away from the traps and triggers and pointing them to our weakest points.

The concept of alternative forms and directions of attack when faced with considerable fortifications can be likened to medieval warfare. Castles were constructed with enormous walls to thwart intruders. Moats were filled, traps were laid, and deadly focal points were engineered to halt an attack. In some of these walls, typically under the surface of the moat, a secret gateway was placed that allowed scouts and spies out of the castle to collect information or even supplies to survive the siege. It is this reality that has repeated itself — a gateway placed facing the world to allow allies access into the stronghold. The differentiating factor between what is being seen now and ancient warfare is that long ago the kingdom would not permit a general, advisor, or any person outside the walls that could have information valuable to the enemy.

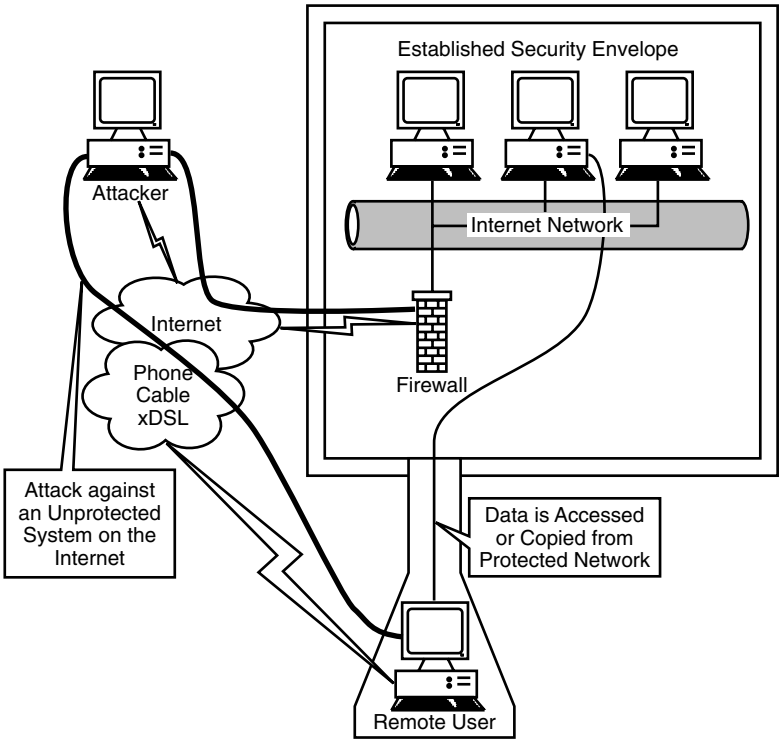

EXHIBIT 43.7 Attacker obtains data from a much less protected point on the Internet.

In stark contrast, today people from every level in the corporate chain access information outside the protected space. This is equivalent to sending a general with attack plans through the gateway, out of the castle, so he can work on the plan in his tent — presumably unprotected. It does not take much effort for an attacker to pounce on the general and collect the information that would normally require accessing the castle directly. In reality, a modern-day attacker would have so much control over the victim that data could be easily modified or collected in a manner that would render the owners oblivious to their activities. Exhibit 43.8 clearly depicts the evolution of the path of least resistance.

Disappointingly, the complicated labyrinthine safeguards we have constructed are squarely pointed at the enemy; meanwhile we are allowing the information out into the wild. The result is that the finely honed and tuned wall of protection is reduced to almost nothing. Where a small set of firewalls protected information on internal networks at a single entry point, there now exist thousands of access points with no firewalls. Not only have we taken a step back but also the problem reduced by firewalls has increased in scale. Early in Internet adoption a single Internet connection with a firewall would suffice. Today, organizations have several Internet connections with complicated protection measures. With the addition of VPNs for remote systems and small home offices, organizations have thousands of Internet connections beyond reasonable control.

Case in Point

Late one Friday, I received a phone call from a friend who worked for a large national construction company as a chief engineer. Calls from him were typical when his computer was acting up or a fishing trip was being planned for the weekend. However, this call started very unusually. He stated that he thought he had been hacked — his hard drive runs late into the night and the recently loaded BlackIce was logging a great deal of unknown traffic. I knew he used a cable modem and a VPN to work from home, either at night or during the day, to avoid traffic and general office interruptions. I was also aware that he used Windows 98 as an operating system and standard programs to complete his work. Additionally, he left his computer on all the time — why not?

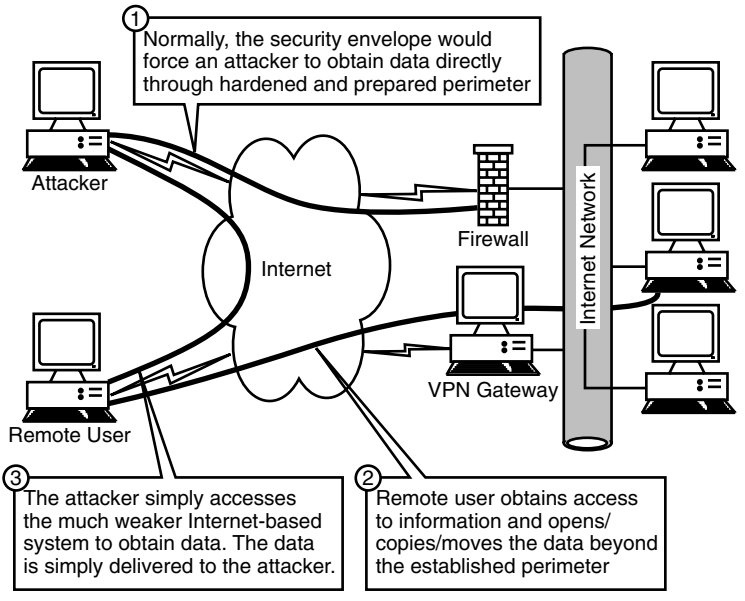

EXHIBIT 43.8 Data is accessed by a system exposed to vulnerabilities and various risks associated with the Internet.

Completely convinced that he had been attacked, I told him not to touch the computer and to start a sniffer using another computer on his home network to see what was going over the wire. In a few minutes, communications were started between his computer and an Internet-based host. It was clear, after looking at the traffic more clearly, that his system was being accessed. Between his experiences, log files from various software he had installed on the system, and previous experiences with other friends in his shoes, I assumed that his system was accessed. I had him unplug the Ethernet from the cable modem and asked how serious could the issue be — in other words, what was on the box that someone would want or appreciate getting.

After a short discussion, it appeared that the hacker was accessing all the bid packages for building projects all over the United States, each encrusted with logos, names, contact information, competition analysis, schedules, and cost projections. It was my friend's job to collect this information and review it for quality control and engineering issues. Further discussions proved that he knew when he last accessed the data based on work habits and general memory. It was at this point that he told me this had been going on for some time and he just got around to calling me. He wanted to try anti-virus programs and freeware first so that he would not bother me with a false alarm. Subsequently, we collectively decided to access the system to try to determine what was accessed and when.

The first thing we found was BackOrifice with basic plug-ins, which led me to believe that this may not have been intentionally directed at him, but rather someone wanting to play with a wide-open Windows system sitting on the Internet. We started checking files for access times; many were accessed in the middle of the night several weeks prior. More investigation turned up hidden directories and questionable e-mails he had received sometime before. At this point, I simply stopped and told him to assume the worst and try to think of anything else that may have been on his system. It turned out that a backup of his TurboTax database — not password protected — was on the system along with approved human resource documents for employees in his department who had recently received a raise.

The entire phone conversation lasted about three hours — that's all it took. I suspect that the call to his manager was much more painful and felt much longer. But was it his fault? His company provided him the Internet connection and the VPN software, and access from home was encouraged. It seemed logical to him and his manager. He needed access to the Internet for research, and he typically got more done at home than at the office. However, an unknown assailant on the Internet, who could be either a hired gun to get the information or a script-kiddie that stumbled into a pot of gold, accessed extremely sensitive information. In either case, it was out there and could have an impact on the business for years.

Solutions

There is, of course, no easy solution to the security dilemma that is presented by the implementation of VPNs. Even with sophisticated technology, organizations still cannot stop hackers. They continue to access systems in heavily protected networks with apparent ease. Much of this can be attributed to poor design, gaps in maintenance, improper configuration, or simple ignorance. In any case, with focused attention on the perimeter, unauthorized access is still happening at an alarming rate. Given this scenario of hundreds if not thousands of remote computers on the Internet, what can be done to protect them? Simply stated, if an internal network cannot be protected when the best efforts are thrown at the problem, there is little hope of protecting the masses at home and on the road.

As with any sound security practice, a security policy is crucial to the protection of information. Specifying data access limitations and operating parameters for information exchange can greatly reduce the exposure of information. In other words, if a certain type of information is not needed for remote work, then remote access systems should not provide access to that information or system. By simply reducing the breadth of access provided by the remote access solution, data can be inherently protected. The practice of limiting what is actually accessible by remote users has materialized in the form of firewalls behind VPN devices seemingly protecting the internal network from the VPN community. Unfortunately, this design has enormous limitations and can limit the scalability of the VPN in terms of flexibility of access. Another eventuality is the inclusion of filtering methods employed in the VPN access device. Filters can be created to control traffic that is injected into the internal network, and in some cases filters can be associated with actual authenticated users or groups.

No matter how access is restricted, at some point a remote user will require sensitive information and anyone implementing services for users has been faced with that "special case." Therefore, technology must take over to protect information. Just as we look to firewalls to protect our internal networks from the Internet, we must look to technology again to protect remote systems from relaying proprietary information into the unknown. The application of host-based protection software is not entirely new, but the growing number of attacks on personal systems has raised awareness of their existence. However, these applications are point solutions and not a solution that is scalable, flexible, or centrally controlled or managed to maintain security. In essence, each user is responsible for his or her realized security posture.

Conclusion

VPNs can be enormously valuable; they can save time, money, expand access, and allow organizations ultimate flexibility in communications. However, the private link supplied by a VPN can open a virtual backdoor to attackers. Organizations that permit sensitive data to traverse a VPN potentially expose that information to a plethora of threats that do not exist on the protected internal network.

There are many types of VPN products available, all with their own methods of establishing the connection, maintaining connectivity, and providing services usually found on the internal network. Unfortunately, if the remote system is not involved in dedicated communications with the central office via the VPN, the system can be considered extremely vulnerable.

The Internet has grown to permeate our lives and daily activities, but there has always been a line drawn in the sand by which separation from total assimilation can be measured. Firewalls, modems, routers, filters, and even software such as browsers can provide a visible point of access to the Internet. As technology becomes more prevalent, the demarcation between the Internet and private networks will begin to blur. Unfortunately, without proper foresight, the allocation of security measures and mitigation processes will not keep up with advances in information terrorism. If not properly planned and controlled, seemingly secure alternative routes into a fortification can negate all other protection; a castle's walls will be ineffective against an attack that does not come directly at them.

Cookies and Web Bugs: What They Are and How They Work Together

William T. Harding, Ph.D., Anita J. Reed, CPA, and Robert L. Gray, Ph.D.

What are cookies and what are Web bugs? Cookies are not the kind of cookies that we find in the grocery store and love to eat. Rather, cookies found on the World Wide Web are small unique text files created by a Web site and sent to your computer's hard drive. Cookie files record your mouse-clicking choices each time you get on the Internet. After you type in a Uniform Resource Locator (URL), your browser contacts that server and requests the specific Web site to be displayed on your monitor. The browser searches your hard drive to see if you already have a cookie file from the site. If you have previously visited this site, the unique identifier code, previously recorded in your cookie file, is identified and your browser will transfer the cookie file contents back to that site. Now the server has a history file of actually what you selected when you previously visited that site. You can readily see this because your previous selections are highlighted on your screen. If this is the first time you have visited this particular site, then an ID is assigned to you and this initial cookie file is saved on your hard drive.

A Web bug is a graphic on a Web page or in an e-mail message that is designed to monitor who is reading the Web page or e-mail message. A Web bug can provide the Internet Protocol (IP) address of the e-mail recipient, whether or not the recipient wishes that information disclosed. Web bugs can provide information relative to how often a message is being forwarded and read. Other uses of Web bugs are discussed in the details that follow. Additionally, Web bugs and cookies can be merged and even synchronized with a person's e-mail address. There are positive, negative, illegal, and unethical issues to explore relative to the use of Web bugs and cookies. These details also follow.

What Is a Cookie?

Only in the past few years have cookies become a controversial issue, but, as previously stated, not the kind of cookies that you find in the grocery store bearing the name "Oreos" or "Famous Amos." These cookies deal with information passed between a Web site and a computer's hard drive. Although cookies are becoming a more popular topic, there are still many users who are not aware of the cookies being stored on their hard drives. Those who are familiar with cookies are bringing up the issues of Internet privacy and ethics. Many companies such as DoubleClick, Inc. have also had lawsuits brought against them that ask the question: are Internet companies going too far?

To begin, the basics of cookies need to be explained. Lou Montulli for Netscape invented the cookie in 1994. The only reason, at the time, to invent a cookie was to enable online shopping baskets. Why the name "cookie"? According to an article entitled "Cookies … Good or Evil?," it is said that early hackers got their kicks from Andy Williams' TV variety show. A "cookie bear" sketch was often performed where a guy in a bear suit tried all kinds of tricks to get a cookie from Williams, and Williams would always end the sketch while screaming, "No cookies! Not now, not ever … NEVER!" A hacker took on the name "cookie bear" and annoyed mainframe computer operators by taking over their consoles and displaying a message "WANT COOKIE." It would not go away until the operator typed the word "cookie," and cookie bear would reply with a thank you. The "cookie" did nothing but damage the operator's nerves. Hence the name "cookie" emerged.

Cookie Contents

When cookies were first being discovered, rumors went around that these cookies could scan information off your hard drive and collect details about you, such as your passwords, credit card numbers, or a list of software on your computer. These rumors were rejected when it was explained that a cookie is not an executable program and can do nothing directly to your computer. In simple terms, cookies are small, unique text files created by a Web site and sent to a computer's hard drive. They contain a name, a value, an expiration date, and the originating site. The header contains this information and is removed from the document before the browser displays it. You will never be able to see this header, even if you execute the view or document source commands in your browser. The header is part of the cookie when it is created. When it is put on your hard drive, the header is left off. The only information left of the cookie is relevant to the server and no one else.

An example of a header is as follows:

```
Set-Cookie: NAME=VALUE; expires=DATE; path=PATH;
domain=DOMAIN_NAME; secure
```

The NAME=VALUE is required. NAME is the name of the cookie. VALUE has no relevance to the user; it is anything the origin server chooses to send. DATE determines how long the cookie will be on your hard drive. No expiration date indicates that the cookie will expire when you quit the Web browser. DOMAIN_NAME contains the address of the server that sent the cookie and that will receive a copy of this cookie when the browser requests a file from that server. It specifies the domain for which the cookie is valid. PATH is an attribute that is used to further define when a cookie is sent back to a server. Secure specifies that the cookie only be sent if a secure channel is being used.

Many different types of cookies are used. The most common type is named a visitor cookie. This keeps track of how many times you return to a site. It alerts the Webmaster of which pages are receiving multiple visits. A second type of cookie is a preference cookie that stores a user's chosen values on how to load the page. It is the basis of customized home pages and site personalization. It can remember which color schemes you prefer on the page or how many results you like from a search. The shopping basket cookie is a popular one with online ordering. It assigns an ID value to you through a cookie. As you select items, it includes that item in the ID file on the server. The most notorious and controversial is the tracking cookie. It resembles the shopping basket cookie, but instead of adding items to your ID file, it adds sites you have visited. Your buying habits are collected for targeted marketing. Potentially, companies can save e-mail addresses supplied by the user and spam you on products based on information they gathered about you.

Cookies are only used when data is moving around. After you type a URL in your browser, it contacts that server and requests that Web site. The browser looks on your machine to see if you already have a cookie file from the site. If a cookie file is found, your browser sends all the information in the cookie to that site with the URL. When the server receives the information, it can now use the cookie to discover your shopping or browsing behavior. If no cookie is received, an ID is assigned to you and sent to your machine in the form of a cookie file to be used the next time you visit.

Cookies are simply text files and can be edited or deleted from the computer system. For Netscape Navigator users, cookies can be found under (C:/Program Files/ Netscape/Users/default or user name/cookie.txt) directory, while Explorer users will find cookies stored in a folder called Cookies under (C:/windows/Cookies). Users cannot harm their computer when they delete the entire cookie folder or selected files. Web browsers have options that alert users before accepting cookies. Furthermore, there is software that allows users to block cookies, such as Zero-knowledge systems, Junkguard, and others that are found at www.download.com.

For advanced users, cookies can also be manipulated to improve their Web usage. Cookies are stored as a text string, and users can edit the expiration date, domain, and path of the cookie. For instance, JavaScript makes the cookies property of the documents object available for processing. As a string, a cookie can be manipulated like any other string literal or variable using the methods and properties of the string object.

Although the cookie is primarily a simple text file, it does require some kind of scripting to set the cookie and to allow the trouble-free flow of information back and forth between the server and client. Probably the most common language used is Perl CGI script. However, cookies can also be created using JavaScript, Livewire, Active Server Pages, or VBScript.

Here is an example of a JavaScript cookie:

```
<SCRIPT language=JavaScript>
  function setCookie (name, value, expires, path, domain,
secure) {
  document.cookie = name + "=" +  escape(value) +
  ((expires) ? "; expires=" +  expires : "") +
  ((path) ? "; path=" + path :  "") +
  ((domain) ? "; domain=" +  domain : "") +
  ((secure) ? "; secure" : "");
  }
  </SCRIPT>.
```

Although the design of the cookie is written in a different language than the more common Perl CGI script that we first observed, the content includes the same name-value pairs. Each one of these scripts is used to set and retrieve only their unique cookie and they are very similar in content. The choice of which one to use is up to the creators' personal preference and knowledge.

When it comes to being able to actually view what the cookie looks like on your system, what you get to see from the file is very limited and not easily readable. The fact is that all of the information on the cookie is only readable in its entirety by the server that set the cookie. Furthermore, in most cases, when you access the files directly from your cookies.txt file or from the windows/cookies directory with a text editor, what you see looks mostly like indecipherable numbers or computer noise. However, Karen Kenworthy of Winmag.com (one super-sleuth programmer) has created a free program that will locate and display all of the cookies on your Windows computer. Her cookie viewer program will display all the information within a cookie that is available except for any personal information that is generally hidden behind the encoded ID value. Exhibit 44.1 shows Karen's Cookie Viewer in action.

As you can see, the Cookie Viewer shows that we have 109 cookies currently inside our Windows\Cookie directory. Notice that she has added a Delete feature to the viewer to make it very easy for the user to get rid of all unwanted cookies. When we highlight the cookie named anyuser@napster[2].txt, we can see that it indeed came from napster.com and is available only to this server. If we are not sure of the Web site a cookie came from, we can go to the domain or IP address shown in this box to decide if we really need that particular cookie. If not, we can delete it! Next we see that the Data Value is set at 02b07, which is our own unique ID. This series of numbers and letters interacts with a Napster server database holding any pertinent information we have previously entered into a Napster form. Next we see the creation date, the expiration date, and a computation of the time between the two dates. We can also see that this cookie should last for ten years. The cookie viewer takes expiration dates that Netscape stores as a 32-bit binary number and makes it easily readable. Finally, we see a small window in regard to the security issue, which is set at the No default.

Positive Things about Cookies

First of all, the purpose of cookies is to keep track of information on your browsing history. When a user accesses a site that uses cookies, up to 255 bytes of information are passed to the user's browser. The next time the user visits that site, the cookie is passed back to the server. The cookie might include a list of the pages that the user has viewed or the user's viewing patterns based on prior visits. With cookies, a site can track usage patterns and customize the information displayed to individuals as they log on to the site.

Second, cookies can provide a wealth of information to marketers. By using Internet cookies, online businesses can target ads that are relevant to specific consumers' needs and interests. Both consumers and marketers can benefit from using cookies. The marketers can get a higher rate of Click-Through viewers, while

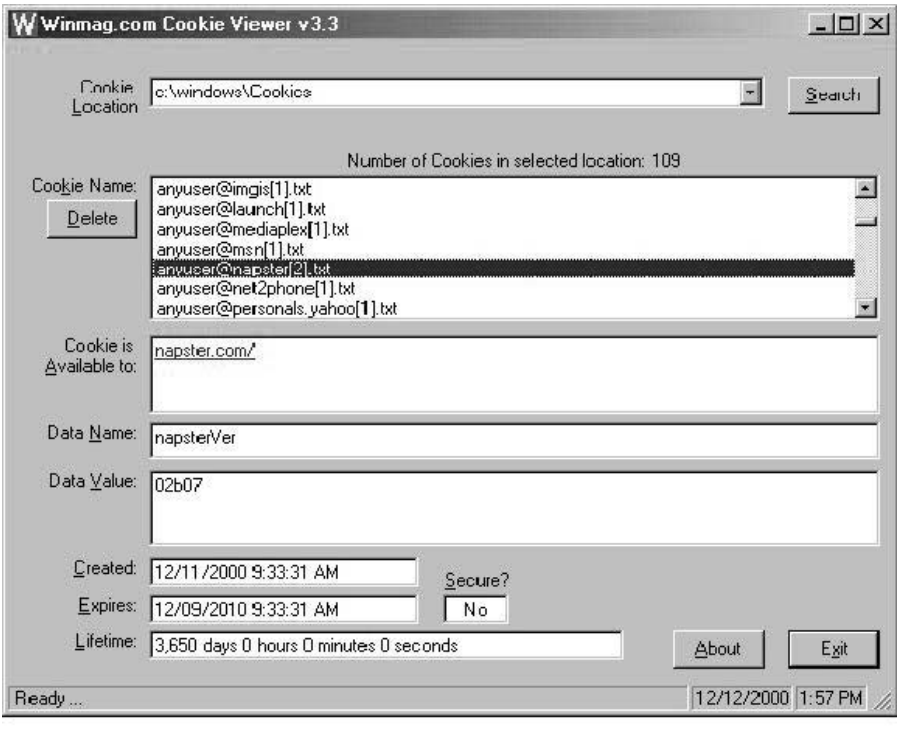

EXHIBIT 44.1 Karen's cookie viewer.

customers can view only the ads that interest them. In addition, cookies can prevent repetitive ads. Internet marketing companies such as Focalink and DoubleClick implement cookies to make sure an Internet user does not have to see the same ads over and over again. Moreover, cookies provide marketers with a better understanding of consumer behavior by examining the Web surfing habits of the users on the Internet. Advanced data mining companies like NCR, Inc. and Sift, Inc. can analyze the information about customers in the cookie files and better meet the needs of all consumers.

An online ordering system can use cookies to remember what a person wants to buy. For example, if a customer spends hours of shopping looking for a book at a site, and then suddenly has to get offline, the customer can return to the site later and the item will still be in his shopping basket.

Site personalization is another beneficial use of cookies. Let's say a person comes to the CNN.com site but does not want to see any sports news; CNN.com allows that person to select this as an option. From then on (until the cookie expires), the person will not have to see sports news at CNN.com.

Internet users can use cookies to store their passwords and user IDs, so the next time they want to log on to the Web site, they do not have to type in the password or user ID. However, this function of cookies can be a security risk if the computer is shared among other users. Hotmail and Yahoo are some of the common sites that use this type of cookie to provide quicker access for their e-mail users.

Cookies have their advantages, described in "Destroying E-Commerce's 'Cookie Monster' Image." Cookies can target ads that are relevant to specific consumers needs and interests. This benefits a user by keeping hundreds of inconvenient and unwanted ads away. The cookies prevent repetitive banner ads. Also, through the use of cookies, companies can better understand the habits of consumer behavior. This enables marketers to meet the needs of most consumers. Cookies are stored at the user's site on that specific computer. It is easy to disable cookies. In Internet Explorer 4.0, choose the View, Internet Options command, click the Advanced tab, and click the Disable All Cookies option.

Negative Issues Regarding Cookies

The main concerns about using cookie technology are the security and privacy issues. Some believe that cookies are a security risk, an invasion of privacy, and dangerous to the Internet. Whether or not cookies are ethical is based on how the information about users is collected, what information is collected, and how this information is used. Every time a user logs on to a Web site, he or she will give away information such as service provider, operating system, browser type, monitor specifications, CPU type, IP address, and what server last logged on.

A good example of the misuse of cookies is the case when a user shares a computer with other users. For example, at an Internet café, people can snoop into the last user's cookie file stored in the computer's hard disk and potentially uncover sensitive information about the earlier user. That is one reason why it is critical that Web developers do not misuse cookies and do not store information that might be deemed sensitive in a user's cookie file. Storing information such as someone's Social Security number, mother's maiden name, or credit card information in a cookie is a threat to Internet users.

There are disadvantages and limitations to what cookies can do for online businesses and Web users. Some Internet consumers have several myths about what cookies can do, so it is crucial to point out things that cookies cannot do:

- Steal or damage information from a user's hard drive
- Plant viruses that would destroy the hard drive
- Track movements from one site to another site
- Take credit card numbers without permission
- Travel with the user to another computer
- Track down names, addresses, and other information unless consumers have provided such information voluntarily

On January 27, 2000, a California woman filed suit against DoubleClick, accusing the Web advertising firm of unlawfully obtaining and selling consumers' private information. The lawsuit alleges that DoubleClick employs sophisticated computer tracking technology, known as cookies, to identify Internet users and collect personal information without their consent as they travel around the Web. In June 2000, DoubleClick purchased Abacus Direct Corporation, a direct marketing service that maintains a database of names, addresses, and the retail purchasing habits of 90 percent of American households. DoubleClick's new privacy policy states that the company plans to use the information collected by cookies to build a database profiling consumers. DoubleClick defends the practice of profiling, insisting that it allows better targeting of online ads which in turn makes the customer's online experiences more relevant and advertising more profitable. The company calls it "personalization."

According to the Electronic Privacy Information Center, "DoubleClick has compiled approximately 100 million Internet profiles to date." Consumers felt this provided DoubleClick with too much access to unsuspecting users' personal information. Consumers did not realize that most of the time they were receiving an unauthorized DoubleClick cookie. There were alleged violations of federal statutes, such as the Electronic Communication Privacy Act and the Stored Wire and Electronic Communications and Transactional Records Access Act. In March 2000, DoubleClick admitted to making a mistake in merging names with anonymous user activity.

Many people say that the best privacy policies would let consumers "opt in," having a say in whether they want to accept or reject specific information. In an article titled "Keeping Web Data Private," Electronic Data Systems (EDS) Corp. in Plano, Texas, was said to have the best practices. Bill Poulous, EDS's director of E-commerce policy stated, "Companies must tell consumers they're collecting personal information, let them know what will be done with it and give them an opportunity to opt out, or block collection of their data." Poulous also comments that policies should be posted where the average citizen can read and understand them and be able to follow them.

What Is a Web Bug?

A Web bug is a graphic on a Web page or in an e-mail message that is designed to monitor who is reading the Web page or an e-mail message. Like cookies, Web bugs are electronic tags that help Web sites and advertisers track visitors' whereabouts in cyberspace. However, Web bugs are essentially invisible on the page and are much smaller — about the size of the period at the end of a sentence. Known for tracking down the creator of the Melissa virus, Richard Smith, Chief Technology Officer of www.privacyfoundation.org, is credited with uncovering the Web bug technique. According to Smith, "Typically set as a transparent image, and only 1×1 pixel in size, a Web bug is a graphic on a Web page or in an e-mail message that is designed to monitor who is reading the Web page or e-mail message." According to Craig Nathan, Chief Technology Officer for Meconomy.com, the 1×1 pixel Web bug "is like a beacon, so that every time you hit a Web page it sends a ping or call-back to the server saying 'Hi, this is who I am and this is where I am.'"

Most computers have cookies, which are placed on a person's hard drive when a banner ad is displayed or a person signs up for an online service. Savvy Web surfers know they are being tracked when they see a banner ad. However, people cannot see Web bugs, and anti-cookie filters will not catch them. So the Web bugs can wind up tracking surfers in areas online where banner ads are not present or on sites where people may not expect to be trailed.

An example of a Web bug can be found at http:www.investorplace.com. There is a Web bug located at the top of the page. By choosing View, Source in Internet Explorer or View, Page Source in Netscape you can see the code at work. The code, as seen below, provides information about an "Investor Place" visitor to the advertising agency DoubleClick:

```
<IMG  SRC="http:ad.doubleclick.net/activity;src=328142;
      type=mmti;  cat=invstr;ord=<Time>?"WIDTH=1
      HEIGHT=1  BORDER=0>
```

It is also possible to check for bugs on a Web page. Once the page has loaded, view the page's source code. Search the page for an IMG tag that contains the attributes WIDTH=1 HEIGHT=1 BORDER=0 (or WIDTH="1" HEIGHT ="1" BORDER="0"). This indicates the presence of a small, transparent image. If the image that this tag points to is on a server other than the current server (i.e., the IMG tag contains the text SRC="http://"), it is quite likely a Web bug.

Privacy and Other Web Bug Issues

Advertising networks, such as DoubleClick or Match Point, use Web bugs (also called "Internet tags") to develop an "independent accounting" of the number of people in various regions of the world, as well as various regions of the Internet, who have accessed a particular Web site. Advertisers also account for the statistical page views within the Web sites. This is very helpful in planning and managing the effectiveness of the content because it provides a survey of target market information (i.e., the number of visits by users to the site). In this same spirit, the ad networks can use Web bugs to build a personal profile of sites a person has visited. This information can be warehoused on a database server and mined to determine what types of ads are to be shown to that user. This is referred to as "directed advertising."

Web bugs used in e-mail messages can be even more invasive. In Web-based e-mail, Web bugs can be used to determine if and when an e-mail message has been read. A Web bug can provide the IP address of the recipient, whether or not the recipient wishes that information disclosed. Within an organization, a Web bug can give an idea of how often a message is being forwarded and read. This can prove helpful in direct marketing to return statistics on the effectiveness of an ad campaign. Web bugs can be used to detect if someone has viewed a junk e-mail message or not. People who do not view a message can be removed from the list for future mailings.

With the help of a cookie, the Web bug can identify a machine, the Web page it opened, the time the visit began, and other details. That information, sent to a company that provides advertising services, can then be used to determine if someone subsequently visits another company page in the same ad network to buy something or to read other material. "It's a way of collecting consumer activity at their online store," says David Rosenblatt, senior vice president for global technology at DoubleClick. However, for consumer watchdogs,

Web bugs and other tracking tools represent a growing threat to the privacy and autonomy of online computer users.

It is also possible to add Web bugs to Microsoft Word documents. A Web bug could allow an author to track where a document is being read and how often. In addition, the author can watch how a "bugged" document is passed from one person to another or from one organization to another.

Some possible uses of Web bugs in Word documents include:

- Detecting and tracking leaks of confidential documents from a company
- Tracking possible copyright infringement of newsletters and reports
- Monitoring the distribution of a press release
- Tracking the quoting of text when it is copied from one Word document to a new document

Web bugs are made possible by the ability in Microsoft Word for a document to link to an image file that is located on a remote Web server. Because only the URL of the Web bug is stored in a document and not the actual image, Microsoft Word must fetch the image from a Web server each and every time the document is opened. This image-linking feature then puts a remote server in the position to monitor when and where a document file is being opened. The server knows the IP address and host name of the computer that is opening the document. A host name will typically include the company name of a business. The host name of a home computer usually has the name of a user's Internet service provider. Short of removing the feature that allows linking to Web images in Microsoft Word, there does not appear to be a good preventative solution. In addition to Word documents, Web bugs can also be used in Excel 2000 and PowerPoint 2000 documents.

Synchronization of Web Bugs and Cookies

Additionally, Web bugs and browser cookies can be synchronized to a particular e-mail address. This trick allows a Web site to know the identity of people (plus other personal information about them) who come to the site at a later date. To further explain this, when a cookie is placed on your computer, the server that originally placed the cookie is the only one that can read it. In theory, if two separate sites place a separate unique cookie on your computer, they cannot read the data stored in each other's cookies. This usually means, for example, that one site cannot tell that you have recently visited the other site. However, the situation is very different if the cookie placed on your computer contains information that is sent by that site to an advertising agency's server and that agency is used by both Web sites. If each of these sites places a Web bug on its page to report information back to the advertising agency's computer, every time you visit either site, details about you will be sent back to the advertising agency utilizing information stored on your computer relative to both sets of cookie files. This allows your computer to be identified as a computer that visited each of the sites.

An example will further explain this. When Bob, the Web surfer, loads a page or opens an e-mail that contains a Web bug, information is sent to the server housing the "transparent GIF." Common information being sent includes the IP address of Bob's computer, his type of browser, the URL of the Web page being viewed, the URL of the image, and the time the file was accessed. Also potentially being sent to the server, the thing that could be most threatening to Bob's privacy, is a previously set cookie value, found on his computer.

Depending on the nature of the preexisting cookie, it could contain a whole host of information from usernames and passwords to e-mail addresses and credit card information. To continue with our example, Bob may receive a cookie upon visiting Web Site #1 that contains a transparent GIF that is hosted on a specific advertising agency's server. Bob could also receive another cookie when he goes to Web Site #2 that contains a transparent GIF which is hosted on the same advertising agency's server. Then the two Web sites would be able to cross-reference Bob's activity through the cookies that are reporting to the advertiser. As this activity continues, the advertiser is able to stockpile what is considered to be non-personal information on Bob's preferences and habits, and, at the same time, there is the potential for the aggregation of Bob's personal information as well.

It is certainly technically possible, through standardized cookie codes, that different servers could synchronize their cookies and Web bugs, enabling this information to be shared across the World Wide Web. If this were to happen, just the fact that a person visited a certain Web site could be spread throughout many Internet servers, and the invasion of one's privacy could be endless.

Conclusion

The basics of cookies and Web bugs have been presented to include definitions, contents, usefulness, privacy concerns, and synchronization. Several examples of the actual code of cookies and Web bugs were illustrated to help the reader learn how to identify them. Many positive uses of cookies and Web bugs in business were discussed. Additionally, privacy and other issues regarding cookies and Web bugs were examined. Finally, the synchronization of Web bugs and cookies (even in Word documents) was discussed.

However, our discussions have primarily been limited to cookies and Web bugs as they are identified, stored, and used today only. Through cookie and Web bug metadata (stored data about data), a great deal of information could be tracked about individual user behavior across many platforms of computer systems. Someday we may see cookie and Web bug mining software filtering out all kinds of different anomalies and consumer trends from cookie and Web bug warehouses! What we have seen thus far may only be the tip of the iceberg. (Special thanks go to the following MIS students at Texas A&M University–Corpus Christi for their contributions to this research: Erik Ballenger, Cynthia Crenshaw, Robert Gaza, Jason Janacek, Russell Laya, Brandon Manrow, Tuan Nguyen, Sergio Rios, Marco Rodriquez, Daniel Shelton, and Lynn Thornton.)

Leveraging Virtual Private Networks

James S. Tiller, CISA, CISSP

Increasingly, virtual private networks (VPNs) are being adopted for many uses, which range from remote access and small office/home office (SOHO) support to Business-to-Business (B2B) communications. Almost as soon as the technology became available, organizations of nearly all business verticals began implementing VPNs in some form or another. Regardless of the business type or market, VPNs seem to permeate all walks of life in the communications environment. They meet several needs for expanded communications and typically can be implemented in a manner that provides a quick return on investment.

Given the availability and scope of different products, implementing VPNs has never been easier. In many cases, VPNs are relatively easy to install and support. Many solutions are shrink-wrapped, in that products are aligned to provide what many companies wish to employ. This is not to imply that VPNs are simplistic, especially in large environments where they can become convoluted with the integration of routing protocols, access controls, and other Internetworking technologies. However, VPNs are, in essence, another form of communication platform and should be leveraged as such.

In addition to the assortment of products and generally known applications of VPNs, the excitement for the technology and the promise of secure communications are only matched by the confusion of which protocol to employ. There are several standards and types of VPNs available for the choosing, each with its own attributes that can accommodate various requirements of the solution differently than the next technology in line. Of course, each vendor has a rendition of that standard, and the method for employing it may be different from others supposedly building on the same foundations. Nevertheless, VPNs are very popular and are being deployed at an amazing rate. One can expect more of the same as time and technology advance.

VPNs are capable of providing a communication architecture that mimics traditional wide area networks. Mostly, these applications utilize the Internet to leverage a single connection to exchange data with multiple remote sites and users. Several virtual networks can be established by employing authentication, encryption, and policy, ultimately building a Web of virtual channels through the Internet.

Early in VPN interest, the Internet was considered unreliable and inconsistent. Until recently, the Internet's capabilities were questionable. Internet connections would randomly fail, data rates would greatly fluctuate, and it was generally viewed as a luxury and considered unmanageably insecure by many. In the light of limited Internet assurance, the concern of successfully transferring mission-critical, time-sensitive communications over the Internet greatly overshadowed security-related concerns. Who cared if one could secure it if the communication was too slow to be useful? As the general needs of the Internet grew, so did the infrastructure. The Internet is generally much more reliable and greater data rates are becoming more affordable. The greater number of Internet access points, increased speeds, better reliability, and advanced perimeter technology have all combined to entice the reluctant to entertain Internet-based VPNs for wide area communications.

In light of the inevitable expansion of adoption, this chapter addresses some concepts of using VPNs in a method that is not typically assumed or sold. Most certainly considered by VPN evangelists, the ideas described here are not new, but rather not common among most implementations. This chapter simply explores some ideas that can allow organizations to take advantage of environmental and technological conditions to amplify the functionality of their networks.

Key Advantages of VPNs

There are several reasons for an organization to deploy a VPN. These can include directives as simple as costs savings and increased functionality or access. Also, the reasoning may be more driven by controlling the access of extranets and the information they can obtain.

In any case, VPNs offer the quick establishment of communications utilizing existing Internet connections and provide flexibility of security-related services. Neither of these attributes are as clear-cut with conventional communications — specifically, Frame Relay (FR). It is difficult to compare the two technologies because the similarities diverge once one gets past virtual circuits; however, time and security can be discussed.

The allocation of FR circuits, especially new locations that do not have a connection to the provider, can be very time-consuming. In the event the network is managed by a third party, it may take excessive work to have a new permanent virtual circuit (PVC) added to the mix, assigned address space, and included in the routing scheme. In addition, every PVC costs money.

As far as security is concerned, the confidentiality of the data traversing the network is directly related to the provider of the communication. If no precautions are employed by the owner of the data prior to being injected onto the wide area network (WAN), the protection of the information is provided by the carrier and its interconnection relationship with other providers.

Time Is Money

In contrast to FR, in this example, VPNs can be quickly established and eliminated with very little administration. Take, for example, a company with an Internet connection and VPN equipment that wishes to establish a temporary link to another organization to obtain services. There could be currently thousands of other VPNs operating over the same connection to various remote sites and users. Even so, no physical changes need to be made and no equipment needs to be purchased — only the configuration needs to be modified to include another site. In recent history, this required a detailed configuration of each terminating point of the proposed VPN. Now, many products have extensive management capabilities that allow remote management of the VPNs. Some operate within the VPN, while others leverage management standards such as SNMPv3 for secured management over the Internet.

Given the ability to sever or create communications almost instantly, the advantages to an ever-changing communication landscape are obvious. It is not uncommon for a business to necessitate a temporary connection to another for the exchange of information. Advertising firms, consulting firms, information brokers, logistics organizations, and manufacturing companies all typically require or could take advantage of communications with their clients or partners. If the capability were there to quickly establish those communications to a controlled location, communications could be allowed to flow within a very short time frame. The same holds true once the relationship or requirement for connectivity has expired. The VPN can be removed without any concern for communication contracts, investment management, or prolonged continuance.

Security Is Money Too

The security a VPN provides may seem evident. The connection is established over the Internet, usually, and data is provided authentication and encrypted for protection while it traverses an open sea of vulnerabilities. However, some advantages are not as obvious. A good example is when multiple connections are required to various external organizations that may integrate at different locations throughout the enterprise.

A geographically large organization may have several connections to other organizations at several of its sites. There may be sites that have several different extranet connections, and in some cases, each connection may have its own router and FR service provider.

There are many security challenges in such environments. Access must be tightly controlled to eliminate attacks from either network into another, or even worse, an attack between extranets using the connectivity provided by the organization's network. Security is sometimes applied by access control lists (ACLs) on the router(s) that limit the activities available to the communication. For some organizations, security is provided by allocating a dedicated network behind a firewall. In many cases, this can suffice with centrally managed firewalls. The only problem is that many firewalls are expensive and it can be difficult to cost-justify their addition to networks with limited requirements or longevity.

In contrast, there are several cost-effective products, in many forms and sizes, that can be effectively deployed to provide secure, flexible VPNs. Now that IPSec services are available in routers, many can provide extensive VPN services along with basic communication, routing protocols, firewall services, authentication, and other attributes that enhance the final solution. Ultimately, a VPN policy can be quickly established and introduced into the router and can be used to control access through a single point. A policy uses specifics within the connection to identify certain communications and apply the appropriate security protection suite as well as limiting access into the network.

Merged Networks

VPNs were initiated into the industry for remote access solutions. Roaming users dialing into vast modem pools were usually provided toll-free numbers, or simply access numbers that they used to connect to the home office. The cost was time sensitive, as was building the remote access solution itself. VPNs allowed the remote user to connect to the Internet and establish a private channel to the home office. The Internet connection was not time sensitive and usually proved to be cost-effective. The cost savings were further realized at the home office in that a single device could support thousands of simultaneous users. This was a quantum leap from the traditional dial-in solution.

During this time, many organizations were considering using the same concept for network-to-network communication. This started in the form of supporting small remote offices or virtual offices for employees working from home. The advent of broadband Internet access for the private community catapulted the use of VPNs to capture the cost-efficient, high-bandwidth access available for homes and remote offices.

It soon became evident that the same concepts could be used to enhance the traditional WAN. The concept of supporting remote offices expanded to support larger and larger sites of the organization. Usually, VPNs were employed at sites that had limited communication requirements or bandwidth. The practice of migrating portions of an organization that had few communication requirements was because the thought is if the VPN fails, there will be negligible impact on business operations. Much of this is because of the unknowns of the Internet and VPN technology itself.

Many organizations today have Internet access points at several sites. These can be leveraged to create VPNs between other offices and partners. The advantages of a mixed WAN, built from traditional WAN technologies and VPNs, become evident under certain conditions.

Logical Independence

Companies usually have one or more corporate offices or data hubs that supply various services, such as e-mail and data management, to other branch offices, small remote offices, virtual home offices, and remote users. Communications between non-hub sites, such as branch offices, can be intensive for large organizations, especially when business units are spread across various sites.

Exhibit 45.1 illustrates a traditional network connecting sites to one another. An FR cloud provides connections through the use of PVCs. To accomplish this, the remote site must have access to the FR cloud. If the

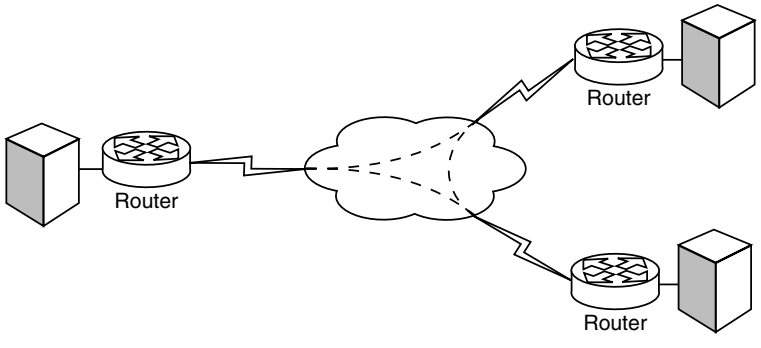

EXHIBIT 45.1 Traditional WAN environment.

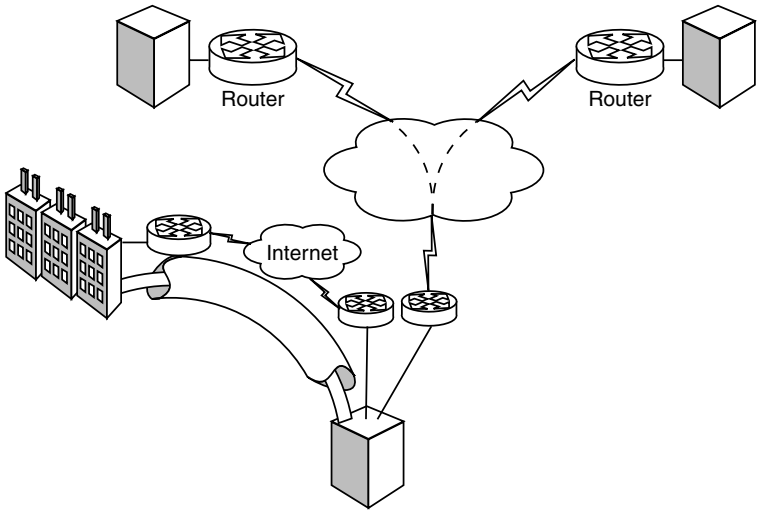

EXHIBIT 45.2 Basic VPN use.

FR service provider does not offer the service in a certain region, the organization may be forced to use another company and rely on the providers to interconnect the FR circuit. To avoid this, some organizations employ VPNs, usually because Internet connections are readily available.

As shown in Exhibit 45.2, a VPN can be quickly integrated into an FR-based WAN to provide communications. The site providing the primary Internet connection for the WAN can allow access to the centralized data. It is feasible to add many remote sites using a VPN. Once the initial investment is made at the corporate site, adding another site only incurs costs at the remote location.

It is worth noting that the VPN can now provide access to remote users from the corporate office, or access for managers to the remote office from home.

As depicted in Exhibit 45.3, the corporate site can be used as a gateway to the other locations across the WAN. In this example, it is obvious how closely the VPN mimics a traditional network. It is not uncommon for a central site to provide communications throughout the WAN. This configuration is usually referred to as "hub & spoke" and many companies employ a version of this architecture.

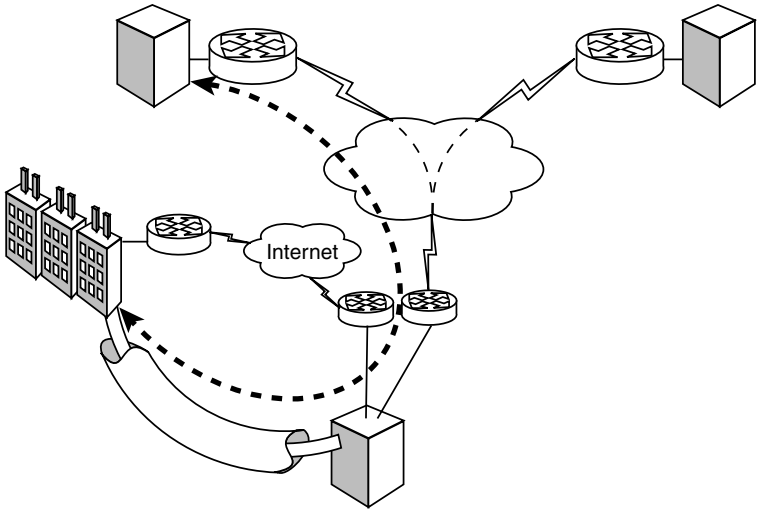

EXHIBIT 45.3 VPN integration.

As remote sites are added, the VPN can be leveraged as a separate WAN and the hub site treated as a simple gateway as with normal hub & spoke WAN operations. The VPN provides ample flexibility, cost savings, and some added advantages, including remote access support, while operating similarly to the customary WAN.

As companies grow, each site is usually provided an Internet connection to reduce the Internet traffic over the WAN. The reality is that more connections to the Internet simply equate to more points for the realization of threats. Nevertheless, organizations that have several connections to the Internet in their environment can leverage the VPN in ways not feasible in the FR world.

As seen in Exhibit 45.4, a VPN can be created to bypass the original corporate site and get to the final destination directly. What is even more interesting is that the process is automatic. For example, if the remote WAN site is addressed 10.10.10.0 and the corporate site providing the VPN termination is 20.20.20.0, the remote warehouse will make a request for 10.10.10.0. If there is only one VPN option, the request will be forwarded across the VPN to the 20.20.20.0 network where the WAN will provide the communication to the 10.10.10.0 network. However, if the 10.10.10.0 network has VPN capabilities, the remote warehouse can be easily configured to forward traffic to 10.10.10.0 to the site's VPN device. The same holds true for the 20.20.20.0 network.

Integration of Routing

Routing protocols are used in complex networks to make determinations in communication management. These protocols traverse the same communication channel as the user data and learn from the path taken. For example, distant-vector routing protocols base their metrics on the distance between sites, while link-state routing protocols ensure that the link is established. In either case, routing decisions can be made based on these basic fundamentals, along with administrative limitations such as cost and bandwidth utilization. These definitions are excessively simplistic; however, the goal is to convey that data is directed through networks based on information collected from the network itself.

Therefore, as traditional networks integrate VPNs, routing decisions take on new meaning. For example, for a five-site WAN that migrated three of them to VPNs, there are few decisions to make between the Internet-based sites. Because the communication conduit is virtual, the routing protocol only "sees" the impression of a circuit. As a routing protocol packet is injected into the data stream that is ultimately tunneled in a VPN, it is passed through a labyrinth of networks that interact with the packet envelope, while the original routing protocol packet is passed quietly in its cocoon. From the routing protocol's perspective, the network is perfect.

Putting aside the fact that the routing protocol is virtually oblivious to the vast networks traversed by the VPN, in the event of a system failure there will not be too many options on the Internet side of the router. If a remote system fails, an alternate route can be instantly constructed, rather than monitored for availability

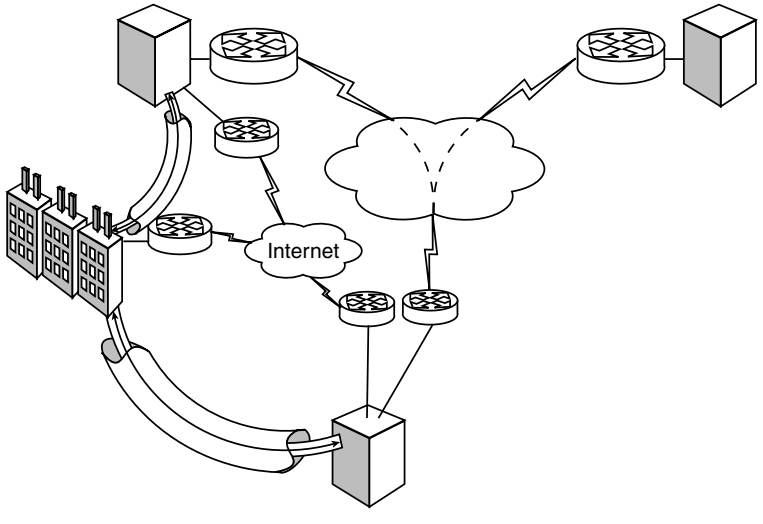

EXHIBIT 45.4 VPN providing logical freedom.

as with routing protocols. A connection can be created to another site that may have a subordinate route to the ultimate destination. This can include a traditional WAN link.

Policy-Based Routing

Some interesting changes are taking place to accommodate the integration of VPNs into conventional networks. The routing decisions are getting segmented and treated much differently. First, routing protocols are being used in simple networks where they are usually not in a traditional WAN, and routing decisions have moved to the edge devices providing the VPN. Meanwhile, the VPN cloud over the Internet is becoming a routing black hole.

To illustrate, OSPF (Open Shortest Path First) is a routing protocol that provides a hierarchical structure by the employment of Areas. Areas provide administrative domains and assist in summarizing routing information that ultimately interacts with Area 0. In this example network, there are three routers in Area 0 — Area Border Routers (ABRs) A, B, and C — each communicating by VPN. In addition to sharing information in Area 0, each has other routers in remote sites that make up supporting Areas.

As demonstrated in Exhibit 45.5, the Internet-based VPN is Area 0 and the remote site clusters represent three sub-areas (also referred to as stub, subordinate, and autonomous areas). Routing information regarding the network is shared between the sub-areas and their respective ABRs. The ABRs, in turn, share that information between them and ultimately with their supported sub-areas. In this scenario, the entire network is aware of communication states throughout and can make determinations based on that data. It is necessary that the ABRs share link information within Area 0 to ensure that sub-area routing data is provided to the other ABRs and sub-areas, and to ensure that the best, or configured, route is being used for that communication. For example, in a traditional WAN, it may be less expensive or simply easier to route from A to C through B. To accomplish this, or any other variation, the ABRs must share Area 0-specific information learned from the network.

Once a VPN is introduced into Area 0, the OSPF running between the ABRs is encapsulated. Therefore, information between Areas is being shared, but little is being learned from Area 0 between the ABRs. In reality, there is little to actually be gained. If the OSPF running between the ABRs were to learn from the network, it would be the Internet and little could be done to alter a route.

The result is that the routing protocol becomes a messenger of information between remote sites but has little impact on the virtual communications. To accommodate complicated VPNs and the fact that there is little to learn from the Internet — and what one can learn might be too complex to be utilized — policies can be created to provide alternates in communications. Because a virtual channel in a VPN architecture is, for the most part, free, one only needs to create a VPN when applicable.

VPN-Determined Routing

As described, in a conventional WAN, it may be applicable to route from A to C through B, especially if C's connection to A fails. Routing protocols observe the breakdown and can agree that re-routing through B is a

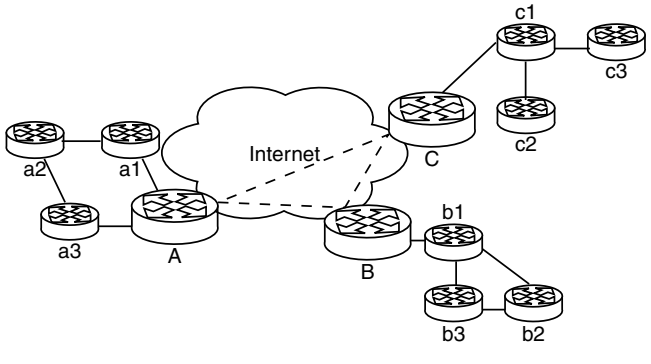

EXHIBIT 45.5 VPN effects on routed networks.

viable alternative. In a VPN, this can get more intense, depending on the configuration. For example, assume the Internet connection goes down at site C but there is a backup to site B, possibly through the supported Areas, such as a connection from c1 to b2. The ABRs know about the alternate route, but the cost is too great for normal use. When the Internet connection goes down, the VPN fails and the routing protocol cannot make a decision because there are literally no options to get across the VPN it is aware of. In short, the exit point for the data and routing protocols is simply an Internet interface. At that point, the VPN policy takes over and routes information through a particular VPN based on destination.

To accommodate this, VPN systems can learn from the routing protocols and include what is learned in the policy. Because the routing protocol is simply injected into an interface and the ultimate VPN it traverses is determined by a policy, the policy will conclude that a VPN between A and B can be leveraged because there is an alternate route between the A and C Areas between c1 and b2.

It is not necessary for the VPN to advertise its VPNs as routes to the routing protocol because they can be created or dropped instantly. The creation and deletion of routes can wreak havoc on a routing protocol. Many routing protocols, such as OSPF, do not converge immediately when a new route is discovered or an existing one is deleted, but it can certainly have an impact, depending on the frequency and duration with which the route appears and disappears.

The final hurdle in this complicated marriage between policy and routing protocol occurs when there are several connections to the Internet at one location. It is at this point that the two-pronged approach to routing requires a third influence. Typically, the Border Gateway Protocol (BGP) is used by ISPs to manage multiple connections to a single entity. The organization interfaces with the ISP's BGP routing tables to learn routes from the ISP to the Internet, as well as the ISP learning changes to the customer's premise equipment. The VPN systems must take the multiple routes into consideration; however, as long as the logical link between sites is not disrupted (such as with IP address changes), the VPN will survive route modifications.

Ultimately, it is necessary to understand that VPNs are typically destination-based routed and the termination point is identified by policy to forward the data to the appropriate VPN termination point. As VPN devices learn from routing protocols, they can become a surrogate for the routing protocol they learn from and provide a seemingly perfect conduit for the sharing of routing information.

Off-Loading the WAN

One of the most obvious uses for VPNs, yet not commonly seen in the field, is WAN off-loading. The premise is to leverage the VPN infrastructure as an augmentation to the WAN, rather than a replacement. VPNs can be implemented with little additional investment or complexity, and collaboration with a WAN will promote some interesting effects.

It is worth stating that when a VPN is implemented as a WAN replacement, the virtual nature of the new infrastructure lends itself to being leveraged easily. This is a prime example of leveraging VPNs. Take an existing infrastructure that may be originally put in place for remote access, mold it into a remote office support structure, and leverage that to provide WAN off-loading. Most of these concepts can be realized from the initial investment if the preliminary planning was comprehensive.

Time-Insensitive Communications

The title of this chapter section surely requires a second look. In today's technical environment, it seems that everything is time sensitive. However, there are applications that are heavily used by the populous of computer users that are not time sensitive.

E-mail is an example of an application that is not time sensitive, when compared to other applications such as chat. Interestingly enough, e-mail is a critical part of business operations for many companies, yet instant delivery is not expected, nor required. A few-minute wait for a message is nearly unnoticeable. In addition to being the lifeblood for organizations, in some cases, e-mail is used as a data-sharing platform. Everyone has witnessed the 5-MB attachment to 1334 recipients and the flood of flames that reflect back to the poor soul who started the whole thing. Of course, there are a few people who reply to all and inadvertently include the original attachment. The concept is made clear: e-mail can create a serious load on the network. It would not be out of line to state that some networks were engineered simply to enhance performance for enlarging e-mail requirements.

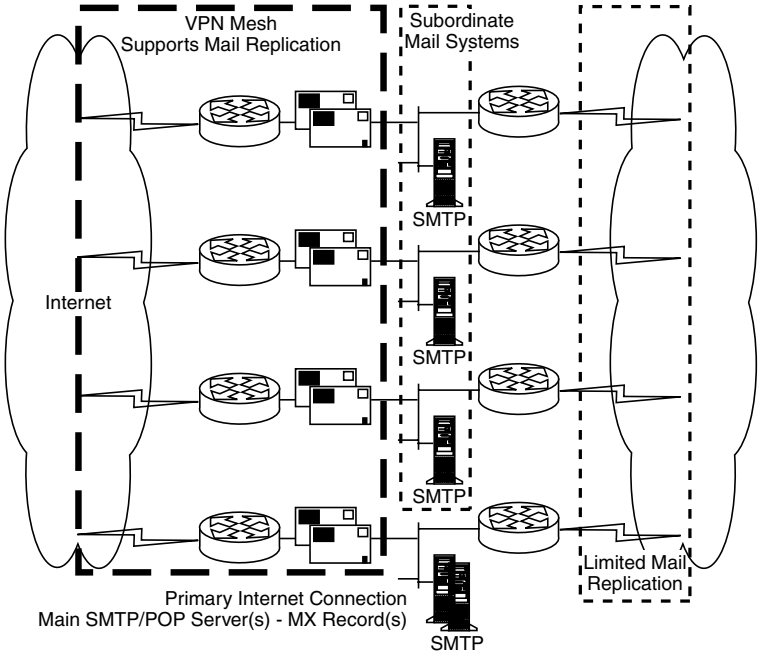

EXHIBIT 45.6 VPN providing alternate communication or specific applications.

A VPN network can be created to mirror the WAN and leveraged for the specific application. For example, in Exhibit 45.6, a VPN can provide the communication platform for the replication of e-mail throughout a domain.

In many e-mail infrastructures, collaboration between mail services is created to get e-mail to its final destination. The public mail service may be connected to the Internet at a single point at the corporate headquarters. As e-mail is received for a user in a remote site, the primary server will forward it to the service that maintains the user's mailbox for later delivery. The mail servers are connected logically and relationships are established, such as sites to collect servers into manageable groups.

The relationships between servers can be configured in such a manner as to direct the flow of data in a direction away from the normal communication channels and toward the VPN. The advantages should become clear immediately. Large attachments, large distributions lists, newsletters, and general communications are shunted onto the Internet where bandwidth restrictions may slow the progress, but the WAN is released from the burden.

Depending on the volume of e-mail relative to other data flows across the WAN, substantial cost savings can be realized above and beyond the original savings accrued during the initial VPN implementation. For example, if bandwidth requirements are reduced on the WAN, the cost can be reduced as well.

The concept of leveraging VPNs is especially significant for international companies that may use only a handful of applications across the expensive WAN links. Some large organizations use posting processes to reduce the load and align efforts around the globe by bulk processing. These packages can be delivered easily over a VPN, reducing the load on the less cost-effective WAN that is used for more time-sensitive applications.

Another example of posting is observed in the retail industry. Many companies are engineered to collect point-of-sale (POS) information and provide limited local processes such as credit card verification and local merchandise management. There comes a point when the information needs to be sent back to a home office for total processes to manage the business from a national or global scale. On one occasion, the communication was provided to the stores by satellite — nearly 120 stores nationwide. A router existed at each location to provide IP connectivity for the POS system, e-mail, and in some cases, phone lines. Between the cost of the VSAT service and the ground-station equipment, an Internet connection and VPN saved nearly 40 percent in costs and the bandwidth was increased by 50 percent. The result was that the posting took much less time, ultimately freeing up cycles on the mainframe for processing, which at the time was becoming crucial.

In addition to fulfilling several needs with a single solution — increased bandwidth and greater efficiency in processing — each store now had VPN capabilities. As the POS application capabilities increased, store-to-store determination could be made directly for regional product supply. That is, the register scanner can locate the nearest store to that location that has the product a customer desires without contacting the corporate office. This is not revolutionary, but the creation of a dynamic VPN for that transaction is.

Security is the final off-loading advantage. Of course, security is a huge selling point for VPNs and the words rarely appear separate from each other. However, this chapter addresses leveraging of the communication technology rather than the implied security. But security is a tangible asset. For example, the e-mail off-load illustration can be configured to protect e-mail in transit. A VPN can be created between each mail server at the operating system level, resulting in the encryption of all inter-domain exchanges. Although mail encryption programs are widely available, many users simply do not use them. When an organization finally gets users to encrypt messages, an administrative key should be included to avoid data loss in the face of a disgruntled employee.

Somewhere in between exists the security advantage of VPNs. Inter-domain traffic is encrypted and users are none the wiser. Of course, this cannot be directly compared to PGP (Pretty Good Privacy) or Certificates, but it keeps the general observer from accessing stray e-mail. For every e-mail system that does not employ encryption for inter-domain delivery, the e-mail is exposed at all points — on the Internet and intranet.

Fail-over

One of the interesting aspects of VPNs is that once they are in place, a world of options begins to open. By multiplexing several virtual connections through a single point — which can also be considered a single cost — the original investment can be leveraged for several other opportunities.

An example is WAN fail-over. WAN fail-over is much like the merger of VPNs and WANs; however, the VPN can provide an alternate route for some or all of the original traffic that would normally have been blocked due to a failure somewhere in the WAN infrastructure.

Consider the following example. A service provider (SP), called Phoenix, that provides not only application services but also FR services to various clients nationwide has a plethora of client and service combinations. Some clients purchase simple FR services, while others use the SP for Internet access. Of these clients, many are end users of applications, such as ERP systems, human resource systems, e-mail, kiosks, off-site storage, and collaboration tools. To maintain the level of service, Phoenix maintains a network operations center (NOC) that provides network management and support for the clients, applications, and communications.

For the FR customers that use the provided communication to access the applications, a VPN can be implemented to support the application in the event the FR were to fail. Many organizations have Internet connections as well as dedicated communications for vital application requirements. Therefore, leveraging one against the other can present great fault tolerance opportunities. This is relatively easy to configure and is an example of how to use the Internet with VPN technology to maintain connectivity.

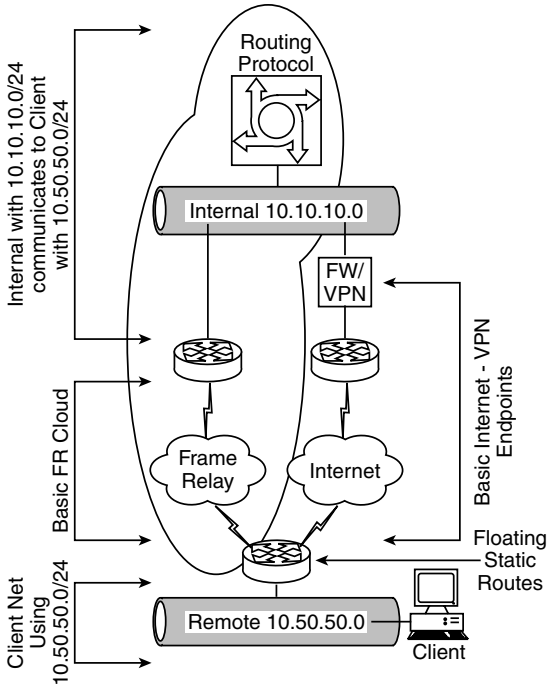
As shown in Exhibit 45.7, a dedicated connection can be created in concert with an Internet connection.

At Phoenix, there exists the standard FR cloud to support clients. This network is connected to the NOC via the core switch. Connected to the switch is the VPN provisioning device. In this example, it is a firewall as well, which provides Internet connectivity. On the client network, there is a router that has two interfaces: one for the dedicated circuit connection and the other to the Internet.

Based on the earlier discussion of routing protocols and VPNs, it does not help to operate routing protocols over the VPN. In reality, it is impossible in this case for two very basic reasons. The routing protocol used is multicast based and many firewalls are multicast unfriendly. Also, it is not a very secure practice to permit routing protocols through a firewall, even if it is for a VPN.

To accommodate the routing protocol restrictions, two design aspects are employed. First is a routing protocol employed as normal through the FR cloud to maintain the large number of customers and their networks. Second, floating static routes are employed on the customer's router. Essentially, a floating static route moves up the routing table when an automated route entry is deleted. For example, if a route is learned by OSPF, it will move to the top of the routing table. If the route is no longer valid and OSPF deletes the route from the routing table, the static route will take precedence.

The solution operates normally, with OSPF seeing the FR as the primary communication (based on administrative cost) back to Phoenix. In the event that a circuit fails, OSPF will delete the route in the client's routing table that directs traffic toward the FR cloud and the Internet route will take over. As a



Note: Here, one router on the client's network provides communication to the Internet as well as to Phoenix. This is shown for simplicity. It is possible that several routers can be used in the configuration with no functional impact.

EXHIBIT 45.7 VPN providing alternate communication or specific applications.

packet, which is destined for the SP, is injected into the interface, the VPN policy will identify the traffic and create a VPN with the SP. Once the VPN is created, data flows freely across the VPN onto the SP's network. As the data returns toward the client, it knows to go to the VPN device because the FR router on their side has performed the same routing deductions and forwards the packet to the VPN device.

The fail-over to the VPN can take some time, depending on how fast the VPN can be established. In contrast, the fail-back is instant. As the FR circuit comes back online, OSPF monitors the link and, once the link is determined to be sound, the routing protocol places the new route back into the routing table. From this point, the traffic simply starts going through the FR cloud. Interestingly, if the FR circuit were to fail prior to the VPN lifetime expiration, the fail-over would be nearly instant as well. Because the VPN is idle, the first packet is sent immediately.

There are some issues with this design; two, in fact, are glaring. If the FR cloud were to completely fail, all the FR customers with VPN backup would request a VPN at the same time, surely overloading the VPN system. There are a couple of options to accommodate such a problem. A load management solution can be implemented that redirects traffic to a cluster of VPN devices, distributing the load across all systems. A cheaper method is to simply modify the VPN policy on the client router to go to a different VPN device than the next. In short, distribute the load manually.

The other issues come into play when the SP wants to implement an FR connection in a network that uses Internet routable IP addresses, or some other scheme. This normally would not be a problem, but there is customer premise equipment (CPE) that needs to be managed by the SP to provide the services. An example is an application gateway server. The NOC would have a set of IP addresses to manage devices over the FR, but after the fail-over, those IP addresses may change.

Similar to Exhibit 45.7, Exhibit 45.8 employs NAT (network address translation) to ensure that no matter the source IP address of the managed elements on the client's network, the SP's NOC will always observe the same IP address.

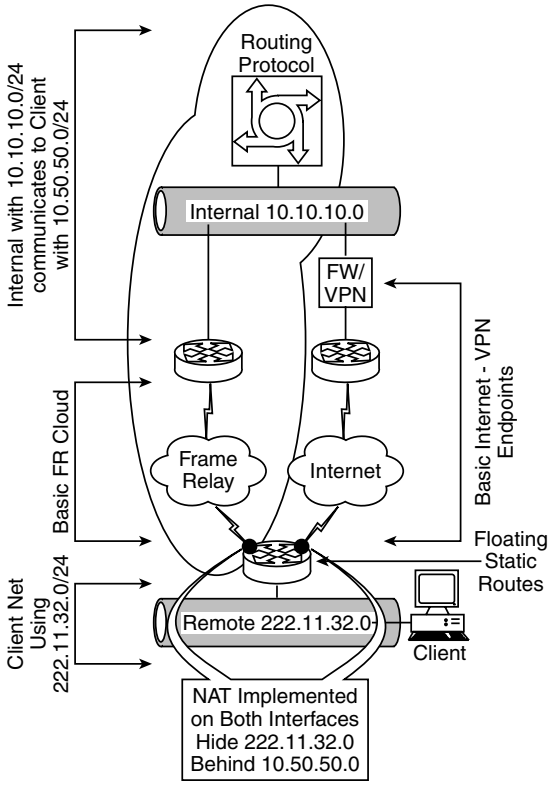


EXHIBIT 45.8 VPN fail-over using network address translation.

Conclusion

As VPNs were introduced to the technical community, network-to-network VPNs were the primary structure. Some vendors pushed the roaming user aspect of VPN technology. Remote user support became the character attached to VPN technology. This was because of the vendor focus, and the Internet was simply not seen as a safe medium.

Today, remote access VPNs are the standard, and the ability to support 5000 simultaneous connections is typical among the popular products. However, the use of VPN communications for conventional network infrastructures has not experienced the same voracious acceptance.

VPNs have been tagged as the "secure remote access" solution, and the value of a virtual connection through a public network has yet to be fully discovered. VPNs are a network and can be treated as such. As long as the fundamentals are understood, accepted, and worked with in the final design, the ability to salvage as much functionality will become apparent.

46

Wireless LAN Security

Mandy Andress, CISSP, SSCP, CPA, CISA

Wireless LANs provide mobility. Who does not want to be able to carry his laptop to the conference room down the hall and still have complete network access without worrying about network cables? Manufacturing companies are even using wireless LANs (WLANs) to monitor shop-floor machinery that is not traditionally accessible by network cabling. Increased mobility and accessibility improves communication, productivity, and efficiency. How much more productive could a team meeting be if all participants meeting in the conference room still had access to the network and the files relating to the project being discussed?

Wireless LANs can also provide a cost benefit. Installing and configuring wired communications can be costly, especially in those hard-to-reach areas. Ladders, drop ceilings, heavy furniture, knee pads, and a lot of time are often necessary to get all components installed and connected properly. By comparison, wireless LAN installations are a breeze. Plug in the access point, install a wireless NIC, and one is all set. An access point is the device that acts as a gateway for wireless devices. Through this gateway, wireless devices access the network. See Exhibit 4646.1 for an illustration.

The increased mobility and cost-effectiveness make wireless LANs a popular alternative. The Gartner Group has predicted that wireless LAN revenue would total $487 million in 2001, and the value of installed wireless LANs will grow to $35.8 billion by 2004. The Cahners In-Stat Group has predicted that the wireless LAN market will grow 25 percent annually over the next few years, from $771 million in 2000 to $2.2 billion in 2004. While these estimates are quite different, they share one common theme: a significant number of new wireless LANs will be deployed and existing installations will be expanded. This growth will occur because increases in speed, decreases in price, and the adoption of a formal standard with broad industry support have all occurred in the past few years.

Standards

Before discussing security issues with wireless LANs, a discussion of the standards that are the basis for communication is in order. In June 1997, the IEEE (Institute of Electrical and Electronic Engineers) finalized the initial standard for wireless LANs, IEEE 802.11. This standard specifies a 2.4-GHz operating frequency with data rates of 1 and 2 Mbps and the ability to choose between using frequency hopping or direct sequence, two noncompatible forms of spread spectrum modulation. In late 1999, the IEEE published two supplements to the initial 802.11 standard: 802.11a and 802.11b.

Like the initial standard, 802.11b operates in the 2.4-GHz band, but data rates can be as high as 11 Mbps and only direct sequence modulation is specified. The 802.11a standard specifies operation in the 5-GHz band using OFDM (orthogonal frequency division multiplexing) with data rates up to 54 Mbps. Advantages of this standard include higher capacity and less RF interference with other types of devices.

Standards 802.11a and 802.11b operate in different frequencies; thus, there is little chance they will be interoperable. They can coexist on one network, however, because there is no signal overlap. Some vendors claim they will provide a dual-radio system with 802.11a and 802.11b in the future.

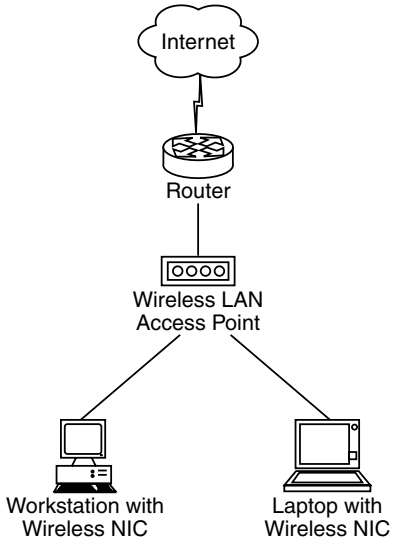

EXHIBIT 46.1 Wireless access points server as the network gateway.

To complicate issues, Europe has developed the HiperLAN/2 standard, led by the European Telecommunications Standards Institute (ETSI). HiperLAN/2 and 802.11a share some similarities: both use OFDM technology to achieve their data rates in the 5-GHz range, but they are not interoperable.

For the remainder of this chapter, discussions will focus on 802.11b wireless LANs because they comprise the current installed base.

Security Issues

Wireless LANs have major security issues. Default configurations, network architecture, encryption weaknesses, and physical security are all areas that cause problems for wireless LAN installations.

Default Installations

Default installations of most wireless networks allow any wireless NIC to access the network without any form of authentication. One can easily drive around with laptop in hand and pick up many network connections. Because this vulnerability is so prevalent, "war driving" is quickly replacing "war dialing" as the method of finding backdoors into a network. Wireless LAN administrators may realize that radio waves are easier to tap passively than cable, but they may not realize just how vulnerable they really are.

Wireless ISPs must be very conscious of their wireless network configurations. If someone is able to access their networks without authentication, they are essentially stealing service. The wireless ISP is losing revenue and the illegal user is taking up valuable bandwidth.

Once a user gains access to the wireless network, whether authorized or unauthorized, the only things preventing him from accessing unauthorized servers or applications are internal security controls. If these are weak or nonexistent, an unauthorized user could easily gain access to one's network through the wireless LAN and then gain complete control of one's network by exploiting internal weaknesses.

Denial-of-service attacks are also a very real threat to wireless networks. If running a mission-critical system on a wireless network, attackers do not need to gain access to any system to cause damage and financial harm to an organization; they just need to flood the network with bogus radio transmissions.

Mitigating Risk

To use wireless LANs in an enterprise or production environment, one must mitigate the inherent risk in current products and standards. Enterprise-level wireless LAN security focuses on two issues: network access

must be limited to authorized users, and wireless traffic should be protected from sniffing. The 802.11b standard does include some security mechanisms, but their scalability is questionable.

MAC Address

One way to secure access to a wireless network is to instruct access points to pass only those packets originating from a list of known addresses. Of course, MAC (Media Access Control) addresses can be spoofed, but an attacker would have to learn the address of an authorized user's Ethernet card before this is successful. Unfortunately, many wireless cards have the MAC address printed right on the face of the card.

Even if the user and administrator can secure the card address, they still have to compile, maintain, and distribute a list of valid MAC addresses to each access point. This method of security is not feasible in a lot of public WLAN applications, such as those found in airports, hotels, and conferences, because they do not know their user community in advance. Additionally, each brand of access point has some limit on the number of addresses allowed.

Service Set ID

Another setting on the access point that can be used to restrict access is the network name, also known as the SSID (Service Set ID). An access point can be configured to allow any client to connect to it or to require that a client specifically request the access point by name. Although this was not meant primarily as a security feature, setting the access point to require the SSID can let the ID act as a shared group password.

As with any password scheme, however, the more people who know the password, the higher the probability that an unauthorized user will misuse it. The SSID can be changed periodically, but each user must be notified of the new ID and reconfigure his wireless NIC.

Wired Equivalent Privacy (WEP)

The 802.11b standard provides encrypted communication between clients and access points via WEP (Wired Equivalent Privacy). Under WEP, users of a given access point often share the same encryption key. To achieve mobility within a campus, all access points must be set to use the same key and all clients have the same encryption key as well. Additionally, data headers remain unencrypted so that anyone can see the source and destination of data transmission.

WEP is a weak protocol that uses 40- and 128-bit RC4. It was designed to be computationally efficient, self-synchronizing, and exportable. These are the characteristics that ultimately crippled it. The following are just a few of the attacks that could easily be launched against WEP:

- Passive attacks to decrypt traffic based on statistical analysis
- Active attacks to inject new traffic from unauthorized mobile stations, based on known plaintext
- Dictionary-building attack that, after analysis of about a day's worth of traffic, allows real-time automated decryption of all traffic

With these limitations, some vendors do not implement WEP, although most provide models with and without it. An access point can be configured to never use WEP or to always require the use of WEP. In the latter case, an encrypted challenge is sent to the client. If the client cannot respond correctly, it will not be allowed to use the access point, making the WEP key another password. As with using the SSID as a password, the administrator could routinely change the WEP key, but would have the same client notification and configuration issues.

Of course, an attacker possessing the WEP key could sniff packets off the airwaves and decrypt them. Nonetheless, requiring WEP substantially raises the minimum skillset needed to intercept and read wireless data.

Authentication Solutions

Some vendors offer proprietary solutions to the authentication/scalability problem. The wireless client requests authorization from the access point, which forwards the request to a RADIUS server. Upon authorization, the RADIUS server sends a unique encryption key for the current session to the access point, which transmits it to the client. While this standard offers a solution to the shared key problem, it currently requires an organization to buy all the equipment from one vendor. Other vendors use public key cryptography to generate per-session keys.

This authentication solution resembles pre-standard implementations of the pending IEEE 802.1x standard that will eventually solve this problem in a vendor-interoperable manner. The 802.1x standard is being developed as a general-purpose access-control mechanism for the entire range of 802 technologies. The authentication mechanism is based on the Extensible Authentication Protocol (EAP) in RADIUS. EAP lets a client negotiate authentication protocols with the authentication server. Additionally, the 802.1x standard allows encryption keys for the connection to be exchanged. This standard could appear in wireless products as early as 2002.

While waiting for 802.1x, there are a few other approaches the administrator can take to increase the security of a wireless LAN.

Third-Party Products

Several products exist to secure wireless LANs. For example, WRQ's NetMotion (www.netmotionwireless.com) requires a user login that is authenticated through Windows NT. It uses better encryption (3DES and Twofish) than WEP and offers management features such as the ability to remotely disable a wireless network card's connection. One of the main issues with this solution is that the server currently must run on Windows NT and client support is only provided for Windows 95, 98, ME, and CE. Support for Windows 2000 server and client is currently under development.

Gateway Control

Gateway solutions create special sub-nets for wireless traffic. Instead of using normal routers, these sub-nets have gateways that require authentication before packets can be routed. The sub-nets can be created with VLAN technology using the IEEE 802.1Q standard. With this standard, administrators can combine selected ports from different switches into a single sub-net. This is possible even if the switches are geographically separated as long as VLAN trunking is supported on the intervening switches. Nodes that use VLAN ports cannot access addresses on other sub-nets without going through a router or gateway, even if those other sub-nets are located on the same physical switch as the VLAN ports.

Once the VLAN is established, administrators need to create a gateway that will pass traffic only from authorized users. A VPN gateway can be used because the function of a VPN server is to require an endpoint. Using a VPN server as the gateway not only requires authentication of the tunnel endpoint, but it also encrypts the wireless stream with a key unique to the tunnel, eliminating the need to use the shared key of WEP.

The VPN approach is hardly ideal, however. Understanding VPN technology, selecting a VPN gateway, configuring the server, and supporting clients are complex tasks that are not easy for the average LAN administrator to accomplish.

Another solution, currently used by Georgia Tech, uses a special firewall gateway. This approach still uses the VLAN approach to aggregate wireless traffic to one gateway; but instead of being a VPN, this gateway is a dual-homed UNIX server running specialized code. The IT staff at Georgia Tech uses the IP Tables firewall function in the latest Linux kernel to provide packet filtering. When a system joins the wireless network, the firewall/router gives it a DHCP address. To authorize access, the client must open a Web browser. The HTTP request from the client triggers an automatic redirect authentication page from the gateway and the authentication request is passed to a Kerberos server. If authentication is successful, a Perl script adds the IP address to the rules file, making it a "known" address to the IP Tables firewall process.

From the user's perspective, he must launch a browser and enter a userid and password to gain access to the network. No client installation or configuration is required. Of course, this method only provides authentication — not encryption — and will not scale over a few hundred simultaneous users. This solution

is unique and elegant in the fact it allows complete on-the-fly network access without making any changes to the client, and it supports network cards from multiple vendors. This configuration is very useful in public WLAN applications (airports, hotels, conferences, etc.).

Conclusion

Wireless LANs have several security issues that preclude them from being used for highly sensitive networks. Poor infrastructure design, unauthorized usage, eavesdropping, interception, DoS attacks, and client system theft are all areas that one needs to analyze and consider. One can mitigate these risks by wrapping the communication in a VPN or developing one's own creative solution, but this can be complicated. New advancements in wireless technology, along with changes in the WEP standard, may improve security as well as usability.

EXPANDING INTERNET SUPPORT WITH IPV6

Gilbert Held

INSIDE

New and Renamed IPv6 Fields; Header Chains; Addressing; IPv6 Address Notation; Address Assignments; Migration Issues

OVERVIEW

The ability to obtain an appreciation for the functionality of IPv6 is best obtained by comparing its header to the IPv4 header. Exhibit 1 provides this comparison, showing the IPv4 header at the top of the illustration, with the IPv6 header below.

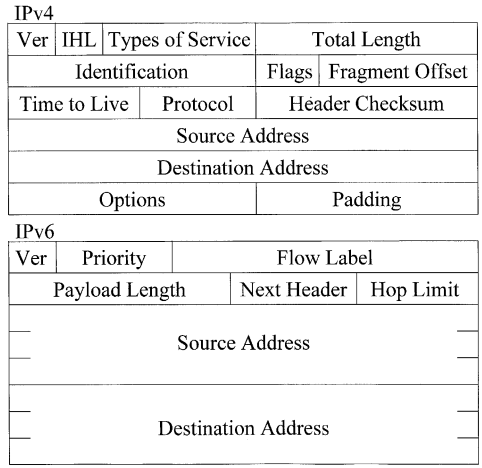
In comparing the two headers shown in Exhibit 1, one notes that IPv6 includes six less fields than the current version of the Internet Protocol. Although at first glance this appears to make an IPv6 header simpler, in actuality the IPv6 header includes a Next Header field that enables one header to point to a following header, in effect resulting in a daisy chain of headers. While the daisy chain adds complexity, only certain routers need to examine the contents of different headers, facilitating router processing. Thus, an IPv6 header, which can consist of a sequence of headers in a daisy chain, enables routers to process information directly applicable to their routing requirements. This makes IPv6 packet processing much more efficient for intermediate routers when data flows between two Internet locations, enabling those routers to process more packets per second than when the data flow consists of IPv4 headers.

A close examination of the two IP headers reveals that only one field kept the same meaning and position. That field is the Version field, which

PAYOFF IDEA

The next-generation Internet Protocol will significantly enhance the ability of the Internet in terms of device addressing, router efficiency, and security. Although the actual implementation of IPv6 is still a few years away, most network managers and administrators will eventually be tasked with planning migration strategies that will enable their organizations to move from the current version of the Internet Protocol to the next-generation Internet Protocol, IPv6. Due to this, it is important to obtain an appreciation for the major characteristics of IPv6, which will then serve as a foundation for discussing migration methods that can be considered to take advantage of the enhanced functionality of the next-generation Internet Protocol.

EXHIBIT 1 — Comparing IPv4 and IPv6



is encoded in the first four bits of each header as a binary value, with 0100 used for IPv4 and 0110 for IPv6.

Continuing the comparison of the two headers, note that IPv6 does away with seven IPv4 fields. Those fields include the Type of Service, Identification, Flags, Fragment Offset, Checksum, Options, and Padding. Because headers can be daisy chained and separate headers now identify specific services, the Type of Service field is no longer necessary. Another significant change between IPv4 and IPv6 concerns fragmentation, which enables senders to transmit large packets without worrying about the capabilities of intermediate routers. Under IPv4, fragmentation required the use of Identification, Flags, and Fragment Offset fields. Under IPv6, hosts learn the maximum acceptable segment size through a process referred to as path MTU (maximum transmission unit) discovery. Thus, this enabled the IPv6 designers to remove those three fields from the new header.

Another difference between IPv4 and IPv6 headers involves the removal of the Header Checksum. In an era of fiber backbones it was thought that the advantage obtained from eliminating the processing associated with performing the header checksum at each router was considerably more than the possibility that transmission errors would go undetected. In addition, since the higher layer (transport layer) and lower layer (IEEE 802 networks) perform checksum operations, the risk of undetected error at the network layer adversely affecting operations is minimal. Two more omissions from the IPv4 header are the Options and Padding fields. Both fields are not necessary in IPv6 because the use of

optional headers enables additional functions to be specified as separate entities. Since each header follows a fixed format, there is also no need for a variable Padding field, as was the case under IPv4.

Perhaps the change that obtains the most publicity is the increase in source and destination addresses from 32 bit fields to 128 bit fields. Through the use of 128-bit addressing fields, IPv6 provides the potential to supply unique addresses for every two- and four-footed creature on Earth and still have enough addresses left over to assign a unique address to every past, present, and future appliance. Thus, the extra 96 bit positions virtually ensures that one will not experience another IP address crunch such as the one now being experienced with IPv4.

NEW AND RENAMED IPV6 FIELDS

IPv6 adds three new fields while relabeling and slightly modifying the use of Total Length and Time to Live fields in Ipv4. Concerning the renamed and revised fields, the Total Length field in IPv4 was changed to a Payload Length. This subtle difference is important, as the use of a payload length now specifies the length of the data carried after the header instead of the length of the sum of both the header and data. The second revision represents the recognition of the fact that the Time to Live field under IPv4, which could be specified in seconds, was difficult — if not impossible — to use due to a lack of time-stamping on packets. Instead, the value used in that field was decremented at each router hop as a mechanism to ensure packets did not endlessly flow over the Internet, since they are discarded when the value of that field reaches zero. In recognition of the actual manner by which that field is used, it was renamed the Hop Limit field under IPv6.

The Priority field is four bits wide, enabling 16 possible values. This field enables packets to be distinguished from one another based on their need for processing precedence. Thus, file transfers would be assigned a low priority, while realtime audio or video would be assigned a higher priority.

Under IPv6, priority field values of 0 through 7 are used for traffic that is not adversely affected by backing off in response to network congestion. In comparison, values 8 to 15 are used for traffic that would be adversely affected by backing off when congestion occurs, such as realtime audio packets being transmitted at a constant rate. Exhibit 2 lists the priority values recommended for different types of congestion-controlled traffic.

Priorities 8 through 15 are used for traffic that would be adversely affected by backing off when network congestion occurs. The lowest priority value in this group, 8, should be used for packets one is most willing to discard under congestion conditions. In comparison, the highest priority, 15, should be used for packets one is least willing to have discarded.

EXHIBIT 2 — Recommended Congestion-Controlled Priorities

Priority	Type of Traffic
0	Uncharacterized traffic
1	Filter traffic, such as Netnews
2	Unattended data transfer (i.e., e-mail)
3	Reserved
4	Attended bulk transfer (i.e., FTP, HTTP)
5	Reserved
6	Interactive traffic (i.e., telnet)
7	Internet controlled traffic (i.e., SNMP)

The Flow Label field, also new to IPv6, allows packets that require the same treatment to be identified. For example, a realtime video transmission that consists of a long sequence of packets would more than likely use a Flow Label identifier as well as a high priority value so that all packets that make up the video are treated the same, even if other packets with the same priority arrive at the same time at intermediate routers.

HEADER CHAINS

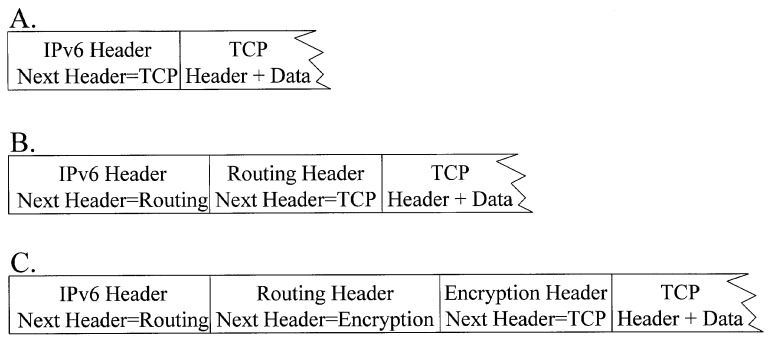
The ability to chain headers is obtained through the use of the IPv6 Next Header field. Currently, the IPv6 specification designates six extension headers. Those headers and a brief description of the functions they perform are listed in Exhibit 3.

To illustrate how the Next Header field in IPv6 is actually used, one can use a few of the headers listed in Exhibit 4 to create a few examples. First, assume that an IPv6 header is followed directly by a TCP header and data, with no optional extension headers. Then, the Next Header field in the IPv6 header would indicate that the TCP header follows as indicated in Exhibit 4A.

EXHIBIT 3 — IPv6 Extension Headers

Extension Header	Description
Hop by hop options	Passes information to all routers in a path
Routing	Defines the route through which a packet flows
Fragment	Provides information that enables destination address to concatenate fragments
Authentication	Verifies the originator
Encrypted security payload	Defines the algorithm and keys necessary to decrypt a previously encrypted payload
Destination options	Defines a generic header that can obtain one or more options identified by options type that can define new extensions on an as-required basis

EXHIBIT 4 — Creating a Daisy Chain of Headers



For a second example, assume that one wants to specify a path or route the packet will follow. To do so, one would add a Routing Header, with the IPv6's Next Header field containing a value that specifies that the Routing Header follows. Then, the Routing Header's Next Header field would contain an appropriate value that specifies that the TCP header follows. This header chain is illustrated in Exhibit 4B.

For a third example, assume one wants to both specify a route for each packet as well as encrypt the payload. To accomplish this, one would change the TCP Header's Next Header field value from the previous example where it indicates that there are no additional headers in the header chain, to a value that serves to identify the Encryption Header as the next header.

Exhibit 4C illustrates the daisy chain of IPv6 headers that would specify that a specific route is to be followed and the information required to decrypt an encrypted payload. Now that one has an appreciation for the general format of the IPv6 header, the use of its header fields, and how headers can be chained to obtain additional functionality, one can focus attention on addressing under IPv6.

ADDRESSING

Under IPv6, there are three types of addresses supported: unicast, multicast, and anycast. The key difference between IPv6 and IPv4 with respect to addressing involves the addition of an anycast type address and the use of 128 bit source and destination addresses.

An anycast address represents a special type of multicast address. Like a multicast address, an anycast address identifies a group of stations that can receive a packet. However, under an anycast addres, only the nearest member of a group receives the packet instead of all members. It is ex-

pected that the use of anycast addressing will facilitate passing packets from network to network as it allows packets to be forwarded to a group of routers without having to know which is the one nearest to the source. Concerning the actual 128 bit address used under IPv6, its expansion by a factor of four over IPv4 resulted in the necessity to introduce methods to facilitate the notation of this expanded address. Thus, the methods by which IPv6 addresses can be noted can be examined.

IPV6 ADDRESS NOTATION

Under IPv4, a 32-bit IP address can be encoded as eight hexadecimal digits. The expansion of the IP address fields to 128 bits results in a requirement to use 32 hexadecimal digits. However, because it is fairly easy to make a mistake that can go undetected by simply entering a long sequence of 32 digits, IPv6 allows each 128 bit address to be represented as eight 16-bit integers separated by colons (:). Thus, under IPv6 notation, one can represent each integer as four hexadecimal digits, enabling a 128 bit address to be encoded or noted as a sequence of eight groups of four hexadecimal digits separated from one another by a colon. An example of a IPv6 address follows:

AB01:0000:OO1A:000C:0000:0000:3A1C:1B1F

Two methods are supported by IPv6 addressing that can be expected to be frequently used by network managers and administrators when configuring network devices. The first method is zero suppression, which allows leading zeros in each of the eight hexadecimal groups to be suppressed. Thus, the application of zero suppression would reduce the previous IPv6 address as follows:

AB01:0:1A:C:0:0:3A1C:1B1E

A second method supported by IPv6 to facilitate the use of 128 bit addresses recognizes that during a migration process, many IPv4 addresses carried within an IPv6 address field will result in a considerable sequence of zero bit positions that cross colon boundaries. This zero density situation can be simplified by the use of a double colon (::), which can replace a single run of consecutive zeros. Thus, one can further simplify the previously zero suppressed IPv6 address as follows:

AB01:0:1A:C::3A1C:1B1E

Note that the use of the double colon can only occur once in an IPv6 address. Otherwise, its use would produce an ambiguous result because there would be no way to tell how many groups of four hexadecimal zeros a double colon represents.

EXHIBIT 5 — Initial IPv6 Address Space Allocation

Address Space Allocation	(binary)	Prefix Fraction of Address Space
Reserved	0000 0000	1/256
Unassigned	0000 0001	1/256
Reserved for NSAP allocation	0000 001	1/128
Reserved for IPX allocation	0000 010	1/128
Unassigned	0000 011	1/128
Unassigned	0000 1	1/32
Unassigned	0001	1/16
Unassigned	001	1/8
Provider-based unicast address	010	1/8
Unassigned	011	1/8
Reserved for geographic-based unicast addresses	100	1/8
Unassigned	101	1/8
Unassigned	110	1/8
Unassigned	1110	1/16
Unassigned	1111 0	1/32
Unassigned	1111 10	1/64
Unassigned	1111 110	1/128
Unassigned	1111 1110 0	1/512
Link local use addresses	1111 1110 10	1/1024
Site local use addresses	1111 1110 11	1/1024
Multicast addresses	1111 1111	1/256

ADDRESS ASSIGNMENTS

With 2^{128} addresses available for assignment, IPv6 designers broke the address space into an initial sequence of 21 address blocks, based on the use of binary address prefixes. As one might surmise, most of the address blocks are either reserved for future use or unassigned because even a small fraction of IPv6 address space is significantly larger than all of the IPv4 address space. Exhibit 5 provides a list of the initial IPv6 address space allocation. Of the initial allocation of IPv6 address space, probably the most important will be the provider-based unicast address. As noted in Exhibit 5, the prefix for this allocated address block is binary 010 and it represents one eighth ($^1/_8$) of the total IPv6 address space. The provider-based unicast address space enables the registry that allocates the address, the Internet service provider (ISP), and the subscriber to be identified. In addition, a subscriber can subdivide his address into a subnetwork and interface or host identifiers similar to the manner by which IPv4 class A through class C addresses can be subdivided into host and network identifiers. The key difference between the two is the fact that an extension to 128 bits enables an IPv6 address to identify organizations that assigned the address to include the registry and ISP. Concerning the registry, in North America, the Internet Network Information Center (Internet NIC) is tasked with distributing IPv4 addresses and can be expected to distribute IPv6 addresses. The European registry is the Network

Coordination Center (NCC) of RIPE, while the APNIC is responsible for distributing addresses for networks in Asian and Pacific countries.

MIGRATION ISSUES

After a considerable amount of deliberation by the Internet community, it was decided that the installed base of approximately 20 million computers using IPv4 would require a dual-stack migration strategy. Instead of one giant cutover sometime in the future, it was recognized that a considerable amount of existing equipment would be incapable of migrating to IPv6. Thus, an IPv6 Internet will be deployed in parallel to IPv4, and all IPv6 hosts will be capable of supporting IPv4. This means that network managers can decide both if and when they should consider upgrading to IPv6. Perhaps the best strategy is, that when in doubt, to obtain equipment capable of operating a dual stack, such as the one shown in Exhibit 5. In addition to operating dual stacks, one must consider one's network's relationship with other networks with respect to the version of IP supported. For example, if an organization migrates to IPv6, but its ISP does not, one will have to encapsulate IPv6 through IPv4 to use the transmission services of the ISP to reach other IPv6 networks. Fortunately, two types of tunneling — configured and automatic — have been proposed to allow IPv6 hosts to reach other IPv6 hosts via IPv4-based networks. Thus, between the use of a dual-stack architecture and configured and automatic tunneling, one will be able to continue to use IPv4 as the commercial use of IPv6 begins, as well as plan for an orderly migration.

RECOMMENDED COURSE OF ACTION

Although the first commercial use of IPv6 is still a few years away, an organization can prepare itself for Ipv6 use by ensuring that acquired hosts, workstations, and routers can be upgraded to support IPv6. In addition, one must consider the fact that the existing Domain Name Server (DNS) will need to be upgraded to support IPv6 addresses, and one must contact the DNS software vendor to determine how and when to implement IPv6 addressing support. By carefully determining the software and possible hardware upgrades, and by keeping abreast of Internet IPv6-related RFCs, one can plan a migration strategy that will allow an organization to benefit from the enhanced router performance afforded by IPv6 addressing.

INTRODUCTION

The components and resources of one network over another network are connected via a Virtual Private Network (VPN). As shown in Exhibit 1, VPNs accomplish this by allowing the user to tunnel through the Internet or another public network in a manner that lets the tunnel participants enjoy the same security and features formerly available only in private networks.

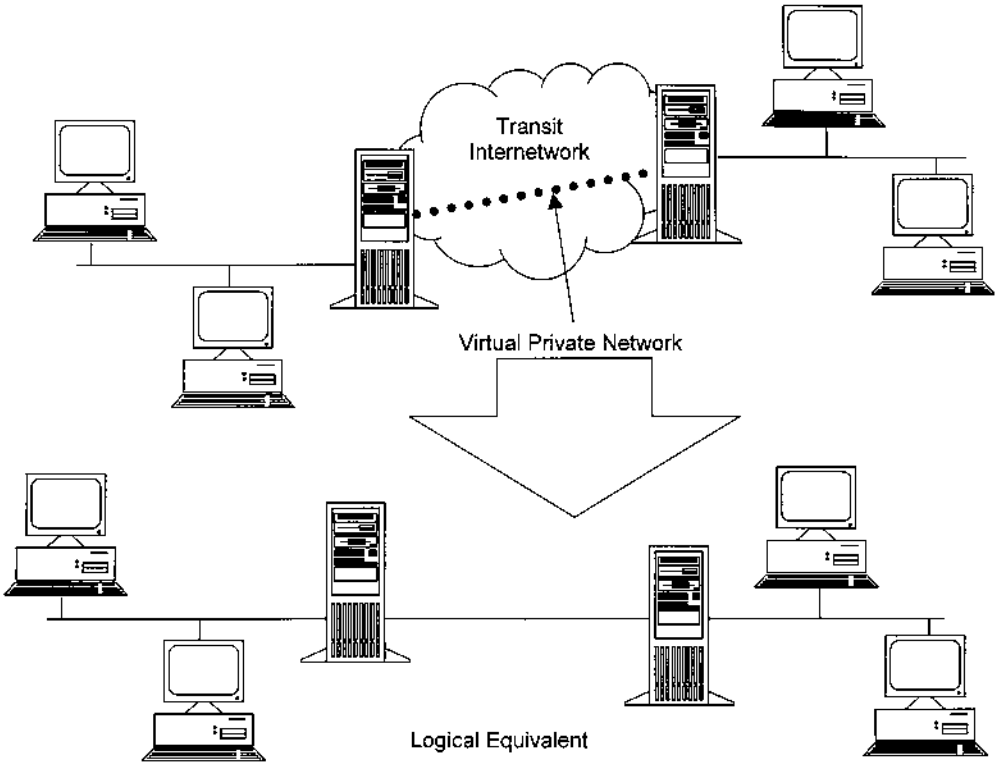
Using the routing infrastructure provided by a public internetwork (such as the Internet), VPNs allow telecommuters, remote employees like salespeople, or even branch offices to connect in a secure fashion to an enterprise server located at the edge of the enterprise local area network (LAN). The VPN is a point-to-point connection between the user's computer and an enterprise server

PAYOFF IDEA

There is no doubt about it: Virtual Private Networks (VPNs) are hot. Secure remote access over the Internet and telecommuting needs are escalating. Distributed enterprise models like extranets are also increasing. The use of VPN technologies by enterprises or corporations require pragmatic, secure Internet remote access solutions that must be easy to use, economical, and flexible enough to meet all of their changing needs. In this article, the reader will learn how enterprises or corporations like Microsoft; UUnet Technologies, Inc., Telco Research, and ATCOM, Inc. are saving more than $28 million every year by using VPNs to do secure remote access over the Internet by their traveling employees and sales reps. The reader will also learn how to make secure Internet remote access information technology (IT) solutions easy to use and easy to manage by telecommunications managers (TMs).

Auerbach Publications

EXHIBIT 1 — Virtual Private Network



from the user's perspective. It also appears as if the data is being sent over a dedicated private link because the nature of the intermediate internetwork is irrelevant to the user. As previously mentioned, while maintaining secure communications, VPN technology also allows an enterprise to connect to branch offices or to other enterprises (extranets) over a public internetwork (such as the Internet). The VPN connection across the Internet logically operates as a wide area network (WAN) link between the sites. In both cases, the secure connection across the internetwork appears to the user as a private network communication (despite the fact that this communication occurs over a public internetwork); hence the name Virtual Private Network.

VPN technology is designed to address issues surrounding the current enterprise trend toward increased telecommuting, widely distributed global operations, and highly interdependent partner operations. Here, workers must be able to connect to central resources and communicate with each other. And, enterprises need to efficiently manage inventories for just-in-time production.

An enterprise must deploy a reliable and scalable remote access solution to provide employees with the ability to connect to enterprise computing resources regardless of their location. Enterprises typically choose one of the following:

- an IT department-driven solution, where an internal information systems department is charged with buying, installing, and maintaining enterprise modem pools and a private network infrastructure
- value-added network (VAN) solutions, where an enterprise pays an outsourced enterprise to buy, install, and maintain modem pools and a telco infrastructure

The optimum solution in terms of cost, reliability, scalability, flexible administration and management, and demand for connections is provided by neither of these traditional solutions. Therefore, it makes sense to find a middle ground where the enterprise either supplements or replaces its current investments in modem pools and its private network infrastructure with a less-expensive solution based on Internet technology. In this manner, the enterprise can focus on its core competencies with the assurance that accessibility will never be compromised, and that the most economical solution will be deployed. The availability of an Internet solution enables a few Internet connections (via Internet service providers, or ISPs) and deployment of several edge-of-network VPN server computers to serve the remote networking needs of thousands or even tens of thousands of remote clients and branch offices, as described next.

VPN Common Uses

The next few subsections of this article describe in more detail common VPN situations.

Secure Remote User Access over the Internet. While maintaining privacy of information, VPNs provide remote access to enterprise resources over the public Internet. A VPN that is used to connect a remote user to an enterprise intranet is shown in Exhibit 2. The user first calls a local ISP Network Access Server (NAS) phone number, rather than making a leased-line, long-distance (or 1-800) call to an enterprise or outsourced NAS. The VPN software creates a virtual private network between the dial-up user and the enterprise VPN server across the Internet using the local connection to the ISP.

Connecting Networks over the Internet. To connect local area networks at remote sites, there exist two methods for using VPNs: using dedicated lines to connect a branch office to an enterprise LAN, or a dial-up line to connect a branch office to an enterprise LAN.

Using Dedicated Lines to Connect a Branch Office to an Enterprise LAN. Both the branch office and the enterprise hub routers can use a local dedicated circuit and local ISP to connect to the Internet, rather than using an expensive long-haul dedicated circuit between the branch office and the enterprise hub. The local ISP connections and the public Internet are used by the VPN software to create a virtual private network between the branch office router and the enterprise hub router.

Using a Dial-Up Line to Connect a Branch Office to an Enterprise LAN. The router at the branch office can call the local ISP, rather than having a router at the branch office make a leased-line, long-distance or (1-800) call to an enterprise or outsourced NAS. Also, in order to create a VPN between the branch office router and the enterprise hub router across the Internet, the VPN software uses the connection to the local ISP as shown in Exhibit 3.

The facilities that connect the branch office and enterprise offices to the Internet are local in both cases. To make a connection, both client/server, and server/server VPN cost savings are largely predicated on the use of a local access phone number. It is recommended that the enterprise hub router that acts as a VPN server be connected to a local ISP with a dedicated line. This VPN server must be listening 24 hours per day for incoming VPN traffic.

Connecting Computers over an Intranet

The departmental data is so sensitive that the department's LAN is physically disconnected from the rest of the enterprise internetwork in some

EXHIBIT 2 — Using a VPN to Connect a Remote Client to a Private LAN

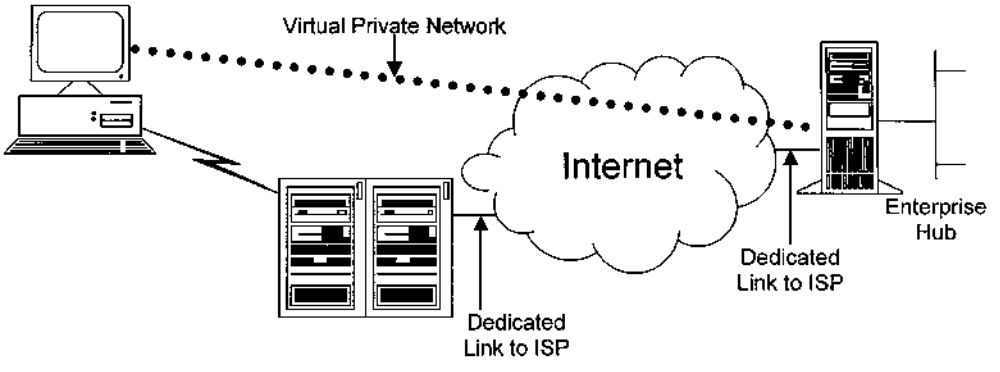


EXHIBIT 3 — Using a VPN to Connect Two Remote Sites

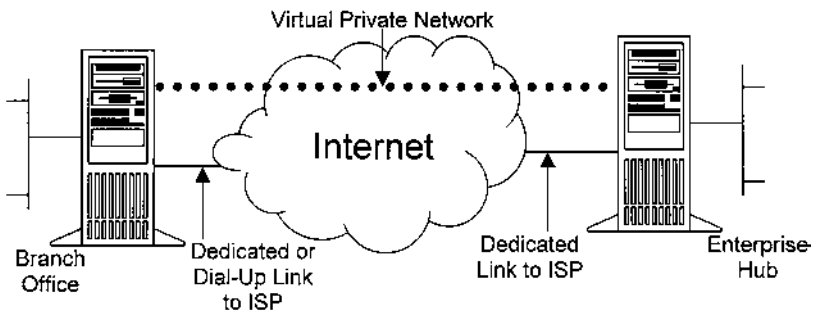


enterprise internetworks. All of this creates information accessibility problems for those users not physically connected to the separate LAN, although the department's confidential information is protected.

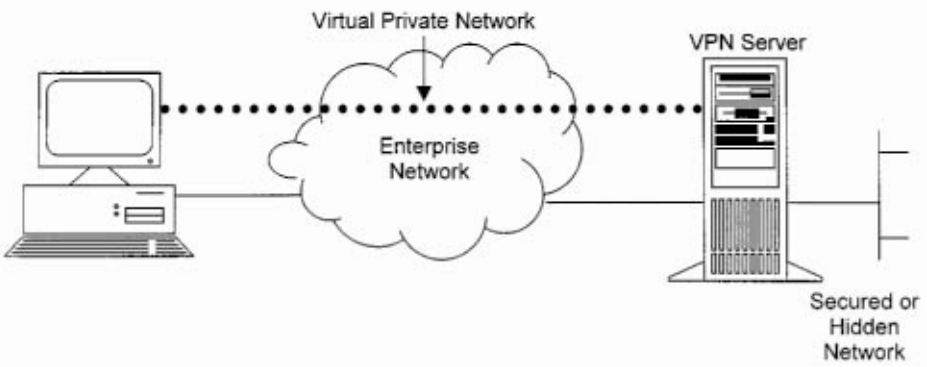
VPNs allow the department's LAN to be separated by a VPN server (see Exhibit 4), but physically connected to the enterprise internetwork. One should note that the VPN server is not acting as a router between the enterprise internetwork and the department LAN. A router would interconnect the two networks, thus allowing everyone access to the sensitive LAN. The network administrator can ensure that only those users on the enterprise internetwork who have appropriate credentials (based on a need-to-know policy within the enterprise) can establish a VPN with the VPN server and gain access to the protected resources of the department by using a VPN. Additionally, all communication across the VPN can be encrypted for data confidentiality. Thus, the department LAN cannot be viewed by those users who do not have the proper credentials.

BASIC VPN REQUIREMENTS

Normally, an enterprise desires to facilitate controlled access to enterprise resources and information when deploying a remote networking solution. In order to easily connect to enterprise local area network (LAN) resources, the solution must allow freedom for authorized remote clients. And, in order to share resources and information (LAN-to-LAN connections), the solution must also allow remote offices to connect to each other. Finally, as the data traverses the public Internet, the solution must ensure the privacy and integrity of data. Also, in the case of sensitive data traversing an enterprise internetwork, the same concerns apply. A VPN solution should therefore provide all of the following at a minimum:

- *Address management:* the solution must assign a client's address on the private net, and must ensure that private addresses are kept private

EXHIBIT 4 — Using a VPN to Connect to Two Computers on the Same LAN



- *Data encryption:* data carried on the public network must be rendered unreadable to unauthorized clients on the network
- *Key management:* the solution must generate and refresh encryption keys for the client and server
- *Multiprotocol support:* the solution must be able to handle common protocols used in the public network; these include Internet Protocol (IP), Internet Packet Exchange (IPX), etc.
- *User authentication:* the solution must verify a user's identity and restrict VPN access to authorized users; in addition, the solution must provide audit and accounting records to show who accessed what information and when

Furthermore, all of these basic requirements are met by an Internet VPN solution based on the Point-to-Point Tunneling Protocol (PPTP) or Layer 2 Tunneling Protocol (L2TP). The solution also takes advantage of the broad availability of the worldwide Internet. Other solutions meet some of these requirements, but remain useful for specific situations, including the new IP Security Protocol (IPSec).

Point-to-Point Tunneling Protocol (PPTP)

PPTP is a Layer 2 protocol that encapsulates PPP frames in IP datagrams for transmission over an IP internetwork, such as the Internet. PPTP can also be used in private LAN-to-LAN networking.

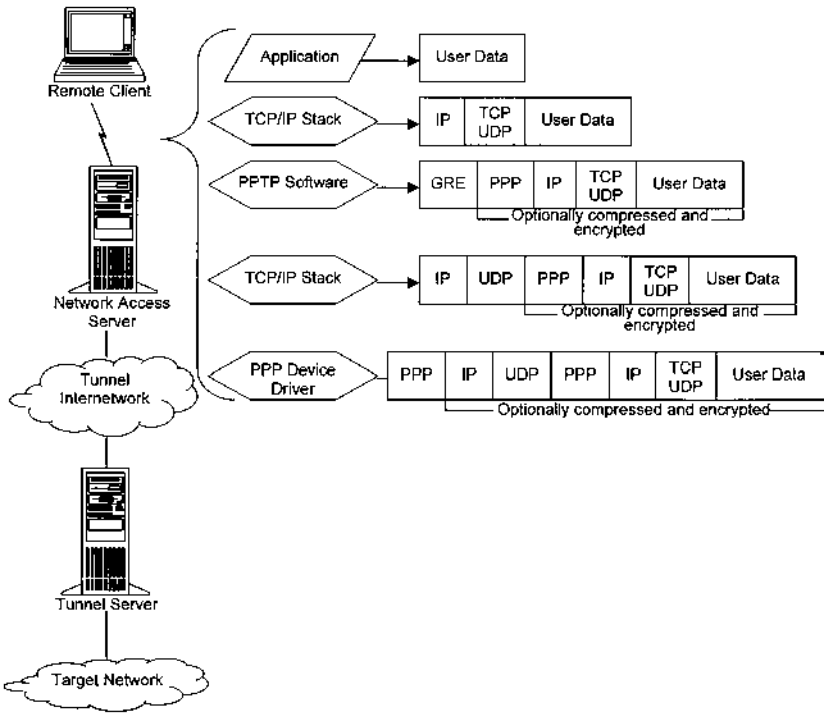
PPTP is documented in the draft RFC, "Point-to-Point Tunneling Protocol."[1] This draft was submitted to the IETF in June 1996 by the member enterprises of the PPTP Forum, including Microsoft Corporation, Ascend Communications, 3Com/Primary Access, ECI Telematics, and U.S. Robotics (now 3Com).

The Point-to-Point Tunneling Protocol (PPTP) uses Generic Routing Encapsulation (GRE) encapsulated Point-to-Point Protocol (PPP) frames for tunneled data and a TCP connection for tunnel maintenance. The payloads of the encapsulated PPP frames can be compressed as well as encrypted. How a PPTP packet is assembled prior to transmission is shown in Exhibit 5. The illustration shows a dial-up client creating a tunnel across an internetwork. The encapsulation for a dial-up client (PPP device driver) is shown in the final frame layout.

Layer 2 Forwarding (L2F)

L2F (a technology proposed by Cisco Systems, Inc.) is a transmission protocol that allows dial-up access servers to frame dial-up traffic in PPP and transmit it over WAN links to an L2F server (a router). The L2F server then unwraps the packets and injects them into the network. Unlike PPTP and L2TP, L2F has no defined client.[2]

EXHIBIT 5 — Construction of a PPTP Packet



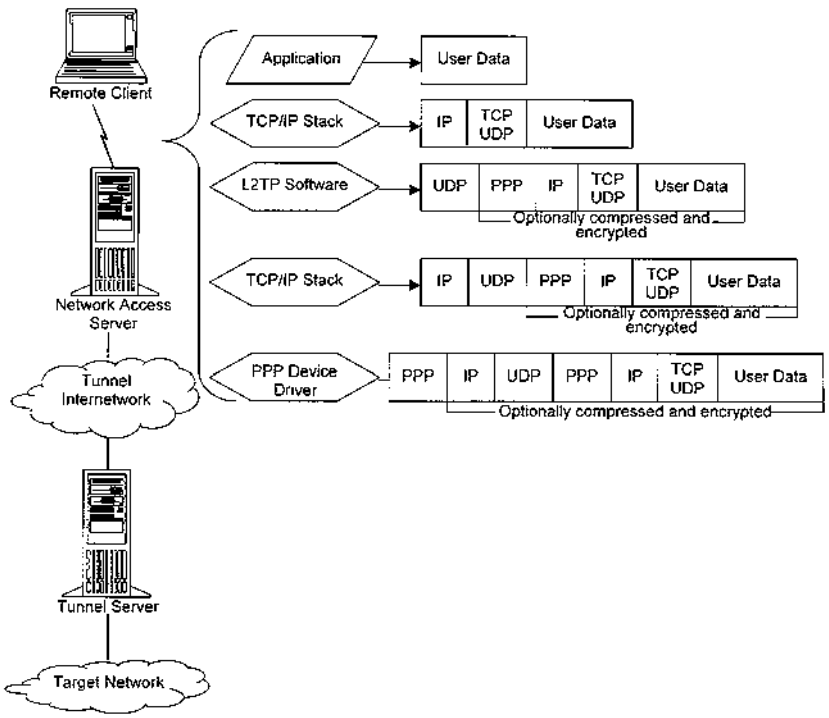
Layer 2 Tunneling Protocol (L2TP)

A combination of PPTP and L2F makes up L2TP. In other words, the best features of PPTP and L2F are incorporated into L2TP.

L2TP is a network protocol that encapsulates PPP frames to be sent over Asynchronous Transfer Mode (ATM), IP, X.25, or Frame Relay networks. L2TP can be used as a tunneling protocol over the Internet when configured to use IP as its datagram transport. Without an IP transport layer, L2TP can also be used directly over various WAN media (such as Frame Relay). L2TP is documented in the draft RFC, Layer 2 Tunneling Protocol "L2TP" (draft-ietf-pppext-l2tp-09.txt). This document was submitted to the IETF in January 1998.

For tunnel maintenance, L2TP over IP internetworks uses UDP and a series of L2TP messages. As the tunneled data, L2TP also uses UDP to send L2TP-encapsulated PPP frames. The payloads of encapsulated PPP frames can be compressed as well as encrypted. How an L2TP packet is assembled prior to transmission is shown in Exhibit 6. A dial-up client

EXHIBIT 6 — Construction of an L2TP Packet



creating a tunnel across an internetwork is shown in the exhibit. The encapsulation for a dial-up client (PPP device driver) is shown in the final frame layout. L2TP over IP is assumed in the encapsulation.

L2TP Compared to PPTP. PPP is used to provide an initial envelope for the data for both PPTP and L2TP. Then, it appends additional headers for transport through the internetwork. The two protocols are very similar. There are differences between PPTP and L2TP, however. For example,

- L2TP provides for header compression. When header compression is enabled, L2TP operates with four bytes of overhead, as compared to six bytes for PPTP.
- L2TP provides for tunnel authentication, while PPTP does not. However, when either protocol is used over IPSec, tunnel authentication is provided by IPSec so that Layer 2 tunnel authentication is not necessary.

- PPTP can only support a single tunnel between endpoints. L2TP allows for the use of multiple tunnels between endpoints. With L2TP, one can create different tunnels for different qualities of service.
- PPTP requires that the internetwork be an IP internetwork. L2TP requires only that the tunnel media provide packet-oriented point-to-point connectivity. L2TP can be used over IP (using UDP), Frame Relay permanent virtual circuits (PVCs), X.25 virtual circuits (VCs), or ATM VCs.

Internet Protocol Security (IPSec) Tunnel Mode

The secured transfer of information across an IP internetwork is supported by IPSec (a Layer 3 protocol standard). Nevertheless, in the context of tunneling protocols, one aspect of IPSec is discussed here. IPSec defines the packet format for an IP over an IP tunnel mode (generally referred to as IPSec Tunnel Mode), in addition to its definition of encryption mechanisms for IP traffic. An IPSec tunnel consists of a tunnel server and tunnel client. These are both configured to use a negotiated encryption mechanism and IPSec tunneling.

For secure transfer across a private or public IP internetwork, IPSec Tunnel Mode uses the negotiated security method (if any) to encapsulate and encrypt entire IP packets. The encrypted payload is then encapsulated again with a plaintext IP header. It is then sent on the internetwork for delivery to the tunnel server. The tunnel server processes and discards the plaintext IP header and then decrypts its contents to retrieve the original payload IP packet. Upon receipt of this datagram, the payload IP packet is then processed normally and routed to its destination on the target network. The following features and limitations are contained within the IPSec Tunnel Mode:

- It is controlled by a security policy: a set of filter-matching rules. This security policy establishes the encryption and tunneling mechanisms available in order of preference and the authentication methods available, also in order of preference. As soon as there is traffic, the two machines perform mutual authentication, and then negotiate the encryption methods to be used. Thereafter, all traffic is encrypted using the negotiated encryption mechanism and then wrapped in a tunnel header.
- It functions at the bottom of the IP stack; therefore, applications and higher-level protocols inherit its behavior.
- It supports IP traffic only.

The remainder of this article discusses VPNs and the use of these technologies by enterprises to do secure remote access (e.g., by traveling employees and sales reps) over the Internet in greater detail.

EASY TO MANAGE AND USE

While squeezing the maximum possible from budget and support staffs, today's enterprises are asking their Information Technology groups (ITGs) to deliver an increasing array of communication and networking services. It appears that the situation is no different at Microsoft Corporation (Redmond, WA). The Microsoft ITG needed to provide secure, Internet-based remote access for its more than 35,000 mobile sales personnel, telecommuters, and consultants around the world.

Microsoft's ITG is currently using and deploying a custom Windows-based remote dial-up and virtual private networking (VPN) solution by using Windows-based clients and enhanced Windows 2000® RAS (Remote Access Server) technology available in the Windows 2000 Option Pack (formerly named Windows NT 5.0). Users are given quick, easy, and low-cost network access. Additional user services are provided with new Windows-based network services from UUnet Technologies, Inc.[3]

Integrated RAS-VPN Clients

According to Microsoft, its ITG has learned that the widespread adoption and use of technology largely depends on how easy and transparent the experience is for the end user. Likewise, Microsoft's ITG has learned not to deploy technologies for which complexity results in an increased support burden on its limited support staff. Microsoft's ITG provided a single client interface with central management to simultaneously make the remote access solution easy to use and manage.

Single Client. A single client is used for both the direct dial-up and virtual private network connections. Users utilize the same client interface for secure transparent access, whether dialing directly to the enterprise network or connecting via a VPN, by using Windows integrated dial-up networking technology (DUN) and Microsoft Connection Manager. In fact, users do not need to concern themselves with which method is employed.

Central Management. Central management is used for remote dial-up and VPN access phone numbers. According to Microsoft, its ITG has found that one of the most common support problems traveling users face is determining and managing local access phone numbers. This problem translates into one of the principal reasons for support calls to Microsoft's user support centers. Using the Connection Manager Administration Kit (CMAK) wizard (which is part of Microsoft's remote access solution), Microsoft's ITG preloads each client PC with an electronic phone book that includes every dial-up remote access phone number for Microsoft's network. The Windows solution also allows phone books to be centrally integrated and managed from a single remote location, and clients to be updated automatically.

WINDOWS COMMUNICATION PLATFORM

In order to provide a flexible and comprehensive network solution, the open extensibility of the Windows 2000 allows Microsoft's ITG to preserve its current hardware network investments while partnering with UUnet Technologies, Inc. According to Microsoft, the Windows platform enabled its ITG to integrate the best-of-breed network services and applications to best meet its client and network administration needs.

High-Speed Internet Access on the Road

Microsoft employees can also connect to high-speed Internet access by plugging into public IPORT[4] jacks in hotels, airports, cafes, and remote locations. The Microsoft ITG integrates the IPORT[5] pay-per-use Internet access features into its custom remote access solution. According to Microsoft, this high-bandwidth, easily available connection helps Microsoft employees be more productive and have a better online experience while on the road.

Secure Internet Access and VPN

Microsoft's ITG, like its counterparts at every enterprise, must ensure that the edge of its network is secure while still providing all employees with the freedom needed to access information worldwide. Microsoft's ITG has also deployed Microsoft Proxy Server to securely separate the LAN from the Internet to meet this need.

To ensure that no intruders compromise the edge of network, the Microsoft Proxy Server firewall capabilities protect Microsoft's network from unauthorized access from the Internet by providing network address translation and dynamic IP-level filtering. Microsoft's ITG uses the powerful caching services in Microsoft Proxy Server to expedite the delivery of information at the same time.

The Proxy Server is able to service subsequent user requests of already-requested information without having to generate additional network traffic by reusing relevant cached information. In addition, in order to operate at peak efficiency with the utmost security, ITG uses Microsoft Proxy Server to enable the Microsoft intranet and remote employees.

RAS Reporting and Internal Usage Chargeback (Billing)

Microsoft pays a substantial amount for remote access fees due to the need to maintain private leased lines and dedicated 800 numbers like many large enterprises with a multitude of branch offices and remote employees. In addition, according to Microsoft, the sheer number of LAN entry points and autonomy afforded its international divisions made centralized accounting and retail reporting for remote access use and roaming users important.

Microsoft's ITG is deploying a VPN solution — bolstered with centralized accounting and reporting of enterprisewide remote access and VPN use — by using Windows 2000, integrated user domain directory, and RADIUS services. As part of this solution, Microsoft is also deploying TRU RADIUS Accountant™ for Windows 2000 from Telco Research.[6]

Furthermore, Microsoft's ITG is also able to generate detailed reporting of remote access and VPN network use for internal cost-accounting purposes while using familiar Windows 2000 management tools by using Telco Research's product. In addition, Microsoft's ITG is able to quickly and easily deploy a turnkey reporting solution built on the intrinsic communication services of Windows 2000 in this manner. According to Microsoft, while maintaining the flexibility to accommodate future change, they receive better security as a result, reduced implementation costs, and enhanced reporting to improve remote access management and chargeback service.

VIP Services: Economical Internet Access And VPN

By working with UUnet Technologies, Inc. (the largest Internet service provider in the world), the Microsoft ITG supplemented its private data network infrastructure and RAS with VPN services. Microsoft's VPN solution is integrated with the UUnet Radius Proxy servers through the Windows 2000 native support for RADIUS under this relationship.

Through the Windows 2000 Remote Access Service integrated RADIUS support, Microsoft's ITG made reliable and secure local access to UUnet Technologies IP network available to all Microsoft mobile employees. This resulted in the delivery of high-quality VPN services over the UUnet Technologies, Inc. infrastructure at a reduced cost. The ITG conservatively estimates that this use of VPN service as an alternative to traditional remote access will save Microsoft more than $7 million per year in remote access fees alone. Additional savings are expected from the elimination of call requests for RAS phone numbers and greatly reduced remote access configuration support.

The ITG utilized the integrated support for RADIUS-based authentication available from the Windows Directory in Windows 2000. This allowed them to retain all existing authentication rights for both Internet and LAN access, avoiding change or redundant replication of directory, and provided for enhanced network security.

According to Microsoft, their ITG was able to instantly extend network access to its more than 50,000 employees in more than 100 countries through its relationship with UUnet Technologies. So that Microsoft employees can access information locally anywhere with reliability guarantees and the support of UUnet, UUnet Technologies' transcontinental backbone provides access throughout North America, Europe, and the Asia–Pacific region.

PLANNING FOR THE FUTURE

Finally, Microsoft's ITG wanted to ensure that its current investment in the remote access infrastructure would not only be able to meet today's needs, but also enable it to make the most of opportunities provided by the digital convergence of network-aware applications in the near future. Evidence of an increased need for higher degrees of client/server network application integration is found in the momentum of Windows 2000 as a platform for IP telephony, media-streaming technologies, and the migration to PBX systems based on Windows 2000.

The flexibility needed to economically address current and future needs of Microsoft's ITG is provided through the use of Windows 2000 as the backbone of the remote access solution. Through partnerships with multiple service providers such as UUnet Technologies, the selection of a Windows-based solution allows ITG the freedom to both centrally manage and incrementally extend the Microsoft direct-dial and VPN infrastructure at a controlled pace and in an open manner.

In order to connect Microsoft subsidiaries, branch offices, and extranet partners securely to the enterprise network over private and public networks, Windows 2000 Routing, RAS, and VPN services — along with tight integration with Microsoft Proxy Server — are already enabling Microsoft's ITG to seamlessly extend its RAS–VPN infrastructure. Furthermore, to meet Microsoft's enterprise needs into the future, the broad application support enjoyed by the Windows communication platform ensures that ITG will continue to have access to a host of rich application services made available by developers and service providers, such as ATCOM, Inc., Telco-Research, and UUnet Technologies, Inc.

CONCLUSION AND SUMMARY

As explained in this article, Windows 2000 native VPN services allow users or enterprises to reliably and securely connect to remote servers, branch offices, or other enterprises over public and private networks. Despite the fact that this communication occurs over a public internetwork in all of these cases, the secure connection appears to the user as a private network communication. Windows VPN technology is designed to address issues surrounding the current enterprise trend toward increased telecommuting and widely distributed global operations, where workers must be able to connect to central resources and where enterprises must be able to efficiently communicate with each other.

This article provided an in-depth discussion of virtual private networking, and described the basic requirements of useful VPN technologies — user authentication, address management, data encryption, key management, and multiprotocol support. It discussed how Layer 2 protocols, specifically PPTP and L2TP, meet these requirements, and how IPSec (a Layer 3 protocol) will meet these requirements in the future.

Every VPN solution needs to address the technological issues cited in the preceding text and provide the flexibility to address enterprise issues like network interoperability, rich application integration, and infrastructure transparency. Enterprise infrastructure decisions need to be made in a manner that empowers client access to local connections and client utilization of the network in a transparent manner to bolster economy and productivity.

Furthermore, escalating remote access and telecommuting needs and an increase in the use of distributed enterprise models like extranets require pragmatic remote access solutions that are easy to use, economical, and flexible enough to meet the changing needs of every enterprise. To support its 50,000+ employees worldwide with best-of-breed remote access and virtual private networking (VPN) services, Microsoft capitalizes on the built-in communication services included in Windows®, integrated VPN firewall and caching support from Microsoft® Proxy Server, and complementary services from partners such as UUnet Technologies, Inc., Telco Research, and ATCOM, Inc.

The remote access infrastructure that Microsoft's Redmond, WA, headquarters uses for its 15,000 HQ employees consists of four dedicated VPN server computers running the Windows 2000 network operating system. Each machine runs three 400-MHz new Pentium III processors, with 204MB of RAM, 3 × 3 GB of local storage, and three 200-Mbps network interface cards.

The UUnet Technologies, Inc. network that supports Microsoft's wholesale remote access and VPN services provides access to one of the largest IP networks in the world. UUnet's backbone infrastructure features a fully meshed network that extends across both the Atlantic and Pacific and includes direct fiber optic connections between Europe, North America, and Asia. UUnet also provides satellite access services for remote areas that lack Internet connections.

Telco Research's TRU RADIUS Accountant™ for Windows 2000 provides Microsoft's ITG with a single source for reporting internal usage and chargeback (billing) information required to control remote access costs. TRU RADIUS easy-to-use applications provide a turnkey analysis of remote access usage and the data needed to proactively manage Microsoft's remote employee costs across its enterprise.

Microsoft's use of UUnet infrastructure to provision its VPN services to its sales force and mobile users is a testament to the quality and reliability of UUnet's multinational IP network. Using Windows 2000 integrated communication services, both UUnet and Microsoft ITG can centrally update Microsoft remote users with the latest local points of presence (POPs) and RAS connection points as soon they become available around the world.

DATA SECURITY MANAGEMENT

APPLETS AND NETWORK SECURITY: A MANAGEMENT OVERVIEW

Al Berg

INSIDE

Applets and the Web, The Security Issue, Java: Secure Applets, Java: Holes and Bugs, Denial-of-Service Threats, JavaScript: A Different Grind, ActiveX: Microsoft's Vision for Distributed Component Computing, An Ounce of Prevention

INTRODUCTION

Applets are small programs that reside on a host computer and are downloaded to a client computer to be executed. This model makes it very easy to distribute and update software. Because the new version of an application only needs to be placed on the server, clients automatically receive and run the updated version the next time they access the application.

The use of applets is possible because of the increasing bandwidth available to Internet and intranet users. The time required to download the programs has been decreasing even as program complexity has been increasing. The development of cross-platform languages such as Sun Microsystems, Inc.'s Java, Microsoft Corp.'s ActiveX, and Netscape Communications Corp.'s JavaScript has made writing applets for many different computers simple — the same exact Java or JavaScript code can be run on a Windows-based PC, a Macintosh, or a UNIX-based system without any porting or recompiling of code. Microsoft is working to port ActiveX to UNIX and Macintosh platforms.

PAYOFF IDEA

Applets, network-based programs that run on client systems, are one of the newest security concerns of network managers. This article describes how applets work, the threats they present, and what security precautions network managers can take to minimize the security exposures presented by applets.

APPLETS AND THE WEB

The World Wide Web is the place that users are most likely to encounter applets today. Java (and to a lesser degree, JavaScript) has be-

Auerbach Publications

come the Webmaster's tool of choice to add interesting effects to Web sites or to deliver applications to end users. Most of the scrolling banners, animated icons, and other special effects found on today's Web pages depend on applets to work. Some Web pages use applets for more substantial applications. For example, MapQuest (http://www.mapquest.com) uses Java and ActiveX to deliver an interactive street atlas of the entire U.S. *Wired* magazine offers a Java-based chat site that, when accessed over the Web, allows users to download an applet that lets them participate in real-time conferencing.

THE SECURITY ISSUE

Every silver lining has a cloud, and applets are no exception. Applets can present a real security hazard for users and network managers. When Web pages use applets, the commands that tell the client's browser to download and execute the applets are embedded in the pages themselves. Users have no way of knowing whether or not the next page that they download will contain an applet, and most of the time, they do not care. The Internet offers an almost limitless source of applets for users to run; however, no one knows who wrote them, whether they were written with malicious intent, or whether they contain bugs that might cause them to crash a user's computer.

Applets and computer viruses have a lot in common. Both applets and viruses are self-replicating code that executes on the user's computer without the user's consent. Some security experts have gone as far as to say that the corporate network manager should prohibit users from running applets at all. However, applets are becoming an increasingly common part of how users interact with the Internet and corporate intranets, so learning to live safely with applets is important for network managers.

WHAT ARE THE RISKS?

According to Princeton University's Safe Internet Programming (SIP) research team, there have been no publicly reported, confirmed cases of security breaches involving Java, though there have been some suspicious events that may have involved Java security problems. The lack of reported cases is no guarantee that there have not been breaches that either were not discovered or were not reported. But it does indicate that breaches are rare.

As Web surfing increasingly becomes a way to spend money, and applets become the vehicle for shopping, attacks on applets will become more and more profitable, increasing the risk. Sun, Netscape, and Microsoft all designed their applet languages with security in mind.

JAVA: SECURE APPLETS

Java programs are developed in a language similar to C++ and stored as source code on a server. When a client, such as a Web browser, requests a page that references a Java program, the source code is retrieved from the server and sent to the browser, where an integrated interpreter translates the source code statements into machine-independent bytecodes, which are executed by a virtual machine implemented in software on the client. This virtual machine is designed to be incapable of operations that might be detrimental to security, thus providing a secure sandbox in which programs can execute without fear of crashing the client system. Java applets loaded over a network are not allowed to:

- Read from files on the client system.
- Write to files on the client system.
- Make any network connections, except to the server from which they were downloaded.
- Start any client-based programs.
- Define native method calls, which would allow an applet to directly access the underlying computer.

Java was designed to make applets inherently secure. Following are some of the underlying language security features offered by Java:

- All of an applet's array references are checked to make sure that programs will not crash because of a reference to an element that does not exist.
- Complex and troublesome pointer variables (found in some vendors' products) that provide direct access to memory locations in the computer do not exist in Java, removing another cause of crashes and potentially malicious code.
- Variables can be declared as unchangeable at runtime to prevent important program parameters from being modified accidentally or intentionally.

JAVA: HOLES AND BUGS

Although Sun has made every effort to make the Java virtual machine unable to run code that will negatively impact the underlying computer, researchers have already found bugs and design flaws that could open the door to malicious applets.

The fact that Sun has licensed Java to various browser vendors adds another level of complexity to the security picture. Not only can security be compromised by a flaw in the Java specification, but the vendor's implementation of the specification may contain its own flaws and bugs.

DENIAL-OF-SERVICE THREATS

Denial-of-service attacks involve causing the client's Web browser to run with degraded performance or crash. Java does not protect the client system from these types of attacks, which can be accomplished simply by putting the client system into a loop to consume processor cycles, creating new process threads until system memory is consumed, or placing locks on critical processes needed by the browser.

Because denial-of-service attacks can be programmed to occur after a time delay, it may be difficult for a user to determine which page the offending applet was downloaded from. If an attacker is subtle and sends an applet that degrades system performance, the user may not know that their computer is under attack, leading to time-consuming and expensive troubleshooting of a nonexistent hardware or software problem.

Java applets are not supposed to be able to establish network connections to machines other than the server they were loaded from. However, there are applets that exploit bugs and design flaws that allow it to establish a back-door communications link to a third machine (other than the client or server). This link could be used to send information that may be of interest to a hacker. Because many ready-to-use Java applets are available for download from the Internet, it would be possible for an attacker to write a useful applet, upload it to a site where Webmasters would download it, and then sit back and wait for information sent by the applet to reach their systems.

WHAT KIND OF INFORMATION CAN THE APPLET SEND BACK?

Due to another implementation problem found in August 1996 by the Safe Internet Programming research team at Princeton University, the possibilities are literally endless. A flaw found in Netscape Navigator versions 3.0 beta 5 and earlier versions, and Microsoft Internet Explorer 3.0 beta 2 and earlier versions, allows applets to gain full read and write access to the files on a Web surfer's machine. This bug means that the attacker can get copies of any files on the machine or replace existing data or program files with hacked versions.

Giving Java applets the ability to connect to an arbitrary host on the network or Internet opens the door to another type of attack. A malicious applet, downloaded to and running on a client inside of a firewalled system, could establish a connection to another host behind the firewall and access files and programs. Because the attacking host is actually inside the secured system, the firewall will not know that the access is actually originating from outside the network.

Another bug found in August 1996 by the Princeton team affects only Microsoft Internet Explorer version 3.0 and allows applets (which are not supposed to be allowed to start processes on the client machine) to execute any DOS command on the client. This allows the applet to delete

or change files or programs or insert new or hacked program code such as viruses or backdoors. Microsoft has issued a patch (available on its Web site at http://www.microsoft.com/ie) to Internet Explorer that corrects the problem.

Princeton's SIP team also found a hole that would allow a malicious application to execute arbitrary strings of machine code, even though the Java virtual machine is only supposed to be able to execute the limited set of Java bytecodes. The problem was fixed in Netscape Navigator 3.0 beta 6 and Microsoft Internet Explorer 3.0 beta 2.

JAVASCRIPT: A DIFFERENT GRIND

Netscape's JavaScript scripting language may be named Java, but it is distinct from Sun's applet platform. JavaScript is Netscape Navigator's built-in scripting language that allows Webmasters to do cross-platform development of applets that control browser events, objects such as tables and forms, and various activities that happen when users click on an object with their mouse.

Like Java, JavaScript runs applications in a virtual machine to prevent them from performing functions that would be detrimental to the operation of the client workstations. Also like Java, there are several flaws in the implementation of the security features of JavaScript. Some of the flaws found in JavaScript include the ability for malicious applets to:

- Obtain users' E-mail addresses from their browser configuration.
- Track the pages that a user visits and mail the results back to the script author.
- Access the client's file system, reading and writing files.

A list of JavaScript bugs and fixes can be found on John LoVerso's Web page at the Open Software Foundation (http://www.osf.org/~ loverso/javascript/).

ActiveX: Microsoft's Vision for Distributed Component Computing. Microsoft's entry in the applet development tool wars, ActiveX, is very different from Java and presents its own set of security challenges. ActiveX is made up of server and client components, including:

- Controls, which are applets that can be embedded in Web pages and executed at the client. Controls can be written in a number of languages, including Visual Basic and Visual C++.
- Documents that provide access to non-HTML content, such as word processing documents or spreadsheets, from a Web browser.
- The Java virtual machine, which allows standard Java applets to run at the client.

- Scripting, which allows the Web developer to control the integration of controls and Java applets on a Web page.
- The server framework, which provides a number of server-side functions such as database access and data security.

Java applets running in an ActiveX environment (e.g., Microsoft's Internet Explorer Web browser) use the same security features and have the same security issues associated with JavaScript. Microsoft offers a Java development environment (i.e., Visual J++) as well as other sandbox languages (i.e., VBScript, based on Visual Basic and JScript, Microsoft's implementation of Netscape's JavaScript) for the development of applications that are limited as to the functions they can perform.

When developers take advantage of ActiveX's ability to integrate programs written in Visual Basic or C++, the virtual machine model of Java no longer applies. In these cases, compiled binaries are transferred from the server to the Web client for execution. These compiled binaries have full access to the underlying computing platform, so there is no reason that the application could not read and write files on the client system, send information from the client to the server (or another machine), or perform a destructive act such as erasing a disk or leaving a virus behind.

USING AUTHENTICODE FOR ACCOUNTABILITY

Microsoft's approach to security for non-Java ActiveX applications is based on the concept of accountability — knowing with certainty the identity of the person or company that wrote a piece of software and that the software was not tampered with by a third party. Microsoft sees the issues related to downloading applets from the Web as similar to those involved in purchasing software; users need to know where the software is coming from and that it is intact. Accountability also means that writers of malicious code could be tracked down and would have to face consequences for their actions.

The mechanism that Microsoft offers to implement this accountability is called Authenticode. Authenticode uses a digital signature attached to each piece of software downloaded from the Internet. The signature is a cryptographic code attached by the software developer to an applet. Developers must enter a private key (known only to them) to sign their application, assuring their identity. The signature also includes an encrypted checksum of the application itself, which allows the client to determine if the applet has changed since the developer released it.

ACTIVEX: THE DOWNSIDE

This approach provides developers and users with access to feature-rich applications, but at a price. If an application destroys information on a user's computer, accountability will not help recover their data or repair

damage done to their business. Once the culprit has been found, bringing them to justice may be difficult because new computer crimes are developing faster than methods for prosecuting them.

Microsoft acknowledges that Authenticode does not guarantee that end users will never download malicious code to their PCs and that it is a first step in the protection of information assets.

Further information on ActiveX can be found on Microsoft's Web site (http://www.microsoft.com/activex) and at the ActiveX Web site run by CNet Technology Corp. (http://www.activex.com).

AN OUNCE OF PREVENTION

So far, this article has discussed problems posed by applets. Following are some steps that can be taken to lessen the exposure faced by users.

Make Sure the Basics Are Covered

Users need to back up their data and programs consistently, and sensitive data should be stored on secure machines. The surest way to avoid applet security problems is to disable support for applet execution at the browser. If the code cannot execute, it cannot do damage.

Of course, the main downside of this approach is that the users will lose the benefits of being able to run applets. Because the ability to run applets is part of the client browser, turning off applets is usually accomplished at the desktop and a knowledgeable user could simply turn applet support back on. Firewall vendors are starting to provide support for filtering out applets, completely or selectively, before they enter the local network.

Users Should Run the Latest Available Versions of Their Web Browsers

Each new version corrects not only functional and feature issues, but security flaws. If an organization is planning to use applets on its Web pages, it is preferable to either write them internally or obtain them from trusted sources. If applets will be downloaded from unknown sources, a technical person with a good understanding of the applet language should review the code to be sure that it does only what it claims to.

Mark LaDue, a researcher at Georgia Tech has a Web page (available at http://www.math.gatech.edu/~mladue/HostileApplets.html) containing a number of hostile applets available for download and testing. Seeing some real applications may help users recognize new problem applets that may be encountered.

CONCLUSION

IS personnel should monitor the Princeton University Safe Internet Programming group's home page (located at http://www.cs.prince-

ton.edu/sip) for the latest information on security flaws and fixes (under News). It is also a good idea to keep an eye on browser vendors' home pages for news of new versions.

Applets offer users and network managers a whole new paradigm for delivering applications to the desktop. Although, like any new technology, applets present a new set of challenges and concerns, their benefits can be enjoyed while their risks can be managed.

Security for Broadband Internet Access Users

James Trulove

High-speed access is becoming increasingly popular for connecting to the Internet and to corporate networks. The term "high-speed" is generally taken to mean transfer speeds above the 56 kbps of analog modems, or the 64 to 128 kbps speeds of ISDN. There are a number of technologies that provide transfer rates from 256 kbps to 1.544 Mbps and beyond. Some offer asymmetrical uplink and downlink speeds that may go as high as 6 Mbps. These high-speed access methods include DSL, cable modems, and wireless point-to-multipoint access.

DSL services include all of the so-called "digital subscriber line" access methods that utilize conventional copper telephone cabling for the physical link from customer premise to central office (CO). The most popular of these methods is ADSL, or asymmetrical digital subscriber line, where an existing POTS (plain old telephone service) dial-up line does double duty by having a higher frequency digital signal multiplexed over the same pair. Filters at the user premise and at the central office tap off the digital signal and send it to the user's PC and the CO router, respectively.

The actual transport of the ADSL data is via ATM, a factor invisible to the user, who is generally using TCP/IP over Ethernet. A key security feature of DSL service is that the transport media (one or two pairs) is exclusive to a single user. In a typical neighborhood of homes or businesses, individual pairs from each premise are, in turn, consolidated into larger cables of many pairs that run eventually to the service provider's CO. As with a conventional telephone line, each user is isolated from other users in the neighborhood. This is inherently more secure than competing high-speed technologies. The logical structure of an ADSL distribution within a neighborhood is shown in Exhibit 47.1A.

Cable modems (CMs) allow a form of high-speed shared access over media used for cable television (CATV) delivery. Standard CATV video channels are delivered over a frequency range from 54 MHz to several hundred megahertz. Cable modems simply use a relatively narrow band of those frequencies that are unused for TV signal delivery. CATV signals are normally delivered through a series of in-line amplifiers and signal splitters to a typical neighborhood cable segment. Along each of these final segments, additional signal splitters (or taps) distribute the CATV signals to users. Adding two-way data distribution to the segment is relatively easy because splitters are inherently two-way devices and no amplifiers are within the segment. However, the uplink signal from users in each segment must be retrieved at the head of the segment and either repeated into the next up-line segment or converted and transported separately.

As shown in Exhibit 47.1B, each neighborhood segment is along a tapped coaxial cable (in most cases) that terminates in a common-equipment cabinet (similar in design to the subscriber-line interface cabinets used in telephone line multiplexing). This cabinet contains the equipment to filter off the data signal from the neighborhood coax segment and transport it back to the cable head-end. Alternative data routing may be provided between the common equipment cabinets and the NOC (network operations center), often over fiber-optic cables. As a matter of fact, these neighborhood distribution cabinets are often used as a transition point for all CATV signals between fiber-optic transmission links and the installed coaxial cable to the users. Several neighborhood segments may terminate in each cabinet. When a neighborhood has been rewired for fiber distribution and cable modem services, the most often outward sign is the appearance of a four-foot high

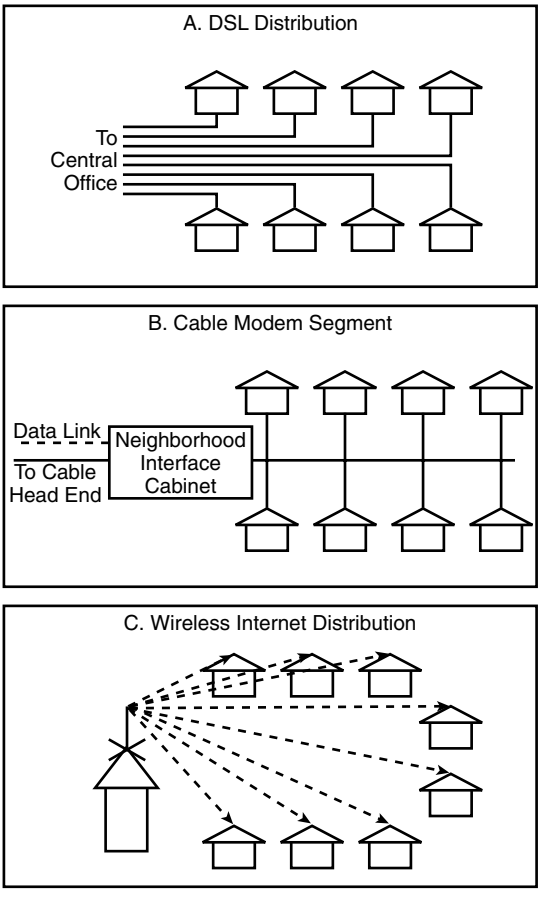

EXHIBIT 47.1 Broadband and wireless Internet access methods.

green or gray metal enclosure. These big green (or gray) boxes are metered and draw electrical power from a local power pole and often have an annoying little light to warn away would-be villains.

Many areas do not have ready availability of cable modem circuits or DSL. Both technologies require the user to be relatively near the corresponding distribution point and both need a certain amount of infrastructure expansion by the service provider. A wireless Internet option exists for high-speed access from users who are in areas that are otherwise unserved. The term "wireless Internet" refers to a variety of noncellular radio services that interconnect users to a central access point, generally with a very high antenna location on a high building, a broadcast tower, or even a mountaintop. Speeds can be quite comparable to the lower ranges of DSL and CM (i.e., 128 to 512 kbps). Subscriber fees are somewhat higher, but still a great value to someone who would otherwise have to deal with low-speed analog dial access.

Wireless Internet is often described as point-to-multipoint operation. This refers to the coverage of several remote sites from a central site, as opposed to point-to-point links that are intended to serve a pair of sites exclusively. As shown in Exhibit 47.1C, remote user sites at homes or businesses are connected by a radio link to a central site. In general, the central site has an omnidirectional antenna (one that covers equally in all radial directions) while remote sites have directional antennas that point at the central antenna.

Wireless Internet users share the frequency spectrum among all the users of a particular service frequency. This means that these remote users must share the available bandwidth as well. As a result, as with the cable modem situation, the actual data throughput depends on how many users are online and active. In addition, all the transmissions are essentially broadcast into the air and can be monitored or intercepted with the proper equipment. Some wireless links include a measure of encryption but the key may still be known to all subscribers to the service.

There are several types of wireless systems permitted in the United States, as with the European Union, Asia, and the rest of the world. Some of these systems permit a single provider to control the rights to a particular frequency allocation. These exclusively licensed systems protect users from unwanted interference from other users and protect the large investment required of the service provider. Other systems utilize a frequency spectrum that is shared and available to all. For example, the 802.11 systems at 2.4 GHz and 5.2 GHz are shared-frequency, nonlicensed systems that can be adapted to point-to-multipoint distribution.

Wireless, or radio-frequency (RF), distribution is subject to all of the same distance limitations, antenna designs, antenna siting, and interference considerations of any RF link. However, in good circumstances, wireless Internet provides a very satisfactory level of performance, one that is comparable to its wired competitors.

Broadband Security Risks

Traditional remote access methods, by their very nature, provide a fair measure of link security. Dial-up analog and dial-on-demand ISDN links have relatively good protection along the path between the user's computer and the access service provider (SP). Likewise, dedicated links to an Internet service provider (ISP) are inherently safe as well, barring any intentional (and unauthorized/illegal) tapping. However, this is not necessarily the case with broadband access methods.

Of the common broadband access methods, cable modems and wireless Internet have inherent security risks because they use shared media for transport. On the other hand, DSL does indeed utilize an exclusive path to the CO but has some more subtle security issues that are shared with the other two methods.

The access-security issue with cable modems is probably the most significant. Most PC users run a version of the Microsoft Windows® operating system, popularly referred to just as Windows. All versions of Windows since Windows 95® have included a feature called peer-to-peer networking. This feature is in addition to the TCP/IP protocol stack that supports Internet-oriented traffic. Microsoft Windows NT® and Windows 2000® clients also support peer-to-peer networking. These personal operating systems share disk, printer, and other resources in a *network neighborhood* utilizing the NetBIOS protocol. NetBIOS is inherently nonroutable although it can be encapsulated within TCP/IP and IPX protocols. A particular network neighborhood is identified by a Workgroup name and, theoretically, devices with different Workgroup names cannot converse.

A standard cable modem is essentially a two-way repeater connected between a user's PC (or local network) and the cable segment. As such, it repeats everything along your segment to your local PC network and everything on your network back out to the cable segment. Thus, all the "private" conversations one might have with one's network-connected printer or other local PCs are available to everyone on the segment. In addition, every TCP/IP packet that goes between one's PC and the Internet is also available for eavesdropping along the cable segment. This is a very serious security risk, at least among those connected to a particular segment. It makes an entire group of cable modem users vulnerable to monitoring, or even intrusion. Specific actions to mitigate this risk are discussed later.

Wireless Internet acts essentially as a shared Ethernet segment, where the segment exists purely in space rather than within a copper medium. It is "ethereal," so to speak. What this means in practice is that every transmission to one user also goes to every authorized (and unauthorized) station within reception range of the central tower. Likewise, a user's transmissions back to the central station are available to anyone who is capable of receiving that user's signal. Fortunately, the user's remote antenna is fairly directional and is not at the great height of the central tower. But someone who is along the path between the two can still pick up the user's signal.

Many wireless Internet systems also operate as a bridge rather than a TCP/IP router, and can pass the NetBIOS protocol used for file and printer sharing. Thus, they may be susceptible to the same type of eavesdropping and intrusion problems of the cable modem, unless they are protected by link encryption.

In addition to the shared-media security issue, broadband security problems are more serious because of the vast communication bandwidth that is available. More than anything else, this makes the broadband user valuable as a potential target. An enormous amount of data can be transferred in a relatively short period of time. If the broadband user operates mail systems or servers, these may be more attractive to someone wanting to use such resources surreptitiously.

Another aspect of broadband service is that it is "always on," rather than being connected on-demand as with dial-up service. This also makes the user a more accessible target. How can a user minimize exposure to these and other broadband security weaknesses?

Increasing Broadband Security

The first security issue to deal with is visibility. Users should immediately take steps to minimize exposure on a shared network. Disabling or hiding processes that advertise services or automatically respond to inquiries effectively shields the user's computer from intruding eyes. Shielding the computer will be of benefit whether the user is using an inherently shared broadband access, such as with cable modems or wireless, or has DSL or dial-up service. Also, remember that the user might be on a shared Ethernet at work or on the road. Hotel systems that offer high-speed access through an Ethernet connection are generally shared networks and thus are subject to all of the potential problems of any shared broadband access.

Shared networks clearly present a greater danger for unauthorized access because the Windows networking protocols can be used to detect and access other computers on the shared medium. However, that does not mean that users are unconditionally safe in using other access methods such as DSL or dial-up. The hidden danger in DSL or dial-up is the fact that the popular peer-to-peer networking protocol, NetBIOS, can be transported over TCP/IP. In fact, a common attack is a probe to the IP port that supports this.

There are some specific steps users can take to disable peer networking if they are a single-PC user. Even if there is more than one PC in the local network behind a broadband modem, users can take action to protect their resources.

Check Vulnerability

Before taking any local-PC security steps, users might want to check on their vulnerabilities to attacks over the Web. This is easy to do and serves as both a motivation to take action and a check on security steps. Two sites are recommended: www.grc.com and www.symantec.com/securitycheck. The grc.com site was created by Steve Gibson for his company, Gibson Research Corp. Users should look for the "shields up" icon to begin the testing. GRC is free to use and does a thorough job of scanning for open ports and hidden servers.

The Symantec URL listed should take the user directly to the testing page. Symantec can also test vulnerabilities in Microsoft Internet Explorer as a result of ActiveX controls. Potentially harmful ActiveX controls can be inadvertently downloaded in the process of viewing a Web page. The controls generally have full access to the computer's file system, and can thus contain viruses or even hidden servers. As is probably known, the Netscape browser does not have these vulnerabilities, although both types of browsers are somewhat vulnerable to Java and JavaScript attacks. According to information on this site, the online free version at Symantec does not have all the test features of the retail version, so users must purchase the tool to get a full test.

These sites will probably convince users to take action. It is truly amazing how a little demonstration can get users serious about security. Remember that this eye-opening experience will not decrease security in any way … it will just decrease a user's false sense of security!

Start by Plugging Holes in Windows

To protect a PC against potential attacks that might compromise personal data or even harm a PC, users will need to change the Windows Networking default configurations. Start by disabling file and printer sharing, or by password-protecting them, if one must use these features. If specific directories must be shared with other users on the local network, share just that particular directory rather than the entire drive. Protect each resource with a unique password. Longer passwords, and passwords that use a combination of upper/lower case, numbers, and allow punctuation, are more secure.

Windows Networking is transported over the NetBIOS protocol, which is inherently unroutable. The advantage to this feature is that any NetBIOS traffic, such as that for printer or file sharing, is blocked at any WAN router. Unfortunately, Windows has the flexibility of encapsulating NetBIOS within TCP/IP packets, which are quite routable. When using IP Networking, users may be inadvertently enabling this behavior. As a matter of fact, it is a little difficult to block. However, there are some steps users can take to isolate their NetBIOS traffic from being routed out over the Internet.

The first step is to block NetBIOS over TCP/IP. To do this in Windows, simply go to the Property dialog for TCP/IP and disable "NetBIOS over TCP/IP." Likewise, disable "Set this protocol to be the default." Now go to bindings and uncheck all of the Windows-oriented applications, such as Microsoft Networking or Microsoft Family Networking.

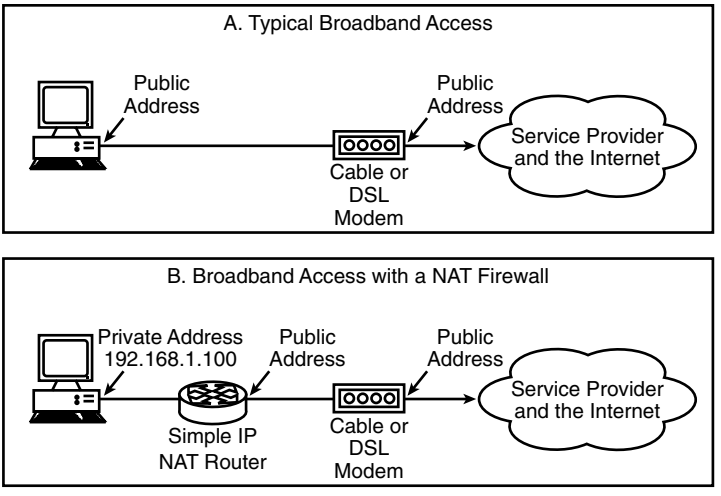

EXHIBIT 47.2 Addition of a NAT firewall for broadband Internet access.

The next step is to give local networking features an alternate path. Do this by adding IPX/SPX compatible protocol from the list in the Network dialog box. After adding IPX/SPX protocol, configure its properties to take up the slack created with TCP/IP. Set it to be the default protocol; check the "enable NetBIOS over IPX/SPX" option, and check the Windows-oriented bindings that were unchecked for TCP/IP. In exiting the dialog, by checking OK, notice that a new protocol has been added, called "NetBIOS support for IPX/SPX compatible Protocol." This added feature allows NetBIOS to be encapsulated over IPX, isolating the protocol from its native mode and from unwanted encapsulation over TCP/IP.

This action provides some additional isolation of the local network's NetBIOS communication because IPX is generally not routed over the user's access device. Be sure that IPX routing, if available, is disabled on the router. This will not usually be a problem with cable modems (which do not route) or with DSL connections because both are primarily used in IP-only networks. At the first IP router link, the IPX will be blocked. If the simple NAT firewall described in the next section is used, IPX will likewise be blocked. However, if ISDN is used for access, or some type of T1 router, check that IPX routing is off.

Now Add a NAT Firewall

Most people do not have the need for a full-fledged firewall. However, a simple routing device that provides network address translation (NAT) can shield internal IP addresses from the outside world while still providing complete access to Internet services. Exhibit 47.2A shows the normal connection provided by a cable or DSL modem. The user PC is assigned a public IP address from the service provider's pool. This address is totally visible to the Internet and available for direct access and, therefore, for direct attacks on all IP ports.

A great deal of security can be provided by masking internal addresses inside a NAT router. This device is truly a router because it connects between two IP subnets, the internal "private" network and the external "public" network. A private network is one with a known private network subnet address, such as 192.168.x.x or 10.x.x.x. These private addresses are nonroutable because Internet Protocol convention allows them to be duplicated at will by anyone who wants to use them. In the example shown in Exhibit 47.2B, the NAT router is inserted between the user's PC (or internal network of PCs) and the existing cable or DSL modem. The NAT router can act as a DHCP (Dynamic Host Control Protocol) server to the internal private network, and it can act as a DHCP client to the service provider's DHCP server. In this manner, dynamic IP address assignment can be accomplished in the same manner as before, but the internal addresses are hidden from external view.

A NAT router is often called a simple firewall because it does the address-translation function of a full-featured firewall. Thus, the NAT router provides a first level of defense. A common attack uses the source IP address of a user's PC and steps through the known and upper IP ports to probe for a response. Certain of

these ports can be used to make an unauthorized access to the user's PC. Although the NAT router hides the PC user's IP address, it too has a valid public IP address that may now be the target of attacks. NAT routers will often respond to port 23 Telnet or port 80 HTTP requests because these ports are used for the router's configuration. The user must change the default passwords on the router, as a minimum; and, if allowable, disable any access to these ports from the Internet side.

Several companies offer simple NAT firewalls for this purpose. In addition, some products are available that combine the NAT function with the cable or DSL modem. For example, LinkSYS provides a choice of NAT routers with a single local Ethernet port or with four switched Ethernet ports. List prices for these devices are less than $200, with much lower street prices.

Install a Personal Firewall

The final step in securing a user's personal environment is to install a personal firewall. The current software environment includes countless user programs and processes that access the Internet. Many of the programs that connect to the Internet are obvious: the e-mail and Web browsers that everyone uses. However, one may be surprised to know that a vast array of other software also makes transmissions over the Internet connection whenever it is active. And if using a cable modem or DSL modem (or router), one's connection is always active if one's PC is on.

For example, Windows 98 has an update feature that regularly connects to Microsoft to check for updates. A virus checker, personal firewall, and even personal finance programs can also regularly check for updates or, in some cases, for advertising material. The Windows update is particularly persistent and can check every five or ten minutes if it is enabled. Advertisements can annoyingly pop up a browser mini-window, even when the browser is not active.

However, the most serious problems arise from the unauthorized access or responses from hidden servers. Chances are that a user has one or more Web server processes running right now. Even the music download services (e.g., MP3) plant servers on PCs. Surprisingly, these are often either hidden or ignored, although they represent a significant security risk. These servers can provide a backdoor into a PC that can be opened without the user's knowledge. In addition, certain viruses operate by planting a stealth server that can be later accessed by an intruder.

A personal firewall will provide a user essential control over all of the Internet accesses that occur to or from his PC. Several products are on the market to provide this function. Two of these are Zone Alarm from Zone Labs (www.zonelabs.com) and Black Ice Defender from Network Ice (www.networkice.com). Other products are available from Symantec and Network Associates. The use of a personal firewall will alert the user to all traffic to or from his broadband modem and allow the user to choose whether he wants that access to occur. After an initial setup period, Internet access will appear perfectly normal, except that unwanted traffic, probes, and accesses will be blocked.

Some of the products alert the user to unwanted attempts to connect to his PC. Zone Alarm, for example, will pop up a small window to advise the user of the attempt, the port and protocol, and the IP address of the attacker. The user can also observe and approve the ability of his applications to access the Internet. After becoming familiar with the behavior of these programs, the user can direct the firewall to always block or allow access. In addition, the user can explicitly block server behavior from particular programs. A log is kept of actions so that the user can review the firewall activities later, whether or not he disables the pop-up alert window.

Thus far, this chapter has concentrated on security for broadband access users. However, after seeing what the personal firewall detects and blocks, users will certainly want to put it on all their computers. Even dial-up connections are at great risk from direct port scanning and NetBIOS/IP attacks. After installation of a personal firewall, it is not unusual to notice probes beginning within the first 30 seconds after connecting. And if one monitors these alerts, one will continue to see such probes blocked over the course of a session. Do not be alarmed. These probes were happening before the firewall was installed, just without the user's knowledge. The personal firewall is now blocking all these attempts before they can do any harm. Broadband users with a consistent public IP address will actually see a dramatic decrease over time in these probes. The intruders do not waste time going where they are unwelcome.

Summary

Broadband access adds significant security risks to a network or a personal computer. The cable modem or DSL connection is normally always active and the bandwidth is very high compared to slower dial-up or ISDN methods. Consequently, these connections make easy targets for intrusion and disruption. Wireless Internet users have similar vulnerabilities, in addition to possible eavesdropping through the airwaves. Cable modem users suffer additional exposure to nonroutable workgroup protocols, such as Windows-native NetBIOS.

Steps should be taken in three areas to help secure PC resources from unwanted intrusions.

1. Eliminate or protect Windows workgroup functions such as file and printer sharing. Change the default passwords and enable IPX encapsulation if these functions are absolutely necessary.
2. Add a simple NAT firewall/router between the access device and PCs. This will screen internal addresses from outside view and eliminate most direct port scans.
3. Install and configure a personal firewall on each connected PC. This will provide control over which applications and programs have access to Internet resources.

New Perspectives on VPNs

Keith Pasley, CISSP, CNE

Wide acceptance of security standards in IP and deployment of quality-of-service (QoS) mechanisms like Differentiated Services (DiffServ) and Resource Reservation Protocol (RSVP) within Multi-Protocol Label Switching (MPLS) is increasing the feasibility of virtual private networks (VPNs). VPNs are now considered mainstream; most service providers include some type of VPN service in their offerings, and IT professionals have grown familiar with the technology. Also, with the growth of broadband, more companies are using VPNs for remote access and telecommuting. Specifically, the small-office/home-office market has the largest growth projections according to industry analysts. However, where once lay the promise of IPSec-based VPNs, it is now accepted that IPSec does not solve all remote access VPN problems.

As user experience with VPNs has grown, so have user expectations. Important user experience issues such as latency, delay, legacy application support, and service availability are now effectively dealt with through the use of standard protocols such as MPLS and improved network design. VPN management tools that allow improved control and views of VPN components and users are now being deployed, resulting in increased scalability and lower ongoing operational costs of VPNs. At one time it was accepted that deploying a VPN meant installing "fat"-client software on user desktops, manual configuration of encrypted tunnels, arcane configuration entry into server-side text-based configuration files, intrusive network firewall reconfigurations, minimal access control capability, and a state of mutual mystification due to vendor hype and user confusion over exactly what the VPN could provide in the way of scalability and manageability. New approaches to delivering on the objective of secure yet remote access are evolving, as shown by the adoption of alternatives to that pure layer 3 tunneling VPN protocol, IPSec. User feedback to vendor technology, the high cost of deploying and managing large-scale VPNs, and opportunity cost analysis are helping to evolve these new approaches to encrypting, authenticating, and authorizing remote access into enterprise applications.

Web-Based IP VPN

A granular focus on Web-enabling business applications by user organizations has led to a rethinking of the problem and solution by VPN vendors.

The ubiquitous Web browser is now frequently the "client" of choice for many network security products. The Web-browser-as-client approach solves a lot of the old problems but also introduces new ones. For example, what happens to any residual data left over from a Web VPN session? How is strong authentication performed? How can the remote computer be protected from subversion as an entry point to the internal network while the VPN tunnel is active? Until these questions are answered, Web browser-based VPNs will be limited from completely obsolescing client/server VPNs.

Most Web-based VPN solutions claim to deliver applications, files, and data to authorized users through any standard Web browser. How that is accomplished differs by vendor. A trend toward turnkey appliances is influencing the development of single-purpose, highly optimized and scalable solutions based on both proprietary and open-source software preinstalled on hardware. A three-tiered architecture is used by most of these vendors. This architecture consists of a Web browser, Web server/middleware, and back-end application.

The Web browser serves as the user interface to the target application. The Web server/middleware is the core component that translates the LAN application protocol and application requests into a Web browser-presentable format. Transport Layer Security (TLS) and Secure Socket Layer (SSL) are the common tunneling protocols used. Authentication options include user name and password across TLS/SSL, two-factor tokens such as RSA SecureID, and (rarely) Web browser-based digital certificates. Due to the high business value assigned to e-mail access, resilient hardware design and performance tuning of software to specific hardware is part of the appeal of the appliance approach. Redundant I/O, RAID 1 disk subsystems, redundant power supplies, hot-swappable cooling fans and disk drives, failover/clustering modes, dual processors, and flash memory-based operating systems are features that help ensure access availability. Access control is implemented using common industry-standard authentication protocols such as Remote Access Dial-In User Service (RADIUS, RFC 2138) and Lightweight Directory Access Protocol (LDAP, RFCs 2251–2256).

Applications

E-mail access is the number-one back-end application for this class of VPN. E-mail has become the lifeblood of enterprise operations. Imagine how a business could survive for very long if its e-mail infrastructure were not available. However, most Web-based e-mail systems allow cleartext transmissions of authentication and mail messages by default. A popular Web mail solution is to install a server-side digital certificate and enable TLS/SSL between the user browsers and the Web mail server. The Web mail server would proxy mail messages to the internal mail server. Variations to this include using a mail security appliance (Mail-VPN) that runs a hardened operating system and Web mail reverse proxy. Another alternative is to install the Web mail server on a firewall DMZ. The firewall would handle Web mail authentication and message proxying to and from the Web server on the DMZ. A firewall rule would be configured to only allow the DMZ Web server to connect to the internal mail server using an encrypted tunnel from the DMZ. E-mail gateways such as the McAfee series of e-mail security appliances focus on anti-virus and content inspection with no emphasis on securing the appliance itself from attack. Depending on how the network firewall is configured, this type of solution may be acceptable in certain environments.

On the other end of the spectrum, e-mail infrastructure vendors such as Mirapoint focus on e-mail components such as message store and LDAP directory server, but they offer very little integrated security of the appliance platform or the internal e-mail server. In the middle is the in-house solution, cobbled together using open-source components and cheap hardware with emphasis on low costs over resiliency, security, and manageability. Another class of Web mail security is offered by remote access VPN generalists such as Netilla, Neoteris, and Whale Communications. These vendors rationalize that the issue with IPSec VPNs is not that you cannot build an IPSec VPN tunnel between two IPSec gateways; rather, the issue is in trying to convince the peer IT security group to allow an encrypted tunnel through its firewall. Therefore, these vendors have designed their product architectures to use common Web protocols such as TLS/SSL and PPTP to tunnel to perimeter firewalls, DMZ, or directly to applications on internal networks.

VPN as a Service: MPLS-Based VPNS

Multi-Protocol Label Switching (MPLS) defines a data-link layer service (see Exhibit 48.1) based on an Internet Engineering Task Force specification (RFC 3031). MPLS specification does *not* define encryption or authentication. However, IPSec is a commonly used security protocol to encrypt IP data carried across an MPLS-based network. Similarly, various existing mechanisms can be used for authenticating users of MPLS-based networks. The MPLS specification defines a network architecture and routing protocol that efficiently forwards and allows prioritization of packets containing higher layer protocol data. Its essence is in the use of so-called labels. An MPLS label is a short identifier used to identify a group of packets that is forwarded in the same manner, such as along the same path, or given the same treatment. The MPLS label is inserted into existing protocol headers or can shimmed between protocol headers, depending on the type of device used to forward packets and overall network implementation.

For example, labels can be shimmed between the data-link and network layer headers or they can be encoded in layer 2 headers. The label is then used to route the so-called labeled packets between MPLS nodes. A network node that participates in MPLS network architectures is called a *label switch router* (LSR). The particular treatment of a labeled packet by an LSR is defined through the use of protocols that assign and distribute

EXHIBIT 48.1 MPLS topologies

Intranet/closed group
Simplest

Hub-and-spoke Internet access
Use a sub-interface for Internet
Use a different sub-interface for VPN

labels. Existing protocols have been extended to allow them to distribute MPLS LSP information, such as label distribution using BGP (MPLS-BGP). Also, new protocols have been defined explicitly to distribute LSP information between MPLS peer nodes. For example, one such newly defined protocol is the Label Distribution Protocol (LDP, RFC 3036). The route that a labeled packet traverses is termed a *label switched path* (LSP). In general, the MPLS architecture supports LSPs with different label stack encodings used on different hops. Label stacking defines the hierarchy of labels defining packet treatment for a packet as it traverses an MPLS internetwork. Label stacking occurs when more than one label is used, within a packet, to forward traffic across an MPLS architecture that employs various MPLS node types. For example, a group of network providers can agree to allow MPLS labeled packets to travel between their individual networks and still provide consistent treatment of the packets (i.e., maintain prioritization and LSP). This level of interoperability allows network service providers the ability to deliver true end-to-end service-level guarantees across different network providers and network domains. By using labels, a service provider and organizations can create closed paths that are isolated from other traffic within the service provider's network, providing the same level of security as other private virtual circuit (PVC)-style services such as Frame Relay or ATM.

Because MPLS-VPNs require modifications to a service provider's or organization's network, they are considered network-based VPNs (see Exhibit 48.2). Although there are topology options for deploying MPLS-VPNs down to end users, generally speaking, MPLS-VPNs do not require inclusion of client devices and tunnels usually terminate at the service provider edge router.

From a design perspective, most organizations and service providers want to set up bandwidth commitments through RSVP and use that bandwidth to run VPN tunnels, with MPLS operating within the tunnel. This design allows MPLS-based VPNs to provide guaranteed bandwidth and application quality-of-service features within that guaranteed bandwidth tunnel. In real terms, it is now possible to not only run VPNs but also enterprise resource planning applications, legacy production systems, and company e-mail, video, and voice telephone traffic over a single MPLS-based network infrastructure. Through the use of prioritization schemes within MPLS, such as Resource Reservation Protocol (RSVP), bandwidth can be reserved for specific data flows and applications. For example, highest prioritization can be given to performance-sensitive traffic that has to be delivered with minimal latency and packet loss and requires confirmation of receipt. Examples include voice and live video streaming, videoconferencing, and financial transactions. A second priority level could then be defined to allow traffic that is mission critical yet only requires an enhanced level of performance. Examples include FTP (e.g., CAD files, video clips) and ERP applications. The next highest priority can be assigned to traffic that does not require specific prioritization, such as e-mail and general Web browsing.

A heightened focus on core competencies by companies, now more concerned with improving customer service and reducing cost, has led to an increase in outsourcing of VPN deployment and management. Service

EXHIBIT 48.2 Sample MPLS Equipment Criteria

Hot standby loadsharing of MPLS tunnels
Authentication via RADIUS, TACACS+, AAA
Secure Shell (SSH) access
Secure Copy (SCP)
Multi-level access modes (EXEC, standard, etc.)
ACL support to protect against DoS attacks
Traffic engineering support via RSVP-TE, OSPF-TE, ISIS-TE
Scalability via offering a range of links: 10/100 Mbps Ethernet, Gigabit Ethernet, 10 Gigabit Ethernet, to OC-3c ATM, OC-3c SONET, OC-12c SONET, and OC-48c SONET
Redundant, hot-swappable interface modules
Rapid fault detection and failover
Network layer route redundancy protocols for resiliency; Virtual Router Redundancy Protocol (VRRP, RFC 2338) for layer 3 MPLS-VPN; Virtual Switch Redundancy Protocol (VSRP); and RSTP for layer 2 MPLS-VPN
Multiple queuing methods (e.g., weighted fair queuing, strict priority, etc.)
Rate limiting
Single port can support tens of thousands of tunnels

providers have responded by offering VPNs as a service using the differentiating capability of MPLS as a competitive differentiator. Service providers and large enterprises are typically deploying two VPN alternatives to traditional WAN offerings such as Frame Relay, ATM, or leased line: IPSec-encrypted tunnel VPNs and MPLS-VPNs. Additional flexibility is an added benefit because MPLS-based VPNs come in two flavors: layer 2 and layer 3. This new breed of VPN based on Multi-Protocol Label Switching (RFC 3031) is emerging as the most marketed alternative to traditional pure IP-based VPNs. Both support multicast routing via Internet Group Membership Protocol (IGMP, RFC 2236), which forwards only a single copy of a transmission to only the requesting port. The appeal of MPLS-based VPNs includes their inherent any-to-any reachability across a common data link. Availability of network access is also a concern of secure VPN design. This objective is achieved through the use of route redundancy along with routing protocols that enhance network availability, such as BGP. MPLS-VPNs give users greater control, allowing them to customize the service to accommodate their specific traffic patterns and business requirements. As a result, they can lower their costs by consolidating all of their data communications onto a single WAN platform and prioritizing traffic for specific users and applications. The resulting simplicity of architecture, efficiencies gained by consolidation of network components, and ability to prioritize traffic make MPLS-VPNs a very attractive and scalable option.

Layer 2 MPLS-VPN

Layer 2 MPLS-VPNs, based on the Internet Engineering Task Force's (IETF) Martini draft or Kompella draft, simply emulate layer 2 services such as Frame Relay, ATM, or Ethernet. With the Martini approach, a customer's layer 2 traffic is encapsulated when it reaches the edge of the service provider network, mapped onto a label-switched path, and carried across a network. The Martini draft describes point-to-point VPN services across virtual leased lines (VLLs), transparently connecting multiple subscriber sites together, independent of the protocols used. This technique takes advantage of MPLS label stacking, whereby more than one label is used to forward traffic across an MPLS architecture. Specifically, two labels are used to support layer 2 MPLS-VPNs. One label represents a point-to-point virtual circuit, while the second label represents the tunnel across the network. The current Martini drafts define encapsulations for Ethernet, ATM, Frame Relay, Point-to-Point Protocol, and High-level Data Link Control protocols. The Kompella draft describes another method for simplifying MPLS-VPN setup and management by combining the auto-discovery capability of BGP (to locate VPN sites) with the signaling protocols that use the MPLS labels. The Kompella draft describes how to provide multi-point-to-multi-point VPN services across VLLs, transparently connecting multiple subscriber sites independent of the protocols used. This approach simplifies provisioning of new VPNs. Because the packets contain their own forwarding information (e.g., attributes contained in the packet's label), the amount of forwarding

state information maintained by core routers is independent of the number of layer 2 MPLS-VPNs provisioned over the network. Scalability is thereby enhanced because adding a site to an existing VPN in most cases requires reconfiguring only the service provider edge router connected to the new site.

Layer 2 MPLS-VPNs are transparent, from a user perspective, much in the same way the underlying ATM infrastructure is invisible to Frame Relay users. The customer is still buying Frame Relay or ATM, regardless of how the provider configures the service. Because layer 2 MPLS-VPNs are virtual circuit based, they are as secure as other virtual circuit- or connection-oriented technologies such as ATM. Because layer 2 traffic is carried transparently across an MPLS backbone, information in the original traffic, such as class-of-service markings and VLAN IDs, remains unchanged. Companies that need to transport non-IP traffic (such as legacy IPX or other protocols) may find layer 2 MPLS-VPNs the best solution. Layer 2 MPLS-VPNs also may appeal to corporations that have private addressing schemes or prefer not to share their addressing information with service providers. In a layer 2 MPLS-VPN, the service provider is responsible only for layer 2 connectivity; the customer is responsible for layer 3 connectivity, which includes routing. Privacy of layer 3 routing is implicitly ensured. Once the service provider edge (PE) router provides layer 2 connectivity to its connected customer edge (CE) router in an MPLS-VPN environment, the service provider's job is done. In the case of trouble-shooting, the service provider need only prove that connectivity exists between the PE and CE. From a customer perspective, traditional, pure layer 2 VPNs function in the same way. Therefore, there are few migration issues to deal with on the customer side. Configuring a layer 2 MPLS-VPN is similar in process to configuring a traditional layer 2 VPN. The "last mile" connectivity, Frame Relay, HDLC, and PPP must be provisioned.

In a layer 2 MPLS-VPN environment, customers can run any layer 3 protocol they would like, because the service provider is delivering only layer 2 connectivity.

Most metropolitan area networks using MPLS-VPNs provision these services in layer 2 of the network and offer them over a high-bandwidth pipe. An MPLS-VPN using the layer 3 BGP approach is quite a complex implementation and management task for the average service provider; the layer 2 approach is much simpler and easier to provision.

Layer 3

Layer 3 MPLS-VPNs are also known as IP-enabled or Private-IP VPNs. The difference between layer 2 and layer 3 MPLS-VPNs is that, in layer 3 MPLS-VPNs, the labels are assigned to layer 3 IP traffic flows, whereas layer 2 MPLS-VPNs encode or shim labels between layer 2 and 3 protocol headers. A traffic flow is a portion of traffic, delimited by a start and stop time, that is generated by a particular source or destination networking device. The traffic flow concept is roughly equivalent to the attributes that make up a call or connection. Data associated with traffic flows are aggregate quantities reflecting events that take place in the duration between the start and stop times of the flow. These labels represent unique identifiers and allow for the creation of label switched paths (LSPs) within a layer 3 MPLS-VPN.

Layer 3 VPNs offer a good solution when the customer traffic is wholly IP, customer routing is reasonably simple, and the customer sites are connected to the SP with a variety of layer 2 technologies. In a layer 3 MPLS-VPN environment, internetworking depends on both the service provider and customer using the same routing and layer 3 protocols. Because pure IPSec VPNs require each end of the tunnel to have a unique address, special care must be taken when implementing IPSec VPNs in environments using private IP addressing based on network address translation. Although several vendors provide solutions to this problem, this adds more management complexity in pure IPSec VPNs.

One limitation of layer 2 MPLS-VPNs is the requirement that all connected VPN sites, using the same provider, use the same data-link connectivity. On the other hand, the various sites of a layer 3 MPLS-VPN can connect to the service provider with any supported data-link connectivity. For example, some sites may connect with Frame Relay circuits and others with Ethernet. Because the service provider in a layer 3 MPLS-VPN can also handle IP routing for the customer, the customer edge router need only participate with the provider edge router. This is in contrast to layer 2 MPLS-VPNs, wherein the customer edge router must deal with an unknown number of router peers. The traditional layer 2 problem of $n^*(n-1)/2$ inherent to mesh topologies carries through to layer 2 MPLS-VPNs as well. Prioritization via class of service is available in layer 3 MPLS-VPNs because the provider edge router has visibility into the actual IP data layer. As such, customers can assign priorities to traffic flows, and service providers can then provide a guaranteed service level for those IP traffic flows.

Despite the complexities, service providers can take advantage of layer 3 IP MPLS-VPNs to offer secure differentiated services. For example, due to the use of prioritization protocols such as DiffServ and RSVP, service providers are no longer hindered by business models based on flat-rate pricing or time and distance. MPLS allows them to meet the challenges of improving customer service interaction, offer new differentiated premium services, and establish new revenue streams.

Summary

VPN technology has come a long way since its early beginnings. IPSec is no longer the only standardized option for creating and managing enterprise and service provider VPNs. The Web-based application interface is being leveraged to provide simple, easily deployable, and easily manageable remote access and extranet VPNs. The strategy for use is as a complementary — not replacement — remote access VPN for strategic applications that benefit from Web browser user interfaces. So-called clientless or Web browser-based VPNs are targeted to users who frequently log onto their corporate servers several times a day for e-mails, calendar updates, shared folders, and other collaborative information sharing. Most of these new Web browser-based VPNs use hardware platforms using a three-tiered architecture consisting of a Web browser user interface, reverse proxy function, and reference monitor-like middleware that transforms back-end application protocols into browser-readable format for presentation to end users. Benefits of this new approach include ease of training remote users and elimination of compatibility issues when installing software on remote systems. Drawbacks include lack of support for legacy applications and limited throughput and scalability for large-scale and carrier-class VPNs.

The promise of any-to-any carrier-class and large-enterprise VPNs is being realized as MPLS-VPN standards develop and technology matures. Interservice provider capability allows for the enforcement of true end-to-end quality-of-service (QoS) guarantees across different provider networks. Multi-Protocol Label Switching can be accomplished at two levels: layer 2 for maximum flexibility, low-impact migrations from legacy layer 2 connectivity, and layer 3 for granular service offerings and management of IP VPNs. MPLS allows a service provider to deliver many services using only one network infrastructure. Benefits for service providers include reduced operational costs, greater scalability, faster provisioning of services, and competitive advantage in a commodity-perceived market. Large enterprises benefit from more efficient use of available bandwidth, increased security, and extensible use of existing well-known networking protocols. Users benefit from the increased interoperability among multiple service providers and consistent end-to-end service guarantees as MPLS products improve. In MPLS-based VPNs, confidentiality, or data privacy, is enhanced by the use of labels that provide virtual tunnel separation. Note that encryption is not accounted for in the MPLS specifications. Availability is provided through various routing techniques allowed by the specifications. MPLS only provides for layer 2 data-link integrity. Higher-layer controls should be applied accordingly.

An Examination of Firewall Architectures

Paul A. Henry, CISSP

> Today, the number-one and number-two (in sales) firewalls use a technique known as stateful packet filtering, or SPF. SPF has the dual advantages of being fast and flexible and this is why it has become so popular. Notice that I didn't even mention security, as this is not the number-one reason people choose these firewalls. Instead, SPF is popular because it is easy to install and doesn't get in the way of business as usual. It is as if you hired a guard for the entry to your building who stood there waving people through as fast as possible.

Firewall Fundamentals: A Review

The current state of *in*security in which we find ourselves today calls for a careful review of the basics of firewall architectures.

The level of protection that *any* firewall is able to provide in securing a private network when connected to the public Internet is directly related to the architectures chosen for the firewall by the respective vendor. Generally speaking, most commercially available firewalls utilize one or more of the following firewall architectures:

- Static packet filter
- Dynamic (stateful) packet filter
- Circuit-level gateway
- Application-level gateway (proxy)
- Stateful inspection
- Cutoff proxy
- Air gap

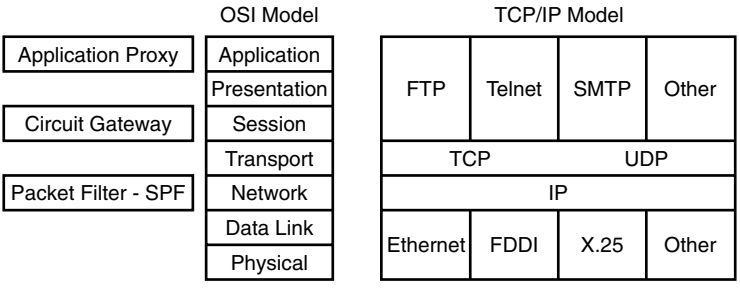

EXHIBIT 49.1 Firewall architectures.

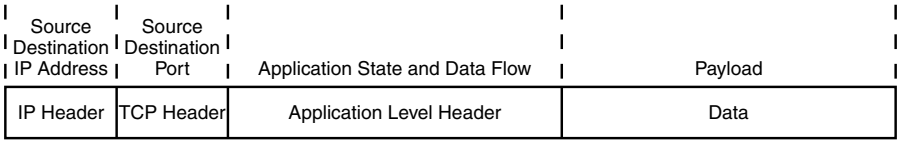

EXHIBIT 49.2 IP packet structure.

Network Security: A Matter of Balance

Network security is simply the proper balance of trust and performance.

All firewalls rely on the inspection of information generated by protocols that function at various layers of the OSI (Open Systems Interconnection) model. Knowing the OSI layer at which a firewall operates is one of the keys to understanding the different types of firewall architectures.

- Generally speaking, the higher up the OSI layer the architecture goes to examine the information within the packet, the more processor cycles the architecture consumes.
- The higher up in the OSI layer at which an architecture examines packets, the greater the level of protection the architecture provides because more information is available upon which to base decisions.

Historically, there had always been a recognized trade-off in firewalls between the level of trust afforded and speed (throughput). Faster processors and the performance advantages of symmetric multi-processing (SMP) have narrowed the performance gap between the traditional fast packet filters and high overhead-consuming proxy firewalls.

One of the most important factors in any successful firewall deployment is *who* makes the trust/performance decisions: (1) the firewall vendor, by limiting the administrator's choices of architectures, or (2) the administrator, in a robust firewall product that provides for multiple firewall architectures.

In examining the firewall architectures in Exhibit 49.1, looking within the IP packet, the most important fields are (see Exhibits 49.2 and 49.3):

- IP Header
- TCP Header
- Application-Level Header
- Data/payload Header

Static Packet Filter

The packet-filtering firewall is one of the oldest firewall architectures. A static packet filter operates at the network layer or OSI layer 3 (see Exhibit 49.4).

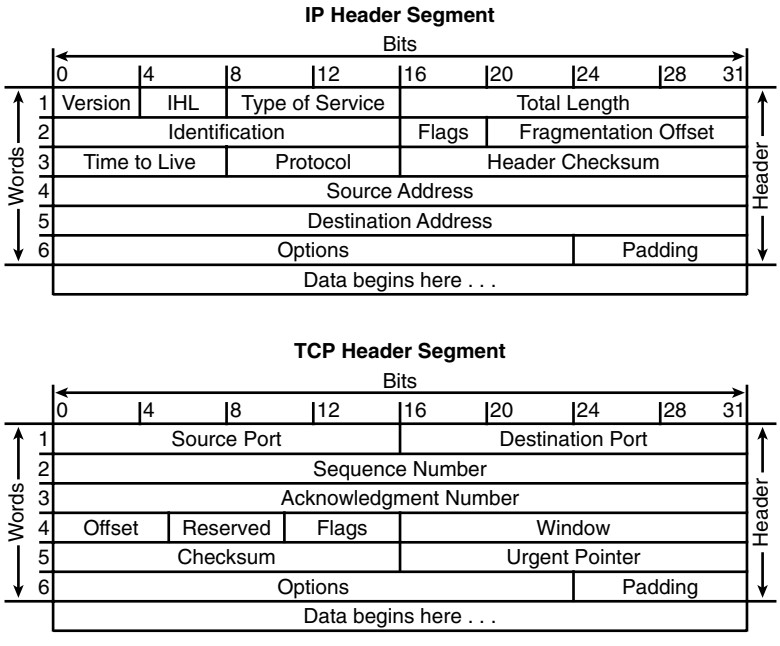

EXHIBIT 49.3 IP header segment versus TCP header segment.

The decision to accept or deny a packet is based upon an examination of specific fields within the packet's IP and protocol headers (see Exhibit 49.5):

- Source address
- Destination address
- Application or protocol
- Source port number
- Destination port number

Before forwarding a packet, the firewall compares the IP Header and TCP Header against a user-defined table — rule base — containing the rules that dictate whether the firewall should deny or permit packets to pass. The rules are scanned in sequential order until the packet filter finds a specific rule that matches the criteria specified in the packet-filtering rule. If the packet filter does not find a rule that matches the packet, then it imposes a default rule. The default rule explicitly defined in the firewall's table *typically* instructs the firewall to drop a packet that meets none of the other rules.

There are two schools of thought on the default rule used with the packet filter: (1) ease of use and (2) security first. *Ease of use* proponents prefer a default *allow all* rule that permits all traffic unless it is explicitly denied by a prior rule. *Security first* proponents prefer a default *deny all* rule that denies all traffic unless explicitly allowed by a prior rule.

Within the static packet-filter rules database, the administrator can define rules that determine which packets are accepted and which packets are denied. The IP Header information allows the administrator to write rules that can deny or permit packets to and from a specific IP address or range of IP addresses. The TCP Header information allows the administrator to write service-specific rules, that is, allow or deny packets to or from ports related to specific services.

The administrator can write rules that allow certain services such as HTTP from any IP address to view the Web pages on the protected Web server. The administrator can also write rules that block a certain IP address or entire ranges of addresses from using the HTTP service and viewing the Web pages on the protected server. In the same respect, the administrator can write rules that allow certain services such as SMTP from a trusted IP address or range of IP addresses to access files on the protected mail server. The administrator could also

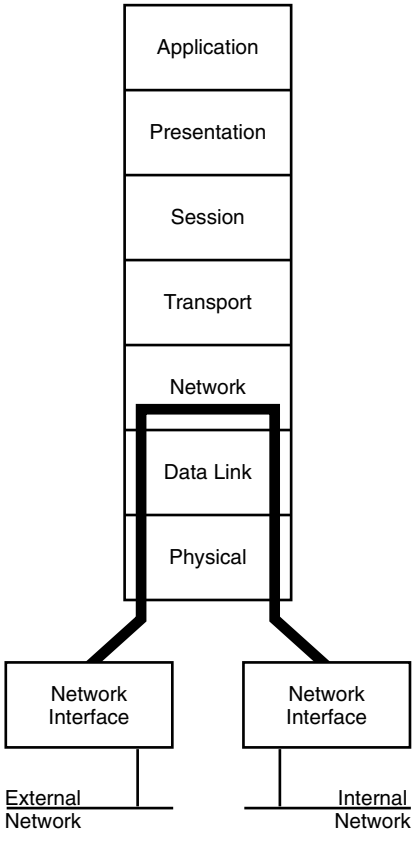

EXHIBIT 49.4 Static packet filter operating at the network layer.

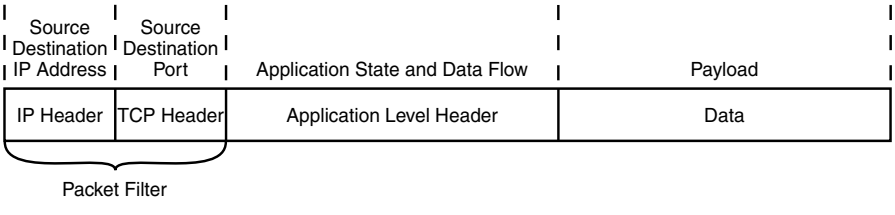

EXHIBIT 49.5 Static packet filter IP packet structure.

write rules that block access for certain IP addresses or entire ranges of addresses to access the protected FTP server.

The configuration of packet-filter rules can be difficult because the rules are examined in sequential order. Great care must be taken in the order in which packet-filtering rules are entered into the rule base. Even if the administrator manages to create effective rules in the proper order of precedence, a packet filter has one inherent limitation:

> A packet filter only examines data in the IP Header and TCP Header; it cannot know the difference between a real and a forged address. If an address is present and meets the packet-filter rules along with the other rule criteria, the packet will be allowed to pass.

Suppose the administrator took the precaution to create a rule that instructed the packet filter to drop any incoming packets with unknown source addresses. This packet-filtering rule would make it more difficult, but

not impossible, for a hacker to access at least some trusted servers with IP addresses. The hacker could simply substitute the actual source address on a malicious packet with the source address of a known trusted client. This common form of attack is called *IP address spoofing*. This form of attack is very effective against a packet filter. The CERT Coordination Center has received numerous reports of IP spoofing attacks, many of which resulted in successful network intrusions. Although the performance of a packet filter can be attractive, this architecture alone is generally not secure enough to keep out hackers determined to gain access to the protected network.

Equally important is what the static packet filter does *not* examine. Remember that in the static packet filter, only specific protocol headers are examined: (1) Source–Destination IP Address and (2) Source–Destination Port numbers (services). Hence, a hacker can hide malicious commands or data in unexamined headers. Further, because the static packet filter does not inspect the packet payload, the hacker has the opportunity to hide malicious commands or data within the packet's payload. This attack methodology is often referred to as a *covert channel attack* and is becoming more popular.

Finally, the static packet filter is *not state aware*. Simply put, the administrator must configure rules for both sides of the conversation to a protected server. To allow access to a protected Web server, the administrator must create a rule that allows both the inbound request from the remote client as well as the outbound response from the protected Web server. Of further consideration is that many services such as FTP and e-mail servers in operation today require the use of dynamically allocated ports for responses, so an administrator of a static packet-filtering-based firewall has little choice but to open up an entire range of ports with static packet-filtering rules.

Static packet filter considerations include:

- Pros:
  - — Low impact on network performance
  - — Low cost, now included with many operating systems
- Cons:
  - — Operates only at network layer and therefore only examines IP and TCP Headers
  - — Unaware of packet payload; offers low level of security
  - — Lacks state awareness; may require numerous ports be left open to facilitate services that use dynamically allocated ports
  - — Susceptible to IP spoofing
  - — Difficult to create rules (order of precedence)
  - — Only provides for a low level of protection

Dynamic (Stateful) Packet Filter

The dynamic (stateful) packet filter is the next step in the evolution of the static packet filter. As such, it shares many of the inherent limitations of the static packet filter with one important difference: *state awareness*.

The typical dynamic packet filter, like the static packet filter, operates at the network layer or OSI layer 3. An advanced dynamic packet filter may operate up into the transport layer — OSI layer 4 (see Exhibit 49.6) — to collect additional state information.

Most often, the decision to accept or deny a packet is based on examination of the packet's IP and Protocol Headers:

- Source address
- Destination address
- Application or protocol
- Source port number
- Destination port number

In simplest terms, the typical dynamic packet filter is *aware* of the difference between a new and an established connection. Once a connection is established, it is entered into a table that typically resides in RAM. Subsequent packets are compared to this table in RAM, most often by software running at the operating system (OS) kernel level. When the packet is found to be an existing connection, it is allowed to pass without any further

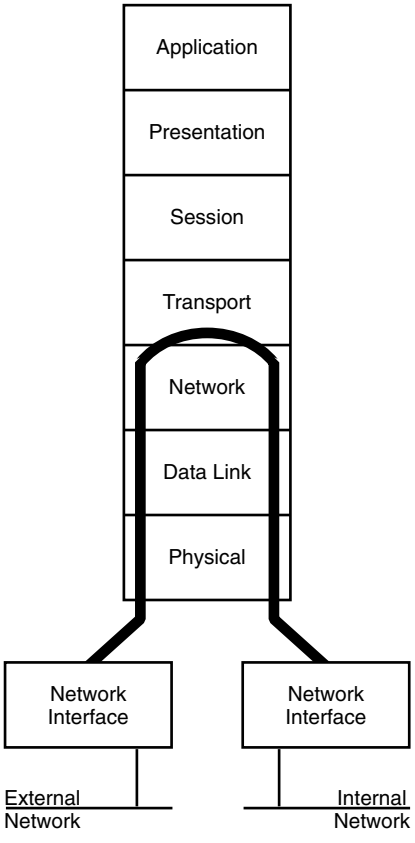

EXHIBIT 49.6 Advanced dynamic packet filter operating at the transport layer.

inspection. By avoiding having to parse the packet-filter rule base for each and every packet that enters the firewall and by performing this already- established connection table test at the kernel level in RAM, the dynamic packet filter enables a measurable performance increase over a static packet filter.

There are two primary differences in dynamic packet filters found among firewall vendors:

1. Support of SMP
2. Connection establishment

In writing the firewall application to fully support SMP, the firewall vendor is afforded up to a 30 percent increase in dynamic packet filter performance for each additional processor in operation. Unfortunately, many implementations of dynamic packet filters in current firewall offerings operate as a single-threaded process, which simply cannot take advantage of the benefits of SMP. Most often to overcome the performance limitation of their single-threaded process, these vendors require powerful and expensive RISC processor-based servers to attain acceptable levels of performance. As available processor power has increased and multi-processor servers have become widely utilized, this single-threaded limitation has become much more visible. For example, vendor *A* running on an expensive RISC-based server offers only 150 Mbps dynamic packet filter throughput, while vendor *B* running on an inexpensive off-the-shelf Intel multi-processor server can attain dynamic packet filtering throughputs of above 600 Mbps.

Almost every vendor has its own proprietary methodology for building the connection table; but beyond the issues discussed above, the basic operation of the dynamic packet filter for the most part is essentially the same.

In an effort to overcome the performance limitations imposed by their single-threaded, process-based dynamic packet filters, some vendors have taken dangerous shortcuts when establishing connections at the firewall. RFC guidelines recommend following the three-way handshake to establish a connection at the firewall.

One popular vendor will open a new connection upon receipt of a single SYN packet, totally ignoring RFC recommendations. In effect, this exposes the servers behind the firewall to single-packet attacks from spoofed IP addresses.

Hackers gain great advantage from anonymity. A hacker can be much more aggressive in mounting attacks if he can remain hidden. Similar to the example in the examination of a static packet filter, suppose the administrator took the precaution to create a rule that instructed the packet filter to drop any incoming packets with unknown source addresses. This packet-filtering rule would make it more difficult, but, again, not impossible for a hacker to access at least some trusted servers with IP addresses. The hacker could simply substitute the actual source address on a malicious packet with the source address of a known trusted client. In this attack methodology, the hacker assumes the IP address of the trusted host and must communicate through the three-way handshake to establish the connection before mounting an assault. This provides additional traffic that can be used to trace back to the hacker.

When the firewall vendor fails to follow RFC recommendations in the establishment of the connection and opens a connection without the three-way handshake, the hacker can simply spoof the trusted host address and fire any of the many well-known single-packet attacks at the firewall, or servers protected by the firewall, while maintaining complete anonymity. One presumes that administrators are unaware that their popular firewall products operate in this manner; otherwise, it would be surprising that so many have found this practice acceptable following the many historical well-known single-packet attacks like LAND, Ping of Death, and Tear Drop that have plagued administrators in the past.

Dynamic packet filter considerations include:

- Pros:
  - — Lowest impact of all examined architectures on network performance when designed to be fully SMP-compliant
  - — Low cost, now included with some operating systems
  - — State awareness provides measurable performance benefit
- Cons:
  - — Operates only at network layer, and therefore only examines IP and TCP Headers
  - — Unaware of packet payload, offers low level of security
  - — Susceptible to IP spoofing
  - — Difficult to create rules (order of precedence)
  - — Can introduce additional risk if connections can be established without following the RFC-recommended three-way handshake
  - — Only provides for a low level of protection

Circuit-Level Gateway

The circuit-level gateway operates at the session layer — OSI layer 5 (see Exhibit 49.7). In many respects, a circuit-level gateway is simply an extension of a packet filter in that it typically performs basic packet filter operations and then adds verification of proper handshaking and the legitimacy of the sequence numbers used to establish the connection.

The circuit-level gateway examines and validates TCP and User Datagram Protocol (UDP) sessions before opening a connection, or circuit, through the firewall. Hence, the circuit-level gateway has more data to act upon than a standard static or dynamic packet filter.

Most often, the decision to accept or deny a packet is based upon examining the packet's IP and TCP Headers (see Exhibit 49.8):

- Source address
- Destination address
- Application or protocol
- Source port number
- Destination port number
- Handshaking and sequence numbers

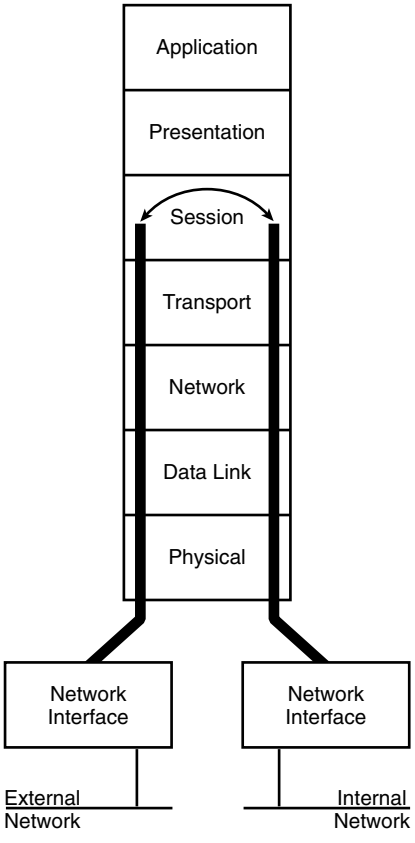

EXHIBIT 49.7 Circuit-level gateway operating at the session layer.

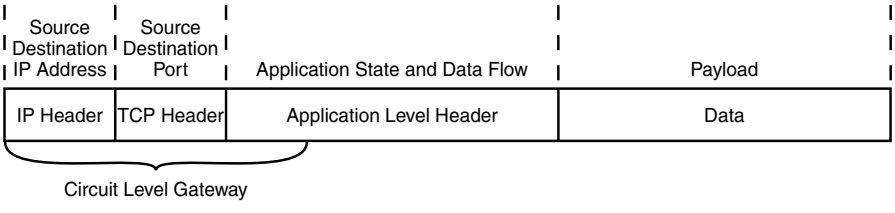

EXHIBIT 49.8 Circuit-level gateway IP packet structure.

Similar to a packet filter, before forwarding the packet, a circuit-level gateway compares the IP Header and TCP Header against a user-defined table containing the rules that dictate whether the firewall should deny or permit packets to pass. The circuit-level gateway then determines that a requested session is legitimate only if the SYN flags, ACK flags, and sequence numbers involved in the TCP handshaking between the trusted client and the untrusted host are logical.

If the session is legitimate, the packet-filter rules are scanned until one is found that agrees with the information in a packet's full association. If the packet filter does not find a rule that applies to the packet, then it imposes a default rule. The default rule explicitly defined in the firewall's table *typically* instructs the firewall to drop a packet that meets none of the other rules.

The circuit-level gateway is literally a step up from a packet filter in the level of security it provides. Further, like a packet filter operating at a low level in the OSI model, it has little impact on network performance. However, once a circuit-level gateway establishes a connection, any application can run across that connection because a circuit-level gateway filters packets only at the session and network layers of the OSI model. In other words, a circuit-level gateway cannot examine the data content of the packets it relays between a trusted network and an untrusted network. The potential exists to slip harmful packets through a circuit-level gateway to a server behind the firewall.

Circuit-level gateway considerations include:

- Pros:
  - — Low to moderate impact on network performance
  - — Breaks direct connection to server behind firewall
  - — Higher level of security than a static or dynamic (stateful) packet filter
- Cons:
  - — Shares many of the same negative issues associated with packet filters
  - — Allows any data to simply pass through the connection
  - — Only provides for a low to moderate level of security

Application-Level Gateway

Like a circuit-level gateway, an application-level gateway intercepts incoming and outgoing packets, runs proxies that copy and forward information across the gateway, and functions as a proxy server, preventing any direct connection between a trusted server or client and an untrusted host. The proxies that an application-level gateway runs often differ in two important ways from the circuit-level gateway:

1. The proxies are application specific.
2. The proxies examine the entire packet and can filter packets at the application layer of the OSI model (see Exhibit 49.9).

Unlike the circuit-level gateway, the application-level gateway accepts only packets generated by services they are designed to copy, forward, and filter. For example, only an HTTP proxy can copy, forward, and filter HTTP traffic. If a network relies only on an application-level gateway, incoming and outgoing packets cannot access services for which there is no proxy. For example, if an application-level gateway ran FTP and HTTP proxies, only packets generated by these services could pass through the firewall. All other services would be blocked.

The application-level gateway runs proxies that examine and filter individual packets, rather than simply copying them and recklessly forwarding them across the gateway. Application-specific proxies check each packet that passes through the gateway, verifying the contents of the packet up through the application layer (layer 7) of the OSI model. These proxies can filter on particular information or specific individual commands in the application protocols the proxies are designed to copy, forward, and filter. As an example, an FTP application-level gateway can filter on dozens of commands to allow a high degree of granularity on the permissions of specific users of the protected FTP service.

Current-technology application-level gateways are often referred to as *strong application proxies*. A strong application proxy extends the level of security afforded by the application-level gateway. Instead of copying the entire datagram on behalf of the user, a strong application proxy actually creates a brand-new empty datagram inside the firewall. Only those commands and data found acceptable to the strong application proxy are copied from the original datagram outside the firewall to the new datagram inside the firewall. Then, and only then, is this new datagram forwarded to the protected server behind the firewall. By employing this methodology, the strong application proxy can mitigate the risk of an entire class of covert channel attacks.

An application-level gateway filters information at a higher OSI layer than the common static or dynamic packet filter, and most automatically create any necessary packet-filtering rules, usually making them easier to configure than traditional packet filters.

By facilitating the inspection of the complete packet, the application-level gateway is one of the most secure firewall architectures available. However, historically some vendors (usually those that market stateful inspec-

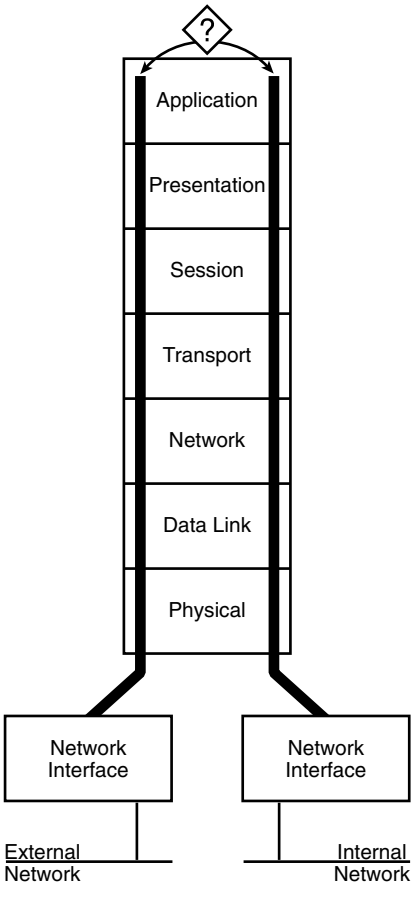

EXHIBIT 49.9 Proxies filtering packets at the application layer.

tion firewalls) and users made claims that the security an application-level gateway offers had an inherent drawback — a lack of transparency.

In moving software from older 16-bit code to current technology's 32-bit environment, and with the advent of SMP, many of today's application-level gateways are just as transparent as they are secure. Users on the public or trusted network in most cases do not notice that they are accessing Internet services through a firewall.

Application-level gateway considerations include:

- Pros:
  - — Application gateway with SMP affords a moderate impact on network performance.
  - — Breaks direct connection to server behind firewall, eliminating the risk of an entire class of covert channel attacks.
  - — Strong application proxy that inspects protocol header lengths can eliminate an entire class of buffer overrun attacks.
  - — Highest level of security.
- Cons:
  - — Poor implementation can have a high impact on network performance.
  - — Must be written securely. Historically, some vendors have introduced buffer overruns within the application gateway.

— Vendors must keep up with new protocols. A common complaint of application-level gateway users is lack of timely vendor support for new protocols.
— A poor implementation that relies on the underlying OS Inetd daemon will suffer from a severe limitation to the number of allowed connections in today's demanding high simultaneous session environment.

Stateful Inspection

Stateful inspection combines the many aspects of dynamic packet filtering, and circuit-level and application-level gateways. While stateful inspection has the inherent ability to examine all seven layers of the OSI model (see Exhibit 49.10), in the majority of applications observed by the author, stateful inspection was operated only at the network layer of the OSI model and used only as a dynamic packet filter for filtering all incoming and outgoing packets based on source and destination IP addresses and port numbers. While the vendor claims this is the fault of the administrator's configuration, many administrators claim that the operating overhead associated with the stateful inspection process prohibits its full utilization.

While stateful inspection has the inherent ability to inspect all seven layers of the OSI model, most installations only operate as a dynamic packet filter at the network layer of the model.

As indicated, stateful inspection can also function as a circuit-level gateway, determining whether the packets in a session are appropriate. For example, stateful inspection can verify that inbound SYN and ACK flags and sequence numbers are logical. However, in most implementations the stateful inspection-based firewall operates

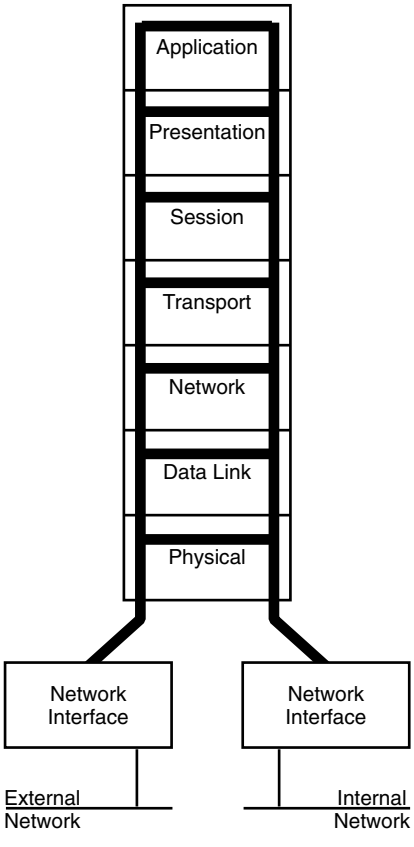

EXHIBIT 49.10 Stateful inspection examining all seven layers of the OSI model.

only as a dynamic packet filter and, dangerously, allows new connections to be established with a single SYN packet. A unique limitation of one popular stateful inspection implementation is that it does not provide the ability to inspect sequence numbers on outbound packets from users behind the firewall. This leads to a flaw whereby internal users can easily spoof the IP address of other internal users to open holes through the associated firewall for inbound connections.

Finally, stateful inspection can mimic an application-level gateway. Stateful inspection can evaluate the contents of each packet up through the application layer and ensure that these contents match the rules in the administrator's network security policy.

Better Performance, But What about Security?

Like an application-level gateway, stateful inspection can be configured to drop packets that contain specific commands within the Application Header. For example, the administrator could configure a stateful inspection firewall to drop HTTP packets containing a *Put* command. However, historically the performance impact of application-level filtering by the single-threaded process of stateful inspection has caused many administrators to abandon its use and to simply opt for dynamic packet filtering to allow the firewall to keep up with network load requirements. In fact, the default configuration of a popular stateful inspection firewall utilizes dynamic packet filtering and not stateful inspection of the most popular protocol on today's Internet — HTTP traffic.

Do Current Stateful Inspection Implementations Expose the User to Additional Risks?

Unlike an application-level gateway, stateful inspection does not break the client/server model to analyze application-layer data. An application-level gateway creates two connections: one between the trusted client and the gateway, and another between the gateway and the untrusted host. The gateway then copies information between these two connections. This is the core of the well-known proxy versus stateful inspection debate. Some administrators insist that this configuration ensures the highest degree of security; other administrators argue that this configuration slows performance unnecessarily. In an effort to provide a secure connection, a stateful inspection-based firewall has the ability to intercept and examine each packet up through the application layer of the OSI model. Unfortunately, because of the associated performance impact of the single-threaded stateful inspection process, this configuration is not the one typically deployed.

Looking beyond marketing hype and engineering theory, stateful inspection relies on algorithms within an inspection engine to recognize and process application-layer data. These algorithms compare packets against known bit patterns of authorized packets. Vendors have claimed that, theoretically, they are able to filter packets more efficiently than application-specific proxies. However, most stateful inspection engines represent a single-threaded process. With current-technology, SMP-based application-level gateways operating on multi-processor servers, the gap has dramatically narrowed. As an example, one vendor's SMP-capable multi-architecture firewall that does not use stateful inspection outperforms a popular stateful inspection-based firewall up to 4:1 on throughput and up to 12:1 on simultaneous sessions. Further, due to limitations in the inspection language used in stateful inspection engines, application gateways are now commonly used to fill in the gaps.

Stateful inspection considerations include:

- Pros:
  - — Offers the ability to inspect all seven layers of the OSI model and is user configurable to customize specific filter constructs.
  - — Does not break the client/server model.
  - — Provides an integral dynamic (stateful) packet filter.
  - — Fast when operated as dynamic packet filter; however, many SMP-compliant dynamic packet filters are actually faster.
- Cons:
  - — The single-threaded process of the stateful inspection engine has a dramatic impact on performance, so many users operate the stateful inspection-based firewall as nothing more than a dynamic packet filter.

— Many believe the failure to break the client/server model creates an unacceptable security risk because the hacker has a direct connection to the protected server.
— A poor implementation that relies on the underlying OS Inetd daemon will suffer from a severe limitation to the number of allowed connections in today's demanding high simultaneous session environment.
— Low level of security. No stateful inspection-based firewall has achieved higher than a Common Criteria EAL 2. Per the Common Criteria EAL 2 certification documents, EAL 2 products are not intended for use in protecting private networks when connecting to the public Internet.

Cutoff Proxy

The cutoff proxy is a hybrid combination of a dynamic (stateful) packet filter and a circuit-level proxy. In the most common implementations, the cutoff proxy first acts as a circuit-level proxy in verifying the RFC-recommended three-way handshake and then switches over to a dynamic packet filtering mode of operation. Hence, it initially works at the session layer — OSI layer 5 — and then switches to a dynamic packet filter working at the network layer — OSI layer 3 — after the connection is completed (see Exhibit 49.11).

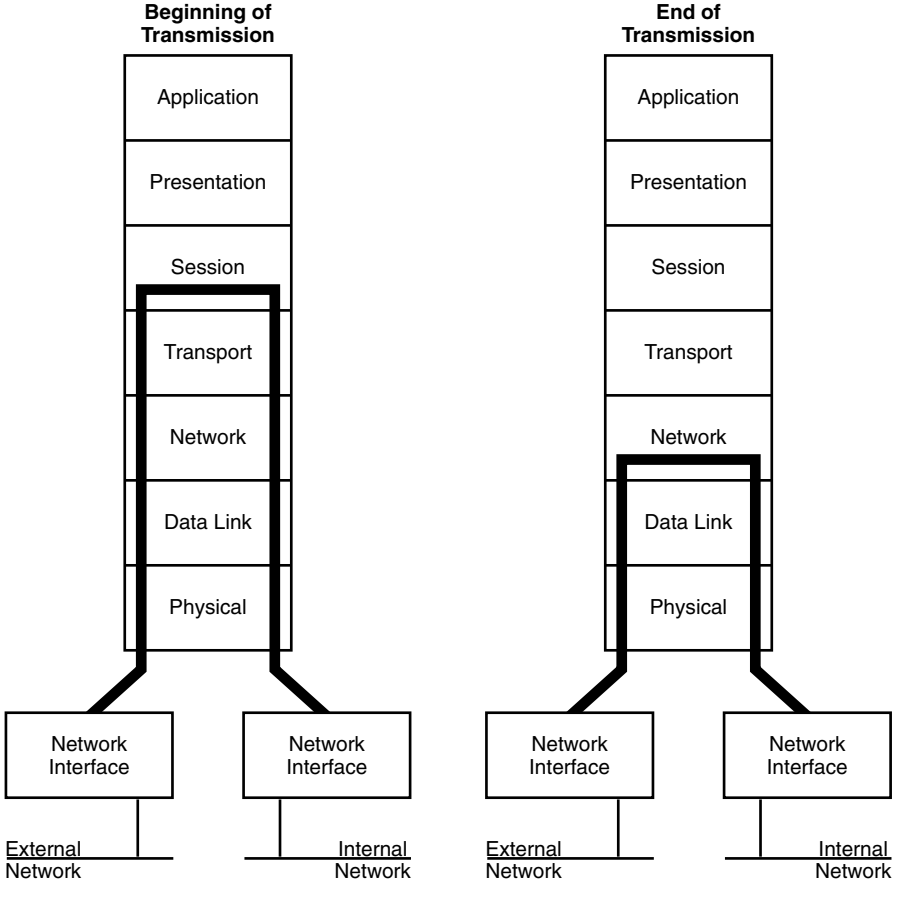

EXHIBIT 49.11 Cutoff proxy filtering packets.

The cutoff proxy verifies the RFC-recommended three-way handshake and then switches to a dynamic packet filter mode of operation.

Some vendors have expanded the capability of the basic cutoff proxy to reach all the way up into the application layer to handle limited authentication requirements (FTP type) before switching back to a basic dynamic packet-filtering mode of operation.

We pointed out what the cutoff proxy does; now, more importantly, we need to discuss what it does *not* do. The cutoff proxy is not a traditional circuit-level proxy that breaks the client/server model for the duration of the connection. There is a direct connection established between the remote client and the protected server behind the firewall. This is not to say that a cutoff proxy does not provide a useful balance between security and performance. At issue with respect to the cutoff proxy are vendors who exaggerate by claiming that their cutoff proxy offers a level of security equivalent to a traditional circuit-level gateway with the added benefit of the performance of a dynamic packet filter.

In clarification, this author believes that all firewall architectures have their place in Internet security. If your security policy requires authentication of basic services and examination of the three-way handshake and does *not* require breaking of the client/server model, the cutoff proxy is a good fit. However, administrators must be fully aware and understand that a cutoff proxy clearly is not equivalent to a circuit-level proxy because the client/server model is not broken for the duration of the connection.

Cutoff proxy considerations include:

- Pros:
  - — There is less impact on network performance than in a traditional circuit gateway.
  - — IP spoofing issue is minimized as the three-way connection is verified.
- Cons:
  - — Simply put, it is not a circuit gateway.
  - — It still has many of the remaining issues of a dynamic packet filter.
  - — It is unaware of packet payload and thus offers low level of security.
  - — It is difficult to create rules (order of precedence).
  - — It can offer a false sense of security because vendors incorrectly claim it is equivalent to a traditional circuit gateway.

Air Gap

The latest entry into the array of available firewall architectures is the air gap. At the time of this writing, the merits of air gap technology remain hotly debated among the security-related Usenet news groups. With air gap technology, the external client connection causes the connection data to be written to a SCSI e-disk (see Exhibit 49.12). The internal connection then reads this data from the SCSI e-disk. By breaking the direct connection between the client to the server and independently writing to and reading from the SCSI e-disk, the respective vendors believe they have provided a higher level of security and a resultant "air gap."

Air gap vendors claim that, while the operation of air gap technology resembles that of the application-level gateway (see Exhibit 49.13), an important difference is the separation of the content inspection from the "front end" by the isolation provided by the air gap. This may very well be true for those firewall vendors that implement their firewalls on top of a standard commercial operating system. But with the current-technology firewall operating on a kernel-hardened operating system, there is little distinction. Simply put, those vendors that chose to implement kernel-level hardening of the underlying operating system utilizing multi-level security (MLS) or containerization methodologies provide no less security than current air gap technologies.

The author finds it difficult to distinguish air gap technology from application-level gateway technology. The primary difference appears to be that air gap technology shares a common SCSI e-disk, while application-level technology shares common RAM. One must also consider the performance limitations of establishing the air gap in an external process (SCSI drive) and the high performance of establishing the same level of separation in a secure kernel-hardened operating system running in kernel memory space.

Any measurable benefit of air gap technology has yet to be verified by any recognized third-party testing authority. Further, the current performance of most air gap-like products falls well behind that obtainable by

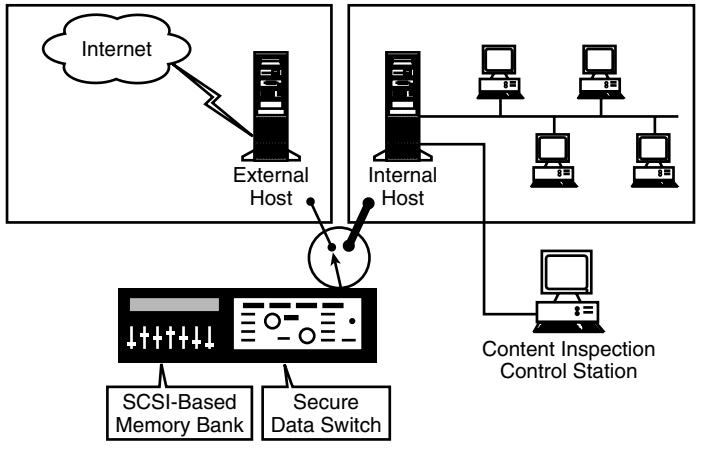

EXHIBIT 49.12 Air gap architecture.

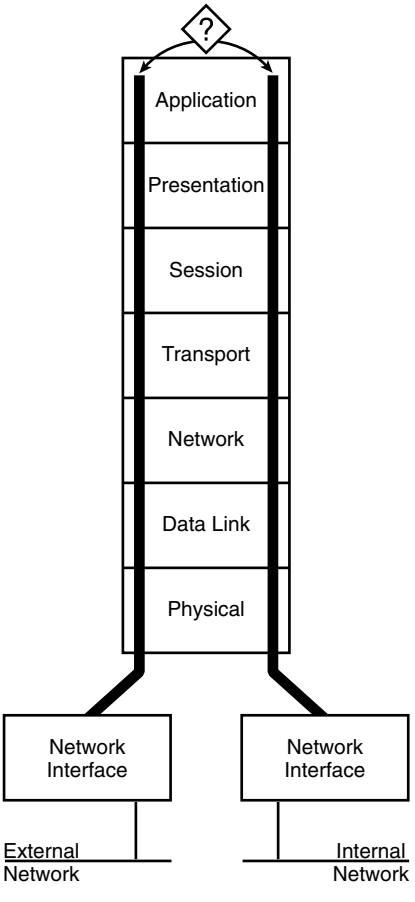

EXHIBIT 49.13 Air gap operating at the application layer.

traditional application-level gateway based products. Without a verifiable benefit to the level of security provided, the necessary performance costs are prohibitive for many system administrators.

Air gap considerations include:

- Pros:
  - It breaks direct connection to the server behind the firewall, eliminating the risk of an entire class of covert channel attacks.
  - Strong application proxy that inspects protocol header lengths can eliminate an entire class of buffer overrun attacks.
  - As with an application-level gateway, an air gap can potentially offer a high level of security.
- Cons:
  - It can have a high negative impact on network performance.
  - Vendors must keep up with new protocols. A common complaint of application-level gateway users is the lack of timely response from a vendor to provide application-level gateway support for a new protocol.
  - It is currently not verified by any recognized third-party testing authority.

Other Considerations

ASIC-Based Firewalls

Looking at typical ASIC-based offerings, the author finds that virtually all are VPN/firewall hybrids. These hybrids provide fast VPN capabilities but most often are only complemented with a limited single-architecture stateful firewall capability.

Today's security standards are in flux, so ASIC designs must be left programmable or "soft" enough that the full speed of ASICs simply cannot be unleashed.

ASIC technology most certainly brings a new level of performance to VPN operations. IPSec VPN encryption and decryption run inarguably better in hardware than in software. However, in most accompanying firewall implementations, a simple string comparison (packet to rule base) is the only functionality that is provided within the ASIC. Hence, the term "ASIC-based firewall" is misleading at best. The majority of firewall operations in ASIC-based firewalls are performed in software operating on microprocessors. These firewall functions often include NAT, routing, cutoff proxy, authentication, alerting, and logging.

When you commit to an ASIC, you eliminate the flexibility necessary to deal with future Internet security issues. Network security clearly remains in flux. While an ASIC can be built to be *good enough* for a particular purpose or situation, is *good enough* today really *good enough* for tomorrow's threats?

Hardware-Based Firewalls

The term *hardware-based firewall* is another point of confusion in today's firewall market. For clarification, most hardware-based firewalls are products that have simply eliminated the spinning media (hard disk drive) associated with the typical server or appliance-based firewalls.

Most hardware firewalls are either provided with some form of solid-state disk, or they simply boot from ROM, load the OS and application from firmware to RAM, and then operate in a manner similar to a conventional firewall.

The elimination of the spinning media is both a strength and a weakness of a hardware-based firewall. *Strength* is derived from limited improvements in MTBF and environmental performance by eliminating the spinning media. *Weakness* is present in severe limitations to the local alerting and logging capability, which most often requires a separate logging server to achieve any usable historical data retention.

Other Considerations: A Brief Discussion of OS Hardening

One of the most misunderstood terms in network security with respect to firewalls today is *OS hardening* or *hardened OS*. Many vendors claim their network security products are provided with a hardened OS. What

you will find in virtually all cases is that the vendor simply turned off or removed unnecessary services and patched the operating system or OS for known vulnerabilities. Clearly, this is not a hardened OS but really a *patched OS*.

What Is a Hardened OS?

A hardened OS (see Exhibit 49.14) is one in which the vendor has modified the kernel source code to provide for a mechanism that clearly provides a security perimeter among the non-secure application software, the secure application software, and the network stack. This eliminates the risk of the exploitation of a service running on the hardened OS that could otherwise provide root-level privilege to the hacker.

In a hardened OS, the security perimeter is established using one of two popular methodologies:

1. *Multi-Level Security (MLS):* establishes a perimeter through the use of labels assigned to each packet and applies rules for the acceptance of said packets at various levels of the OS and services
2. *Compartmentalization:* provides a sandbox approach whereby an application effectively runs in a dedicated kernel space with no path to another object within the kernel

Other security-related enhancements typically common in kernel-level hardening methodologies include:

- Separation of event logging from root
- Mandatory access controls
- File system security enhancements
- Log EVERYTHING from all running processes

What Is a Patched OS?

A patched OS is typically a commercial OS from which the administrator turns off or removes all unnecessary services and installs the latest security patches from the OS vendor. A patched OS has had no modifications made to the kernel source code to enhance security.

Is a Patched OS as Secure as a Hardened OS?

Simply put, no. A patched OS is only secure until the next vulnerability in the underlying OS or allowed services is discovered. An administrator may argue that when he has completed installing his patches and turning off services, his OS is, in fact, secure. The bottom-line question is: with more than 100 new vulnerabilities being posted to Bug Traq each month, how long will it remain secure?

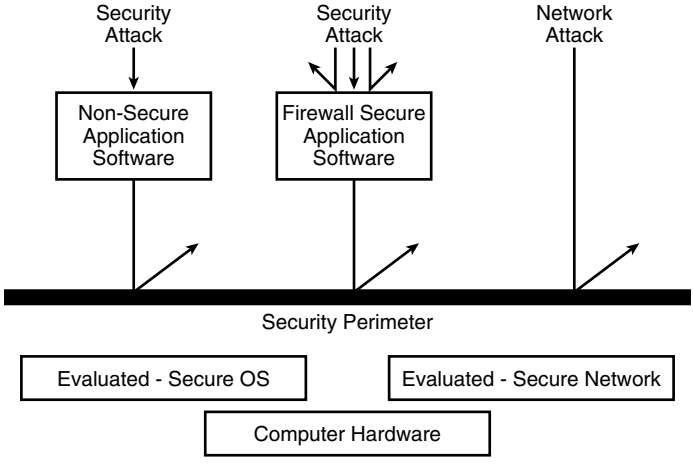

EXHIBIT 49.14 Hardened OS.

How Do You Determine if a Product Is Provided with a Hardened OS?

If the product was supplied with a commercial OS, you can rest assured that it is *not* a hardened OS. The principal element here is that, to harden an OS, you must own the source code to the OS so you can make the necessary kernel modification to harden the OS. If you really want to be sure, ask the vendor to provide third-party validation that the OS is, in fact, hardened at the kernel level, (e.g., http://www.radium.ncsc.mil/tpep/epl/historical.html).

Why Is OS Hardening Such an Important Issue?

Too many in the security industry have been lulled into a false sense of security. Decisions on security products are based primarily on popularity and price, with little regard for the actual security the product can provide.

Where Can You Find Additional Information about OS Vulnerabilities?

- www.securiteam.com
- www.xforce.iss.net
- www.rootshell.com
- www.packetstorm.securify.com
- www.insecure.org/sploits.html

Where Can You Find Additional Information about Patching an OS?

More than 40 experts in the SANS community have worked together over a full year to create the following elegant and effective scripts:

- For Solaris, http://yassp.parc.xerox.com/
- For Red Hat Linux, http://www.sans.org/newlook/projects/bastille_ linux.htm

Lance Spitzner (http://www.enteract.com/~lspitz/pubs.html) has written a number of excellent technical documents, including:

- Armoring Linux
- Armoring Solaris
- Armoring NT

Stanford University (http://www.stanford.edu/group/itss-ccs/security/Bestuse/Systems/) has also released a number of informative technical documents:

- Red Hat Linux
- Solaris
- SunOS
- AIX 4.x
- HPUX
- NT

Conclusion

Despite claims by various vendors, no single firewall architecture is the "holy grail" in network security. It has been said many times and in many ways by network security experts: if you believe any one technology is going to solve the Internet security problem, you do not understand the technology and you do not understand the problem.

Unfortunately for the Internet community at large, many administrators today design the security policy for their organizations around the limited capabilities of a specific vendor's product. The author firmly believes all firewall architectures have their respective place or role in network security. Selection of any specific firewall architecture should be a function of the organization's security policy and should not be based solely on the limitation of the vendor's proposed solution. The proper application of multiple firewall architectures to

support the organization's security policy in providing the acceptable balance of trust and performance is the only viable methodology in securing a private network when connecting to the public Internet.

One of the most misunderstood terms in network security with respect to firewalls today is *OS hardening*, or *hardened OS*. Simply put, turning off or removing a few unnecessary services and patching for known product vulnerabilities does not build a hardened OS. Hardening an OS begins with modifying the OS software at the kernel level to facilitate building a security perimeter. This security perimeter isolates services and applications from providing root access in the event of application- or OS-provided service compromise. Effectively, only a properly implemented hardened OS with a barrier at the kernel level will provide for an impenetrable firewall platform.

Deploying Host-Based Firewalls across the Enterprise: A Case Study

Jeffery Lowder, CISSP

Because hosts are exposed to a variety of threats, there is a growing need for organizations to deploy host-based firewalls across the enterprise. This chapter outlines the ideal features of a host-based firewall — features that are typically not needed or present in a purely *personal* firewall software implementation on a privately owned PC. In addition, the author describes his own experiences with, and lessons learned from, deploying agent-based, host-based firewalls across an enterprise. The author concludes that host-based firewalls provide a valuable additional layer of security.

A SEMANTIC INTRODUCTION

Personal firewalls are often associated with (and were originally designed for) home PCs connected to "always-on" broadband Internet connections. Indeed, the term *personal firewall* is itself a vestige of the product's history: originally distinguished from *enterprise* firewalls, *personal* firewalls were initially viewed as a way to protect home PCs.[1] Over time, it was recognized that personal firewalls had other uses. The security community began to talk about using personal firewalls to protect notebooks that connect to the enterprise LAN via the Internet and eventually protecting notebooks that physically reside on the enterprise LAN.

Consistent with that trend — and consistent with the principle of defense-in-depth — it can be argued that the time has come for the potential usage of personal firewalls to be broadened once again. Personal firewalls should really be viewed as *host-based* firewalls. As soon as one makes the distinction between host-based and network-based firewalls, the additional use of a host-based firewall becomes obvious. Just as organizations deploy host-based *intrusion detection systems* (IDS) to provide an additional detection capability for critical servers, organizations should consider deploying host-based *firewalls* to provide an additional layer of access control for critical servers (e.g., exchange servers, domain controllers, print servers, etc.). Indeed, given that many host-based firewalls have an IDS capability built in, it is conceivable that, at least for some small organizations, host-based firewalls could even *replace* specialized host-based IDS software.

The idea of placing one firewall behind another is not new. For years, security professionals have talked about using so-called internal firewalls to protect especially sensitive back-office systems.[2] However, internal firewalls, like network-based firewalls in general, are still dedicated devices. (This applies to both firewall appliances such as Cisco's PIX and software-based firewalls such as Symantec's Raptor.) In contrast, host-based firewalls require no extra equipment. A host-based firewall is a firewall software package that runs on a preexisting server or client machine. Given that a host-based firewall runs on a server or client machine (and is responsible for protecting *only* that machine), host-based firewalls offer greater functionality than network-based firewalls, even including internal firewalls that are dedicated to protecting a single machine. Whereas both network- and host-based firewalls have the ability to filter inbound and outbound network connections, only host-based firewalls possess the *additional* capabilities of blocking network connections linked to specific programs and preventing the execution of mail attachments.

To put this into proper perspective, consider the network worm and Trojan horse program QAZ, widely suspected to be the exploit used in the November 2000 attack on Microsoft's internal network. QAZ works by hijacking the NOTEPAD.EXE program. From the end user's perspective, Notepad still appears to run normally; but each time Notepad is launched, QAZ sends an e-mail message (containing the IP address of the infected machine) to some address in China.[3] Meanwhile, in the background, the Trojan patiently waits for a connection on TCP port 7597, through which an intruder can upload and execute any applications.[4] Suppose QAZ were modified to run over TCP port 80 instead.[5] While all firewalls can block outbound connections on TCP port 80, implementing such a configuration would interfere with legitimate traffic. Only a host-based firewall can block an outbound connection on TCP port 80 associated with NOTEPAD.EXE and notify the user of the event. As Steve Riley notes, "Personal firewalls

that monitor outbound connections will raise an alert; seeing a dialog with the notice 'Notepad is attempting to connect to the Internet' should arouse anyone's suspicions."[6]

STAND-ALONE VERSUS AGENT-BASED FIREWALLS

Host-based firewalls can be divided into two categories: stand-alone and agent-based.[7] Stand-alone firewalls are independent of other network devices in the sense that their configuration is managed (and their logs are stored) on the machine itself. Examples of stand-alone firewalls include ZoneAlarm, Sygate Personal Firewall Pro, Network Associates' PGP Desktop Security, McAfee Personal Firewall,[8] Norton Internet Security 2000, and Symantec Desktop Firewall.

In contrast, agent-based firewalls are not locally configured or monitored. Agent-based firewalls are configured from (and their logs are copied to) a centralized enterprise server. Examples of agent-based firewalls include ISS RealSecure Desktop Protector (formerly Network ICE's Black ICE Defender) and InfoExpress's CyberArmor Personal Firewall.

We chose to implement agent-based firewall software on our hosts. While stand-alone firewalls are often deployed as an enterprise solution, we wanted the agent-based ability to centrally administer and enforce a consistent access control list (ACL) across the enterprise. And as best practice dictates that the logs of network-based firewalls be reviewed on a regular basis, we wanted the ability to aggregate logs from host-based firewalls across the enterprise into a single source for regular review and analysis.

OUR PRODUCT SELECTION CRITERIA

Once we adopted an agent-based firewall model, our next step was to select a product. Again, as of the time this chapter was written, our choices were RealSecure Desktop Protector or CyberArmor. We used the following criteria to select a product:[9]

- *Effectiveness in blocking attacks.* The host-based firewall should effectively deny malicious inbound traffic. It should also at least be capable of effectively filtering outbound connections. As Steve Gibson argues, "Not only must our Internet connections be fortified to prevent *external intrusion,* they also [must] provide secure management of *internal extrusion.*"[10] By internal extrusion, Gibson is referring to outbound connections initiated by Trojan horses, viruses, and spyware. To effectively filter outbound connections, the host-based firewall must use cryptographic sums. The host-based firewall must first generate cryptographic sums for each authorized application and then regenerate and compare that sum to the one stored in the database before any program (no matter what the filename) is allowed access. If the application

does not maintain a database of cryptographic sums for all authorized applications (and instead only checks filenames or file paths), the host-based firewall may give an organization a false sense of security.

- *Centralized configuration.* Not only did we need the ability to centrally define the configuration of the host-based firewall, we also required the ability to *enforce* that configuration. In other words, we wanted the option to prevent end users from making security decisions about which applications or traffic to allow.
- *Transparency to end users.* Because the end users would not be making any configuration decisions, we wanted the product to be as transparent to them as possible. For example, we did not want users to have to 'tell' the firewall how their laptops were connected (e.g., corporate LAN, home Internet connection, VPN, extranet, etc.) in order to get the right policy applied. In the absence of an attack, we wanted the firewall to run silently in the background without noticeably degrading performance. (Of course, in the event of an attack, we would want the user to receive an alert.)
- *Multiple platform support.* If we were only interested in personal firewalls, this would not have been a concern. (While Linux notebooks arguably might need personal firewall protection, we do not have such machines in our environment.) However, because we are interested in implementing host-based firewalls on our servers as well as our client PCs, support for multiple operating systems is a requirement.
- *Application support.* The firewall must be compatible with all authorized applications and the protocols used by those applications.
- *VPN support.* The host-based firewall must support our VPN implementation and client software. In addition, it must be able to detect and transparently adapt to VPN connections.
- *Firewall architecture.* There are many options for host-based firewalls, including packet filtering, application-level proxying, and stateful inspection.
- *IDS technology.* Likewise, there are several different approaches to IDS technology, each with its own strengths and weaknesses. The number of attacks detectable by a host-based firewall will clearly be relevant here.
- *Ease of use and installation.* As an enterprisewide solution, the product should support remote deployment and installation. In addition, the central administrative server should be (relatively) easy to use and configure.
- *Technical support.* Quality and availability are our prime concerns.
- *Scalability.* Although we are a small company, we do expect to grow. We need a robust product that can support a large number of agents.
- *Disk space.* We were concerned about the amount of disk space required on end-user machines as well as the centralized policy and logging server. For example, does the firewall count the number of times

an attack occurs rather than log a single event for every occurrence of an attack?
- *Multiple policy groups.* Because we have diverse groups of end users, each with unique needs, we wanted the flexibility to enforce different policies on different groups. For example, we might want to allow SQL-Net traffic from our development desktops while denying such traffic for the rest of our employees.
- *Reporting.* As with similar enterprise solutions, an ideal reporting feature would include built-in reports for top intruders, targets, and attack methods over a given period of time (e.g., monthly, weekly, etc.).
- *Cost.* As a relatively small organization, we were especially concerned about the cost of selecting a high-end enterprise solution.

OUR TESTING METHODOLOGY

We eventually plan to install and evaluate both CyberArmor and RealSecure Desktop Protector by conducting a pilot study on each product with a small, representative sample of users. (At the time this chapter was written, we were nearly finished with our evaluation of CyberArmor and about to begin our pilot study of ISS Real Secure.) While the method for evaluating both products according to most of our criteria is obvious, our method for testing one criterion deserves a detailed explanation: effectiveness in blocking attacks. We tested the effectiveness of each product in blocking unauthorized connections in several ways:

- *Remote Quick Scan from HackYourself.com.*[11] From a dial-up connection, we used HackYourself.com's Quick Scan to execute a simple and remote TCP and UDP port scan against a single IP address.
- *Nmap scan.* We used nmap to conduct two different scans. First, we performed an ACK scan to determine whether the firewall was performing stateful inspection or a simple packet filter. Second, we used nmap's operating system fingerprinting feature to determine whether the host-based firewall effectively blocked attempts to fingerprint target machines.
- *Gibson Research Corporation's LeakTest.* LeakTest determines a firewall product's ability to effectively filter *outbound* connections initiated by Trojans, viruses, and spyware.[12] This tool can test a firewall's ability to block LeakTest when it masquerades as a trusted program (OUTLOOK.EXE).
- *Steve Gibson's TooLeaky.* TooLeaky determines whether the firewall blocks unauthorized programs from controlling trusted programs. The TooLeaky executable tests whether this ability exists by spawning Internet Explorer to send a short, innocuous string to Steve Gibson's Web site, and then receiving a reply.[13]
- *Firehole.* Firehole relies on a modified dynamic link library (DLL) that is used by a trusted application (Internet Explorer). The test is whether

the firewall allows the trusted application, under the influence of the malicious DLL, to send a small text message to a remote machine. The message contains the currently logged-on user's name, the name of the computer, and a message claiming victory over the firewall and the time the message was sent.[14]

CONFIGURATION

One of our reasons for deploying host-based firewalls was to provide an additional layer of protection against Trojan horses, spyware, and other programs that initiate outbound network connections. While host-based firewalls are not designed to interfere with Trojan horses that do not send or receive network connections, they can be quite effective in blocking network traffic to or from an unauthorized application when configured properly. Indeed, in one sense, host-based firewalls have an advantage over anti-virus software. Whereas anti-virus software can only detect Trojan horses that match a known *signature*, host-based firewalls can detect Trojan horses based on their network *behavior*. Host-based firewalls can detect, block, and even terminate any unauthorized application that attempts to initiate an outbound connection, even if that connection is on a well-known port like TCP 80 or even if the application causing that connection appears legitimate (NOTEPAD.EXE).

However, there are two well-known caveats to configuring a host-based firewall to block Trojan horses. First, the firewall must block all connections initiated by new applications *by default*. Second, the firewall must not be circumvented by end users who, for whatever reason, click "yes" whenever asked by the firewall if it should allow a new application to initiate outbound traffic. Taken together, these two caveats can cause the cost of ownership of host-based firewalls to quickly escalate. Indeed, other companies that have already implemented both caveats report large numbers of help desk calls from users wanting to get a specific application authorized.[15]

Given that we do not have a standard desktop image and given that we have a very small help desk staff, we decided to divide our pilot users into two different policy groups: pilot-tech-technical and pilot-normal-regular (See Exhibit 10-1).

The first configuration enabled users to decide whether to allow an application to initiate an outbound connection. This configuration was implemented only on the desktops of our IT staff. The user must choose whether to allow or deny the network connection requested by the connection. Once the user makes that choice, the host-based firewall generates a checksum and creates a rule reflecting the user's decision. (See Exhibit 10-2 for a sample rule set in CyberArmor.)

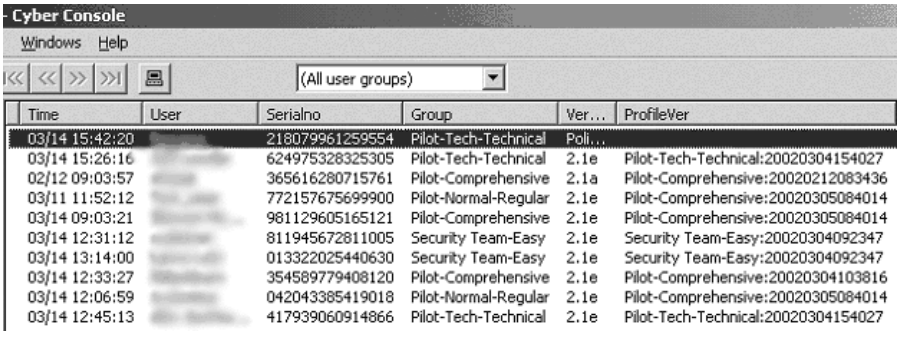

Exhibit 10-1. CyberArmor policy groups.

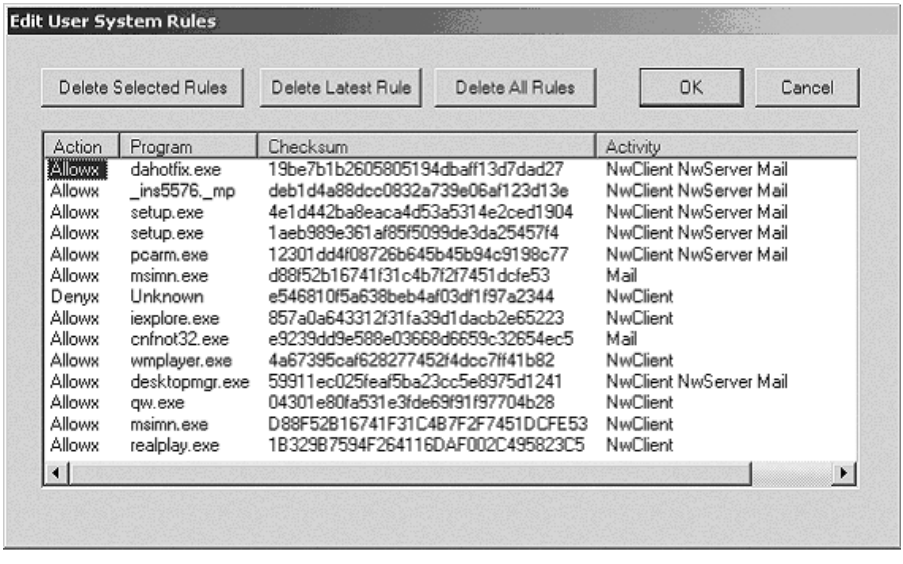

Exhibit 10-2. Sample user-defined rules in CyberArmor.

The second configuration denied all applications by default and only allowed applications that had been specifically authorized. We applied this configuration on all laptops outside our IT organization, because we did not want to allow nontechnical users to make decisions about the configuration of their host-based firewall.

LESSONS LEARNED

Although at the time this chapter was finished we had not yet completed our pilot studies on both host-based firewall products, we had already

learned several lessons about deploying agent-based, host-based firewalls across the enterprise. These lessons may be summarized as follows.

1. Our pilot study identified one laptop with a nonstandard and, indeed, unauthorized network configuration. For small organizations that do not enforce a standard desktop image, this should not be a surprise.
2. The ability to enforce different policies on different machines is paramount. This was evident from our experience with the host-based firewall to restrict outbound network connections. By having the ability to divide our users into two groups, those we would allow to make configuration decisions and those we would not, we were able to get both flexibility and security.
3. As is the case with network-based intrusion detection systems, our experience validated the need for well-crafted rule sets. Our configuration includes a rule that blocks inbound NetBIOS traffic. Given the amount of NetBIOS traffic present on both our internal network as well as external networks, this generated a significant amount of alerts. This, in turn, underscored the need for finely tuned alerting rules.
4. As the author has found when implementing network-based firewalls, the process of constructing and then fine-tuning a host-based firewall rule set is time consuming. This is especially true if one decides to implement restrictions on outbound traffic (and not allow users or a portion of users to make configuration decisions of their own), because one then has to identify and locate the exact file path of each authorized application that has to initiate an outbound connection. While this is by no means an insurmountable problem, there was a definite investment of time in achieving that configuration.
5. We did not observe any significant performance degradation on end user machines caused by the firewall software. At the time this chapter was written, however, we had not yet tested deploying host-based firewall software on critical servers.
6. Our sixth observation is product specific. We discovered that the built-in reporting tool provided by CyberArmor is primitive. There is no built-in support for graphical reports, and it is difficult to find information using the text reporting. For example, using the built-in text-reporting feature, one can obtain an "alarms" report. That report, presented in spreadsheet format, merely lists alarm messages and the number of occurrences. Source IP addresses, date, and time information are not included in the report. Moreover, the alarm messages are somewhat cryptic. (See Exhibit 10-3 for a sample CyberArmor Alarm Report.) While CyberArmor is compatible with Crystal Reports, using Crystal Reports to produce useful reports requires extra software and time.

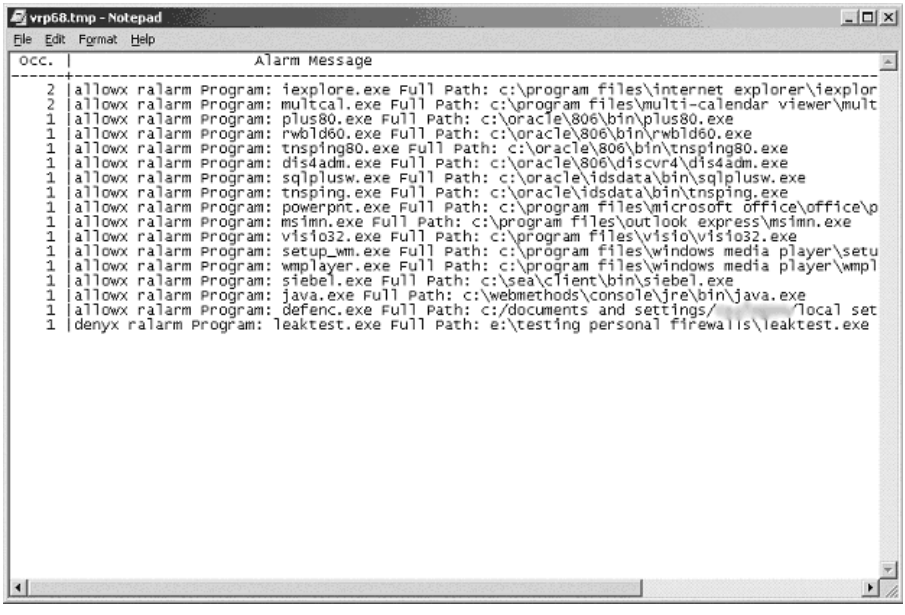

Exhibit 10-3. Sample CyberArmor alarm report.

HOST-BASED FIREWALLS FOR UNIX?

Host-based firewalls are often associated with Windows platforms, given the history and evolution of personal firewall software. However, there is no reason in theory why host-based firewalls cannot (or should not) be implemented on UNIX systems as well. To be sure, some UNIX packet filters already exist, including ipchains, iptables, and ipfw.[16] Given that UNIX platforms have not been widely integrated into commercial host-based firewall products, these utilities may be very useful in an enterprisewide host-based firewall deployment. However, such tools generally have two limitations worth noting. First, unlike personal firewalls, those utilities are packet filters. As such, they do not have the capability to evaluate an outbound network connection according to the application that generated the connection. Second, the utilities are not agent based. Thus, as an enterprise solution, those tools might not be easily scalable. The lack of an agent-based architecture in such tools might also make it difficult to provide centralized reporting on events detected on UNIX systems.

CONCLUSIONS

While host-based firewalls are traditionally thought of as a way to protect corporate laptops and privately owned PCs, host-based firewalls can also provide a valuable layer of additional protection for servers. Similarly, while host-based firewalls are typically associated with Windows platforms,

they can also be used to protect UNIX systems as well. Moreover, host-based firewalls can be an effective tool for interfering with the operation of Trojan horses and similar applications. Finally, using an agent-based architecture can provide centralized management and reporting capability over all host-based firewalls in the enterprise.

Acknowledgments

The author wishes to acknowledge Frank Aiello and Derek Conran for helpful suggestions. The author is also grateful to Lance Lahr, who proofread an earlier version of this chapter.

Instant Messaging Security Issues

William Hugh Murray, CISSP

> Nothing useful can be said about the security of a mechanism except in the context of a specific application and environment.
>
> **— Robert H. Courtney, Jr.**

> Privacy varies in proportion to the cost of surveillance to the government.
>
> **— Lawrence Lessig**

Instant messaging (IM) has moved from home to office, from a toy to an enterprise application. It has become part of our social infrastructure and will become part of our economic infrastructure. Like most technology, it has many uses — some good, some bad. It has both fundamental and implementation-induced issues. This chapter describes IM and gives examples of its implementation. It describes operation and examines some sample uses. It identifies typical threats and vulnerabilities, and examines the security issues that IM raises. It identifies typical security requirements and the controls available to meet them. Finally, it makes security recommendations for users, operators, enterprises, and parents.

Introduction and Background

Instant messaging, or chat, has been around for about 15 years. However, for most of its life, its use has been sparse and its applications trivial. Its use expanded rapidly with its inclusion in America Online's service. For many children, it was the first application of the Internet and the second application of the computer after games. Although many enterprises still resist it, it is now part of the culture. It is an interesting technology in that it originated in the consumer market and is migrating to the enterprise market. Like Web browsing before it, IM is entering the enterprise from the bottom up — from the user to the enterprise.

There may be as many as 100 million IM users but, because many users have multiple handles and subscribe to multiple services, it is difficult to know with any confidence. K. Petersen of *The Seattle Times* reports that many users have two or more IM clients open most of the time.

For most of its life, IM operated in a fairly benign environment. That is, it operated in the Internet in the days when the Internet was fairly benign. As is true of the Internet in general, business and government have been late to the party.

> On 9/11, communications in the nation, and in New York City in particular, were severely disrupted, mostly by unanticipated load. One could make a phone call out of the city but could not call into the city. Most news sites on the WWW did not respond to many requests; responses were limited to a line or two. Broadcast TV in the city was disrupted by loss of its primary antennas; only a few had backup. Cable TV, and broadcast TV outside the city, worked as intended, in part because they were

not sensitive to load. Cell phones worked well for a few minutes but soon fell over to load. The two-way communication that worked best under load was instant messaging. "First responders" found themselves using pagers (one way), SMS on cell phones, AOL Instant Messaging, BlackBerrys, and other forms of instant messaging.

At the risk of using a cliché, IM is a new paradigm. It is altering the way we see the world and will ultimately change the world. IM is changing the workplace as e-mail did before it. (Yes, e-mail changed the workplace. Although not all of us have been around long enough to notice, it has not always been as it is now.)

I was "chatting" with my colleague, Roger, yesterday. We were talking about a new IM client that we were installing on our PDAs. (We both use Handspring Treo communicators, cell phones integrated with a Palm OS PDA.) He said, "IM is the killer application for PDAs." I was surprised. I told him that I was working on this chapter and asked him to elaborate. He went on to say that for those of us who now work primarily from home and road (includes both of us and many of our colleagues), IM is now our virtual water cooler. It is where we conduct that business that we used to conduct by walking the halls or meeting in the cafeteria. It is also our peek-in-the-office-door to see if it is a convenient time to talk. Even if he plans to call a colleague on the phone, he sends an instant message first. IM complements the other spontaneous things that we do with a PDA.

In the discussion below you will see that IM is a network of people built on a network of hardware. Once the servers and protocols are in place, then its capabilities and its integration with other communication methods are limited only by the sophistication of the software clients. IM is the spontaneous collaboration tool of choice.

Description

This section describes instant messaging (IM) while later sections elaborate by discussing illustrative systems and typical operation.

At its most abstract, IM is a client/server application in which users communicate in short messages in near-real-time. The client performs input and output, the Internet provides transport and connectivity, while the servers provide message addressing, and, optionally, message forwarding.

IM's most popular instantiation is AOL Instant Messaging (AIM). There is an AIM client built into the AOL client. There are also AIM clients built into other applications and application suites.

IM users are represented as named windows on the desktop or within the client application. To send a message to the user represented by a window, one simply places the cursor in the window (making it the active window) and types in a message. That message then appears almost simultaneously in the window on someone else's system that represents the other end of the connection.

At its simplest, traffic is *one-to-one.* However, there is a *group mode* in which A sends an invitation to members of an affinity group to participate in a *one-to-many* or ***many-to-many mode.*** There is a second many-to-many mode where a "chat room" is established. The virtual room may be devoted to a group, a topic, or a discussion. Participants can enter or leave the *room* — that is, the discussion — at will. Participants in the room may be represented by nametags or by icons.

In theory, IM is synchronous: that is, a message from A to B is followed by a response from B to A. In practice, it is more "near synchronous;" that is, in part because of message origination latency, messages may be slightly out of order with two or more simultaneous threads.

IM is a relatively open application. While networks, servers, rooms, or groups may be closed to all but named and designated participants, most of them are open to all comers. The infrastructure (i.e., clients, servers, and connections) are open to all.

IM is also relatively interoperable. While most networks and servers interoperate primarily with their peers, many different clients can interoperate with others and many clients will operate with multiple networks and servers. The Trillian Professional client from Cerulean Studios will support simultaneous connections over the AOL, MS, Yahoo, ICQ, and multiple IRC networks. Time Warner, operator of both AIM and ICQ, has announced plans to permit interoperation of the two. Not only do IM systems interoperate with one another, but also with e-mail and voice mail.

Systems

This section identifies some of the more significant IM systems.

AOL IM

Far and away the most popular consumer IM system is AOL IM (AIM). Measured by numbers of registered users or traffic, no other system comes close. AOL well understands that the value of an IM system grows geometrically with the number of regular users.

While IM is bundled into the AOL client, and while it was originally intended for AOL's dial customers, it also uses the Internet where it is open to all comers. Anyone, AOL customer or not, can register a name on the AIM server. A number of stand-alone clients are available, including one from Netscape, AOL's software subsidiary. AOL encourages ISPs (Internet service providers) and other services to bundle an AOL client into their offering.

ICQ

Time Warner is also the operator of Internet CQ (ICQ). Amateur radio operators will recognize the model. While AOL IM is like the telephone, ICQ is more like a ham radio channel. While it is possible to set up a conference call, the telephone is primarily one-to-one. While it is possible to use a ham radio in one-to-one mode, it is essentially a many-to-many medium.

IRC

While some Internet historians date IM from ICQ in 1996, most recognize Internet Relay Chat (IRC), which originated in 1988, as the granddaddy of all instant messaging. IRC was built as an alternative to and elaboration of the (UNIX-to-UNIX) *talk* command. While IRC servers usually run on UNIX systems, clients are available for Wintel systems, IBM VM, EMACS, Macintosh, NeXTStep, VMS, and others. Early IRC clients were command-line driven and oriented. Many purists still prefer to use it in that mode. However, modern clients use a graphical user interface. For example, BitchX is a GUI client for UNIX/X-Windows systems.

Like ICQ, IRC is fundamentally many-to-many. A user does not connect to another user by username, but rather to a channel by reference to a channel name. Indeed, IRC users do not even have their own registered name. A user's input within a channel is identified only by an arbitrary nickname, which is good only as long as the user remains connected to the channel. A user does not own a nickname. As long as a nickname is not in current use, then anyone can use it. Thus, IRC is even more anonymous than most IM systems. (There was a registry of IRC nicknames, nickserv, but its use was voluntary. A user did not need to register his nickname; channels did not check the registry. Such a voluntary registry had so little value that nickserv has been down since the spring of 1994 and no one has seen fit to establish a replacement.)

There are also Web-based clients for IRC. Like Web-mail servers, these are servers that turn two-tier client/servers into three-tier. The real IRC client operates on a server and then is accessed by a WWW client (i.e., a browser). This means that a user need not have the ICQ client on his own system, but can access IRC from more places and more information will appear in the clear in the "network."

Lotus Sametime Connect

The Lotus Sametime Connect system is offered for enterprise IM and offers such features as exploitation of an existing enterprise directory (Notes server) and end-to-end encryption with key management (based on Lotus Notes public key infrastructure). In addition to text, Sametime supports voice and image.

NetMeeting

NetMeeting (NM) is a full-function collaboration client. While NM uses directories to resolve addresses, it usually operates peer-to-peer in a single network address space (or across address spaces via a proxy). In addition to chat, NM supports voice-chat, moving image, whiteboard (think graphical chat), file transfer, application sharing, and even desktop sharing.

Yahoo!

Yahoo! Messaging is Web based, consumer oriented, and public. It supports both user-to-user messages and chat rooms. There is a user registry but no public user directory; and there is a big directory of chat rooms.

MS Windows Messenger

Windows Messenger is the integration of IM into the MS Windows operating system. It uses the .Net Passport server to register users under their e-mail addresses or a local directory to register them under their usernames. Many of the features of NetMeeting (e.g., file send and receive, voice, video, whiteboard, application sharing, and desktop sharing) are integrated into the Messenger client function.

Others

Additional IM systems include Jabber (enterprise IM), businessim, Akonix (a gateway for enterprise use of public IM), 12planet (enterprise chat server), e/pop (enterprise), and GTV (enterprise IM with public gateway).

Operation

This section describes typical IM operations.

Installing the Client

For most users this is a necessary step and is usually as simple as clicking on an icon and responding to one or two prompts. Most IM clients are included in some other operating system or application the user already has. However, one may have to locate the client of choice in the Internet and download a copy. If one is an AOL or MSN user, IM is included in the clients for these networks. (Sometimes, the issue is getting rid of one of these.) The user may be prompted to set one or two global options at installation time.

Starting the Client

Starting the client is usually as simple as clicking on an icon. IM clients are often in the start-up list and many will try to put themselves there at installation time.

Sign-up

For many systems, new users must register their user IDs, "screen-names," handles, or aliases. In consumer systems, this may be as simple as responding to a prompt or two from the client program. In enterprise systems, it may be automatic for those who are already in the employee or user directory but may involve completing and signing a form and getting management approval for those who are not.

Populating Contact Lists

A sometimes necessary and always useful step is to populate one's contact or buddy list. This is usually as simple as entering the contact's username. Optionally, users can be organized into groups. Most clients will check usernames against the registry and report names that the registry does not recognize.

Connection

Connecting the client to the service is usually as simple as starting the software. It may even be automatic at system start-up. The client and server look to one another like an IP address and a port number. For most consumer and enterprise systems, this information is embedded in the client software and not visible or meaningful to the user. For IRC networks or multi-network clients, it may involve identifying and entering an IP address.

Log-on

IM services may require the user to log on with his handle. Client applications usually remember this value so that it can be selected from a drop-down list or entered by default. Most IM services also expect a passphrase. Again, clients usually include the ability to remember passphrases and enter them automatically. The security implication should be clear. Log-on to IM services is unusually persistent; in most systems it does not time-out.

> weemanjr (a.k.a. Tigerbait, Gatorbait, or Bitesize) recently visited me. He used my laptop and client software to log on to AOL IM. In fact, he did it so often that he set the default screen name to weemanjr, stored his passphrase, and set the client to log him on automatically. While I cannot see his passphrase, I do have beneficial use of it. Note that weemanjr might have connected from a place more hostile.

Contact Lists

Most client applications have the capability to store the names of an arbitrary number of contacts or correspondents and to organize them into folders. The collection of names of a user's correspondents is called a contact list or "buddy list." One enterprise IM system, Lotus Sametime Connect, provides two separate contact lists: one for insiders, based on the Lotus Notes directory server, and one for outsiders registered on the AOL IM server.

At log-on time, the contact list is restored to the client application. It may have been stored on the client side or the server side. Other things equal, the client side is more resistant to disclosure but not available from as many places as when stored on the server side. After the contact list is restored, it can be run against the server and the status of the each contact reflected in the client application contact list window.

I also have use of weemanjr's buddy list. It has two folders: "buddies" and "girls." The handles of the buddies suggest that they are male skateboard buddies or fellow game players. The handles of the girls suggest that they are (self-identified) flirts, flirting and gossiping being the principal activities of girls of weemanjr's age. Young people often use their birth dates to qualify otherwise common and descriptive names. Therefore, this buddy list leaks information, not only about the gender of the party, but also her age. This information suggests that weemanjr may have correspondents who do not know the code or are a little too old to interest him.

Sending Messages

When one clicks on the name or icon of a contact, the client application will attempt to open a connection to the contact; if the attempt is successful, then an application window associated with the sender will open on the receiver's system. The client application will put into the window identifying and state information. This information can include the recipient's name, online/offline, time since last activity, and, optionally, the capabilities of his client (e.g., voice, image, icon display, file send/receive).

One can type a message into the (bottom half of the) window; when new-line/return is keyed, the message is sent. All messages are displayed in the upper half of the window identified by the name of the sender.

Groups

One can invite multiple recipients to join an *ad hoc* group. A window will be opened on all participating client applications. All traffic among all participants in the group will appear in the associated window on all the windows. Each message will be labeled with the name of its sender. The group disappears when the last user leaves it.

Channels and Rooms

Channels and rooms are persistent discussions, usually associated with a topic or subject. Users can join a channel or a room at will, see all the traffic, send messages, and leave at will. Traffic can be labeled with the name of the sender. Depending on the application, the window may or may not show the handles of those connected to the channel or room; there may be unnoticed "lurkers." Channels, rooms, and their traffic may persist, even after the last user disconnects.

Sending and Receiving Files

Depending on the functionality included in the client application, one can "drag and drop" links, e-mail addresses, "emoticons" (e.g., smiley face), or other (arbitrary) objects into a connection window. If and how these appear on the recipient's system is a function of the recipient's application.

The sender drags the tag or icon of an object (e.g., program or data file) into the window representing an IM connection to another user. A window will open on the system of the receiver asking whether or not he wants to receive the file. If so, he is prompted for the location (e.g., folder or directory) in which to store it and the name to assign to it.

> Consider that weemanjr might easily have contaminated my system with a virus by accepting a file sent to him in IM.

Applications

The most general application of IM is to carry on a *conversation* between two or more people. For children, this conversation is a form of *socializing*; for adults, it might be. Subjects include current events, sports, queries, gossip, etc.

Depending on the support built into the client, many other applications can "piggyback" on (be encapsulated within) IM. For example, many clients support file transfer.

Similarly, the client can support the passing of sounds, voices, images, moving images, other arbitrary objects, applications, or even control of an entire system. The most sophisticated IM client, MS NetMeeting, supports all of these simultaneously. (NetMeeting is in a class by itself. It is so much more sophisticated than other IM clients that it is often not recognized as a member of the class.) Because the role of the server is message forwarding and addressing, no change in the functionality of the server may be required to achieve this level of sophistication.

IM for *customer and user support* has become an essential part of many business strategies. Telephone support personnel also use it as a "back-channel" to get assistance while they are talking to their customers or subscribers.

Consulting, design, and programming teams use IM for *collaboration,* even when they are all sitting around the same table. It adds so much to productivity that many of us simply refuse to work without it.

In the enterprise, IM supplements the public address, bulletin boards, and e-mail for making *announcements.* It is particularly useful for such announcements as virus warnings or weather emergencies where timeliness is essential.

Finally, IM is used for the "*grapevine,*" the alternative communication channel that most organizations resist but which, nonetheless, may be essential to their efficiency.

Capabilities

Bots

Some servers and clients support the ability to run processes other than simple addressing and forwarding. This capability exists to support easy functional extension of the application, that is, to make it easy to introduce new software. One IRC client (Bitchx) resulted from incorporating functionality added to an earlier client via a sophisticated script.

These added programs can be completely arbitrary. They can be written and instantiated by anyone with sufficient privilege or special knowledge. Those servers with this capability can be viewed as general-purpose computing engines attached to the Internet.

Most have security controls (e.g., lock-words or passphrases) to prevent their being contaminated or co-opted as attack engines. However, that leaves many that can be exploited. We have seen "bot wars" in which one or more bots are used to mount exhaustive attacks against the controls of otherwise more secure bots.

Rogue hackers use IM servers to hide the origin of attacks. In one scenario, compromised systems connect to a chat room and wait for a message. The rogue hacker then connects to that room and uses it to send a message containing the time and target of an exhaustive or denial-of-service attack. Said another way, the channel or room is used to coordinate all the listening and attacking systems.

Icons

Many client applications implement the capability for one user to send another user an icon to identify the sending user's window on the receiving user's system. Because these images might be offensive, most of these applications also include the capability to control the inclusion of the icon, even to display it a few bits at a time to avoid an ugly surprise.

Vulnerabilities

The vulnerabilities of IM are not likely to surprise anyone. They are the same vulnerabilities that we see in other parts of the Internet. Nonetheless, it is useful, if not necessary, to enumerate them. They fall into the same fundamental classes.

Fundamental Vulnerabilities

Fundamental vulnerabilities are those that are inherent in the environment or the application. They do not result from any action or inaction; they just are. They can be compensated for but they cannot be eliminated.

The biggest fundamental vulnerability of IM is that it is open. It is open as to services; anyone can put one up. Networks are open as to servers; by default, anyone can add one. IM is open as to users; again, by default, anyone can enroll for a service. This makes the network vulnerable to interference or contamination and the traffic vulnerable to leakage. While it is possible to create closed IM populations or networks, such closed populations and networks are significantly less useful than the open ones. Moreover, many client applications make it easy for users and clients to create connections between two otherwise disjointed networks.

User anonymity is a second fundamental vulnerability. The use of handles or aliases is the standard in IM. The strength of the bond between these aliases and a unique identity varies from spurious to sufficient to localize errors but sufficiently loose as to effectively hide malice. This dramatically reduces user accountability and, in some cases, can be used to successfully hide the identity of responsible parties. It seems to invite malice.

Because any kind of data hiding involves prearrangement between the sender and the receiver, most traffic in the IM moves in the clear. This means it may leak in the network. While this is offset by the fact that most of the traffic is trivial, it means that, in general, IM might not be suitable for enterprise applications. Moreover, the use of IM is so casual and spontaneous that users do cross the line between trivial traffic and sensitive traffic without even realizing it.

Implementation-Induced Vulnerabilities

Implementation-induced vulnerabilities do not have to exist. They are introduced by acts, omissions, or choices of the implementers. Most are the result of error or oversight.

Most implementation-induced vulnerabilities in IM are not unique to it. They are shared with the rest of the Internet. They include poor-quality software, often not identified with its provenance. Like much of the software in the Internet, this software *does not check or control its input* and is vulnerable to contamination by that input (the dreaded buffer overflow). Like much of the software in the Internet, it contains *escape mechanisms* that enable the knowledgeable to escape the application and its controls. Many servers are vulnerable to *interference from other applications* running in the same hardware or software environment. Much of this software employs *in-band controls.*

In some services, user data, (e.g., buddy lists and directory entries) are stored on servers. This is a legitimate design choice; it makes the application more portable. For example, one can use one's buddy list from one's (wireless) PDA or from an airport or coffee shop kiosk. However, it replaces millions of little targets with two or three large ones. It magnifies the consequences of a successful attack against those servers. Such a successful attack results in the compromise of the confidentiality of large amounts of data. Some of this data may be sensitive to disclosure. For example, contact lists encapsulate information about personal associations; directory entries may contain information about personal interests, not to say compulsions. To some degree, users have not thought about the sensitivity of this information. To some extent they are willing to share it in this context. Many do not care in any case. However, some would not want to have it posted on the Internet.

Operator-Induced Vulnerabilities

To the extent that we rely on IM for anything, we rely on the operators of the servers. In some, perhaps even most, cases, we have contracts with the operators. These agreements contain the terms of service for the service; these TOS bind mostly the user. In general, the operators promise "best efforts," but to the extent we can rely on them for anything, we can rely on what the TOS promises.

However, some services (e.g., IRC) are collaborative in nature. There is no single provider to whom we can look. The network may be no stronger than the weakest server in it.

User-Induced Vulnerabilities

Similarly, the things that users do to introduce vulnerabilities should be familiar.

Weak Passwords

Although IM passwords can be attacked (on the servers) by bots, most client applications do not enforce strong password rules. By default, most IM applications permit the user to store the user's password and submit it automatically. And although most clients will automatically enter long pass-phrases, users still prefer short ones.

Use of Default Settings

Users prefer default configurations; they simplify setup and encapsulate special knowledge about the use of a product. For events such as receipt of a message, client applications seem to default to "ask." For example, if the user does not specify whether or not to receive a message, the Trillian client will ask. However, for other choices, it may not ask. The default setting is to send the message when the Enter key is pressed. This may result in the message being sent accidentally before it is reviewed. One might not even understand that there is a safer option.

Accepting Bait Objects

Users can always compromise their systems and enterprise networks by accepting bait objects. Said from the attacker's perspective, when all else fails, exploit user behavior. As we have seen, IM has grown from being text-only to include arbitrary objects. All that is necessary to compromise a user is to find bait that he does not resist. Bait for individuals may exploit knowledge of their interests. Fishing in chat rooms exploits the fact that at a big enough party, some people will eat the soggy potato chips. Every fisherman knows that if the fish are not biting, change the bait. If they still do not bite, move to a new spot. IM is a big space with a lot of fish.

Other

All lists of vulnerabilities should end with "other." Although we are pretty good at identifying broad categories of vulnerabilities, no group of people is likely to identify all the dumb things that users will do.

Issues

This section discusses some of the security-related issues surrounding IM.

Policy and Awareness

Most damage from the use of IM will be done in error by otherwise well-intentioned users. As with most technology, the problems are really people problems. If management must rely on user behavior, it is essential that it describes that behavior to users. Management may set almost any policy that it likes but it may not be silent.

One useful rule is that security policy should treat all communications media consistently. Users should be able to choose the most efficient medium for a message. They should not be forced to choose an inefficient medium simply to satisfy arbitrary rules, security or otherwise.

Efficiency

Management questions whether IM really improves productivity enough to compensate for its intrusiveness and its potential to distract users from work. It is instructive that management no longer asks the same question about the most intrusive technology of all, the telephone. In any case, it is not as if management has much choice. The pattern of growth for the use of IM is well established and is not likely to reverse, or even level off. Management had best get used to it; workers will. Workers will integrate IM into their work styles as they have the telephone, the computer, and e-mail. It will not be seen as a distraction but simply as part of the workspace.

> When I first entered business in the early 1950s, desks did not come with a telephone by default. It was a perk just to have one's name on the directory. I say "on" because it was often only one or two pages in length. There was no direct-inward-dialing (DID); all incoming calls went through the operator. Some business phones did not even have dials; the operator completed outbound calls. In the world of flat-rate telephone service, I no longer try to recover the cost of business phone calls from my clients.

Personal Use

A significant policy issue for all communications is that of personal use. Management has a fundamental responsibility to conserve the resources of the enterprise. It must instruct users as to how enterprise resources may be consumed. With regard to personal use, IM should be treated the same as the telephone or the mailroom. If management permits personal use of the telephone, then it should permit personal use of IM under similar rules.

> As recently as 20 years ago, my employer sent me a detailed accounting of all toll calls made from the phone assigned to me. I was expected to identify those that were "personal" and write a check to the cashier to cover those calls. Those of you too young to remember it will say, "How quaint." Even then, the cost of those "personal" calls was trivial when compared to the value of my time spent on them. Sometime in these 20 years, as the cost of telephone calls has plummeted, the total cost of accounting for personal use began to exceed the reduction in expenses that could be achieved, and we stopped doing that. Now, workers bring their cell phones to work and make and receive their personal calls on them.

Anonymity

As we have already noted, the use of aliases and "handles" is the default in IM. While these handles may be related to name, role, or (e-mail) address, they are often related to a persona that the user would like to project. Some users have many. Directory entries are also used, as much to project this image as to inform.

Depending on the service or environment, the handle may or may not be bound to the user's identity. For example, AOL IM users must assert a name as the destination for messages. However, AIM permits the user to assert more than one arbitrary name. However, once registered, a name belongs to the user. He may abandon it; but unless and until he does so, it is his. IRC reserves a nickname only for the life of a connection.

Visibility

The other side of anonymity is visibility — that is, how the IM system makes one known to other users. A system that hides you completely may not be useful at all. However, one that makes one very visible may leak more information than the subject realizes. If A sends a message to B, A may receive a message that says B is/is not online. If A and B are in each other's contact list, there may be information available to each about the status (online/offline, active/inactive, home/away) of the other. Many servers will return information about all of those in the user's contact list when the user registers on the server.

> When weemanjr is connected and logged on to AIM, the icon next to his name in my client lights up. If I pass my cursor over his icon, I am given information about the state of his connection, for example, whether or not he is online, how long he has been online or when he was last seen; whether he is connected via the AOL dial-up client or via the Internet, and what the capabilities of his client

are. Of course, I must know his ID, weemanjr. I might assume that his IM name is the same as his e-mail address or AOL screen name but I would be wrong. However, if one made that assumption about me, one would be correct.

Intrusion

At its best and from time to time, instant messages intrude. Although they are not as intrusive as spam, and certainly less intrusive than the telephone, they are still intrusive. Most client applications provide controls to permit the user to reject traffic from specified users; the permissive policy. Indeed, they permit the rejection of all traffic except that from specified users: the restrictive policy. In either case, some action is required on the part of the user to elect and administer the policy.

Leakage

To the extent that the enterprise worries about the security of IM, it is usually concerned with the leakage of confidential information. IM can leak information in many ways. The user can leak information inadvertently or from motives such as anger or spite. Information can leak in transmission. It can leak to privileged users of servers or from compromised servers. It can leak through directories or registries.

Note that contact lists can be stored locally or on the server. Although servers need be trusted to some degree or another, information stored there is vulnerable to leakage. The aggregation of this information on a server is a more attractive target than the individual records stored on the client side.

Enterprise IM systems will record some traffic in logs. These logs become targets and may leak information.

Wireless

Increasingly, IM includes wireless. Most Internet-enabled cell phones include an IM client, usually for AOL IM or Yahoo! There are AOL and Yahoo! clients for Palm OS and Windows Pocket PC devices. While traffic to these devices may be partially hidden by the transport mechanism, these devices do not yet support end-to-end encryption.

IM is also used over wireless LAN technology (802.11) to laptops. These devices can support both link encryption (e.g., SSL) and end-to-end encryption. Wireless LAN encryption, standard (WEP) or proprietary, may be useful or indicated where one is aware of wireless links. However, the real issue is that cheap wireless makes the transport layer unreliable. This should be compensated for by the use of end-to-end encryption.

Immediacy

When the IM "send" key is pressed, any damage that might be done has already been done. Neither the user nor management gets a second chance. Premature or accidental sends may result if the send key is the same as the return or new-line key. Some IM applications permit one to set the client preferences so that sending a message requires strong intent.

Late Binding

As we have seen, IM manifests a distinct preference for late programmability; that is, it may be easy to modify the function of the client application program. After all, much of IM was "built by programmers for programmers." One implication of this is that it is difficult to rely on consistent behavior from these offerings.

Fraud

IM, with anonymity or even without it, is used to perpetrate all kinds of scams and frauds. Users tend to believe messages that pop up on their screens, particularly if they appear to come from trusted sources. For example, a message might suggest that the recipient enter a passphrase, enter a command, or click on an icon or a link. This is a way of getting that action invoked with the identity and privileges of the recipient.

Trust

As a general rule, IM users rely upon their ability to recognize one another by content; they do not rely on the environment, and trust is not much of an issue. However, in the future, populations will be larger, and the requirement for trusted directories and registries will also be higher.

Surveillance

Management can use surveillance as a control to direct or restrain the use of communication in general and IM in particular. In some cases, it should do so. However, if surveillance of any communication medium becomes pervasive, or even routine, that will stifle its use and diminish its value. Management's interest in the content of communication must be balanced against the right of the worker to reasonable privacy.

IM is some place between telephone and e-mail in terms of spontaneity and in terms of the value and permanence of the record that it leaves. Similarly, the cost and utility of automated surveillance of IM is also between that of the telephone and that of e-mail. Those who have automated surveillance of voice telephone will certainly want to automate surveillance of IM. However, those who have not automated surveillance of e-mail will certainly not want to automate surveillance of IM.

Any record of surveillance of communication is more sensitive to disclosure than the original communication itself. It becomes a target of attack and of "fishing expeditions." Good practice suggests that such a record be used early and then destroyed.

Offensive Content

At least at the margins, society, including the Internet, contains some ugliness. IM is no exception to this. This is troubling, in part because IM is an application that children like and because its favorite application for children is socializing. Children also use IM to satisfy (sexual) curiosity that they are discouraged from satisfying in other places. They use it to practice saying things that they are inhibited from saying aloud and face-to-face.

Coupled with the routine hiding or misrepresentation of user identity (e.g., age, gender, appearance, class, role), the result is that children may be exposed to ugliness and even to seduction. One might make a case that the Internet may be safer from seduction than home, school, church, mall, or playground, but that is small comfort, particularly if it is likely.

Similar behavior or content in the enterprise may compromise the enterprise's responsibility to provide a commodious workplace. Said another way, the enterprise may be held responsible for protecting its employees from ugliness, even if they seek it out.

Discipline

IM space is very tolerant but it does have standards of polite behavior. As with any other social population, there are sanctions for violating these standards. As with any rude behavior, the first sanction is shunning by the community. Those who behave in a rude manner will find themselves "blocked," that is, ostracized.

The service provider may impose harsher sanctions. For example, AOL vigorously enforces its terms of service.

> Littleone was "in an ICQ chat room." He used language that violated the AOL terms of service. This was language that littleone was not likely to have used without the cloak of anonymity provided by IM. It was language that littleone would not want his mother to hear, from him or anyone else. His mother, the account owner, reminded him of the language after she received a call from AOL support representatives. The support reps told her that if she could not clean up littleone's act, they would cancel her account.

While one cannot be completely banned from IRC, channel owners can and do block rude users by IP address. They have been known to ostracize entire domains or address ranges in order to enforce their standards of behavior.

Enterprise management exercises a great deal of power and discipline. IM is a part of the workplace and management is responsible and accountable for what happens there. Because management can be held accountable for some user IM behavior, it must exercise some control. At a minimum, management must tell workers

what use is appropriate and what is not. As with any other security violation, management can use disciplinary measures — from reprimand to termination.

Controls

As you might expect, IM comes with controls that can be used to protect its users and its traffic. The user, parents and guardians, or managers can use these features to manage risk. However, keep in mind that IM is inherently high risk and will usually remain so even with the prudent application of these controls.

Enrollment

Many IM systems require a user to register a unique public identifier. Other users will use this identifier to address messages to him. The service will use this identifier to find the network address to which to send the messages. At the same time, the user may be required to exchange a secret with the service. This passphrase will be used to authenticate the user to ensure that the service sends messages to only the party intended by the sender.

While some systems will accept only one enrollment from those who are already its users, most will permit an arbitrary number from just about anyone.

Directories

Services may maintain a directory of users and their addresses. Users can use this directory to locate the identifier of those to whom they wish to send a message. In many public systems, the information in the directory is supplied by the user and is not reliable. Some service providers may use account and billing information to improve the association between a user identifier and, for example, a real name and address. For example, AOL maintains a directory of its users. Access to this directory is available to AOL subscribers. AOL permits subscribers to limit access to their own directory entries. In private systems, management may own the directory and ensure that all users are authorized, properly named, and that any descriptive information (e.g., department, function, or role) in the directory is reliable.

Identification and Authentication

Most IM applications provide controls that can be used to identify and authenticate senders and recipients. Most permit both the identifier and the passphrase to be of a length sufficient to make identity both obvious and difficult to forge. However, many implement a preference for connectivity over security; that is, they start, connect, and even log on automatically. This recognizes that value goes up with the number and persistence of connections. It requires that the password or passphrase be stored locally. Because the value of connectivity is so high, the connection does not time out. Thus, once the machine has been properly initialized, the connection(s) and the identity are available to anyone with access to the machine. It may not be sufficient to learn the passphrase but it is sufficient to use it for a while. Of course, it is very difficult to protect a system from someone who has physical access to it in a running state, so this is as much a physical security issue as an I&A one.

Thus, passwords resist attack on the server at the expense of requiring that the desktop be supervised or that the screen and keyboard time out while maintaining the connection (as with Windows NT or 2000).

On the other hand, storing passwords and entering them automatically means that errors and retries do not rise (rapidly) with length. Long names make identity more patent and reduce addressing errors. Long passphrases resist exhaustive and guessing attacks.

Although passwords are the only authenticators supported by IM programs, these can be complemented by any strong authentication methods used on the client machine. For example, if the BIOS and OS passwords are used, then these protect the stored IM password.

Preferences

Client applications enable the user to specify preferences. Many of these are security relevant. The user may be able to specify what is to happen at system start, at client start, at connect, and on receipt of a message. For

example, the user may say start the client at system start, connect and log on at application start, load contact list and contact status at application start, and then set "away" status and default away message. The user may be able set alarm events, sounds, and actions. He may be able to specify events and messages to log, where to store the log, and what program to use to view it (e.g., Notepad, Excel). The user may be able to specify the default directory for storing received files. He may be able to specify whether to accept icons automatically, never to accept them, or to ask the user.

Blocking

IM applications provide the user with the ability to block messages from all users by default and from specified users. Blocking reduces the chances of intrusion, harassment, or offensive content.

Blocking at the client is based on sender name. It is used to protect the recipient from intrusion, ugliness, and spam. By default, a message from a sender not in the recipient's contact list may be blocked; the user will be asked if he wishes to receive the message and add the sender to the contact list.

Blocking can also be done at the enterprise perimeter or server. Here it can be based on sender name or recipient name. Sender name blocking works as above. Blocking on recipient name might be used as an upstream control to protect the recipient from a denial-of-service attack where the sender name is randomized. Products are available for centralized administration of blocking across a network or a user population.

Direct Connection

Some client applications enable users to connect directly to one another so that the traffic does not go through the server and cannot be seen by the privileged users of that server.

Encryption

Similarly, some enterprise IM client applications enable users to encrypt their communications. Many IM applications encrypt using (one-way) SSL user-to-server and server-to-user. This implementation requires that the message be decrypted from A's key and re-encrypted under that of B at the server. This means that the server must be trusted not to leak the message content. The IM server is trusted to some degree in any case; within the enterprise, it may be highly trusted. The advantage of this system is that information can be encrypted many-to-many between non-peer clients. The only requirement is that all clients support SSL.

A few products enable traffic to be encrypted end-to-end but only to peer systems. For example, Trillian Professional clients can communicate directly and encrypt their sessions end-to-end. Although this requires an extra election on the part of the users and a little additional setup time, it does lower the risk of leakage between the systems. Lotus Sametime Connect uses the Lotus Notes PKI to automatically create end-to-end IM sessions between two or more users within the enterprise while permitting unencrypted sessions to other users registered on the AIM server outside the enterprise.

Logging

Enterprise IM clients and services offer logging capabilities, including logs that are made at the server and are not under the control of the user. This permits the traffic to be audited for evidence of information leakage, fraud, harassment, or other prohibited activity (e.g., order solicitation by stockbrokers, prohibited use of healthcare information). Although it might be possible to log telephone traffic in a similar way, the cost of auditing those logs would be prohibitive. As enterprises come to understand this, IM becomes not only a permissible medium for this kind of communication, but also the preferred medium.

Enterprise management should keep in mind that the value of logs decreases rapidly with time but that their nuisance value increases. Their value for ensuring that you do the right thing decreases as their potential to demonstrate that you did not do the right thing goes up. Logs may contain sensitive information and may be targets. Access controls over their use are necessary to ensure that they are useful but do not leak information.

Reporting

Enterprise IM products report both IM usage and message traffic content. Properly privileged users and administrators not only see the content of the traffic, but also can map it back to the descriptive information about the sender and recipient in the directory and registry servers. Some products permit this information to be viewed by means of a thin client (Web browser).

Auditing

Auditing can be viewed as the reconciliation of what happened to what was intended and expected. It can also be viewed as the review of the logs to understand their content. There are data reduction, analysis, and visualization products that the manager or auditor can use to help him convert the log contents into information to guide policy formation and problem remediation. These products include general-purpose tools such as sorts, spreadsheets, databases, and data-mining tools. They also include specialized tools that encapsulate special knowledge about what to look for, how to find it, and what to do with it.

Filtering

Products are available to filter messages and other data objects for keywords suggesting sensitive or inappropriate content or virus signatures. They can be used to resist information leakage and system and network contamination. For efficient use, these products require both policy (to specify what traffic should not flow) and administration (to convert that policy into rules that the filter can use). They add latency to the message flow and produce false positives that might block legitimate traffic. They are most applicable in such regulated enterprises as healthcare and financial services where not only policy but also regulations are available to guide rule writing.

As IM use increases and computers become more efficient, filter applications can be expected to become more effective and efficient.

Alarms and Messaging

Products that filter IM traffic for viruses and sensitive content will generate alarms. These alarms must be communicated to those who are in a position to initiate the necessary corrective action. Failure to respond consistently to alarms will invite or encourage abuse.

Recommendations

Like safety on the highway or security on the telephone, security in IM will be the result of the efforts of users and institutions. Because no one person or institution can achieve security by acting alone, the following recommendations are organized by role.

- General:
  - — Prefer the AOL IM registry for a reasonable balance between connectivity and order.
  - — Prefer MS NetMeeting for complete functionality and end-to-end traffic hiding.
  - — Prefer enterprise directories for reliability and authenticity.
- For enterprises:
  - — Publish and enforce appropriate policies. Consider personal use, software, and content (including threatening, sexually explicit, or ugly). Consider leakage of proprietary information.
  - — Prefer enterprise IM client and server application products.
  - — Use only management-chosen and -trusted applications, from reliable sources, and in tamper-evident packaging.

- Prefer closed networks and enterprise-managed servers for security.
- Control traffic at the perimeter or gateways; use appropriate firewalls and proxies.
- Use enterprise directories.
- Require long passphrases.
- Require or prefer direct client-to-client connections and end-to-end encryption for enterprise data.
- Log and audit traffic; except where discouraged by regulation, destroy the log as soon as the audit has been completed.
- Filter traffic where indicated by policy or regulation.

• For network and server operators:
- Publish and enforce appropriate terms of service.
- Configure servers as single application systems.
- Do not permit late changes to system; do not run script or command processors (no "bots").
- Provide secure channel for (out-of-band) server controls.
- Consider separate device for registry database.

• For users:
- Use the most functionally limited client that meets your requirements.
- Prefer popular consumer systems such as AOL, MS Messenger, and Yahoo!.
- Use the most limited settings sufficient for your intended use.
- Accept messages and other data objects (e.g., files, icons, images) only from those already known to you; block all other traffic by default.
- Choose your username(s) to balance your privacy against ease-of-use for your contacts.
- Use long passphrases to resist exhaustive attacks.
- Place only necessary data in public directories.
- Use the "ask me" setting for most preferences until you have identified a pattern of response.
- Do not accept unexpected objects; do not respond to unexpected prompts or messages.
- Do not enter objects or text strings suggested by others into your client.

• For parents and guardians:
- Know your children's contacts.
- Use blocking controls to limit the contacts of young children to people known to you.

• As children mature, balance protection against privacy.

Conclusion

IM, like much of modern technology, is an inherently risky technology. On the other hand, it is also a very productive and efficient technology. As with the telephone and e-mail, its value will increase with the number of regular users. At some point it will reach critical mass, the point at which the benefit to users gives them such a competitive advantage over non-users that non-users are forced to cross over.

This year we have seen a huge increase in the number of enterprise IM products and a significant increase in the number of IM products on office desktops. The rest of us had best get ready.

As with most technology, the value of IM must be balanced against its risk, and the risk must be managed. Both management and end users must make the trade-offs between utility and security. However, we should react to this technology with prudence — not fear. IM will become part of our economic infrastructure as it has become part of our social infrastructure. We should build it accordingly. Modern enterprise IM tools provide the enterprise with valuable tools to enable them to achieve a reasonable balance between risk and reward.

Most enterprises will decide to rely on users to manage the content of IM the way that they rely on them to manage the content of phone calls, e-mail, and snail mail. Some will prefer this medium because it can leave a usable record. A small number will elect to use automated recording, surveillance, and filtering to demonstrate efforts to comply with contracts or government regulations. We should use these tools where there is a genuine requirement. We should resist the temptation to use them simply because they are cheap.

E-mail Security

Bruce A. Lobree

WHEN THE FIRST TELEGRAPH MESSAGE WAS FINALLY SENT, THE START OF THE ELECTRONIC COMMUNICATIONS AGE WAS BORN. Then about 50 years ago, people working on a mainframe computer left messages or put a file in someone else's directory on a Direct Access Storage Device (DASD) drive, and so the first electronic messaging system was born. Although most believe that electronic mail, or e-mail as it is called today, was started with the ARPA net, that is not the case. Electronic communication has been around for a much longer period than that, and securing that information has always been and will always be a major issue for both government and commercial facilities as well as the individual user.

When Western Telegraph started telegraphing money from point to point, this represented the beginnings of electronic transfers of funds via a certified system. Banks later began connecting their mainframe computers with simple point-to-point connections via SNA networks to enhance communications and actual funds transfers. This enabled individual operators to communicate with each other across platforms and systems enabling expedited operations and greater efficiencies at reduced operating costs.

When computer systems started to "talk" to each other, there was an explosion of development in communications between computer users and their respective systems. The need for connectivity grew as fast as the interest in it was developed by the corporate world. The Internet, which was originally developed for military and university use, was quickly pulled into this communications systems with its redundant facilities and fail-safe design, and was a natural place for electronic mail to grow toward.

Today (see Exhibit 3-1), e-mail, electronic chat rooms, and data transfers are happening at speeds that make even the most forward-thinking people wonder how far it will go. Hooking up networks for multiple-protocol communications is mandatory for any business to be successful. Electronic mail must cross multiple platforms and travel through many networks for it to go from one point to another. Each time it moves between networks and connections, this represents another point where it can be intercepted, modified, copied, or in worst-case scenario stopped altogether.

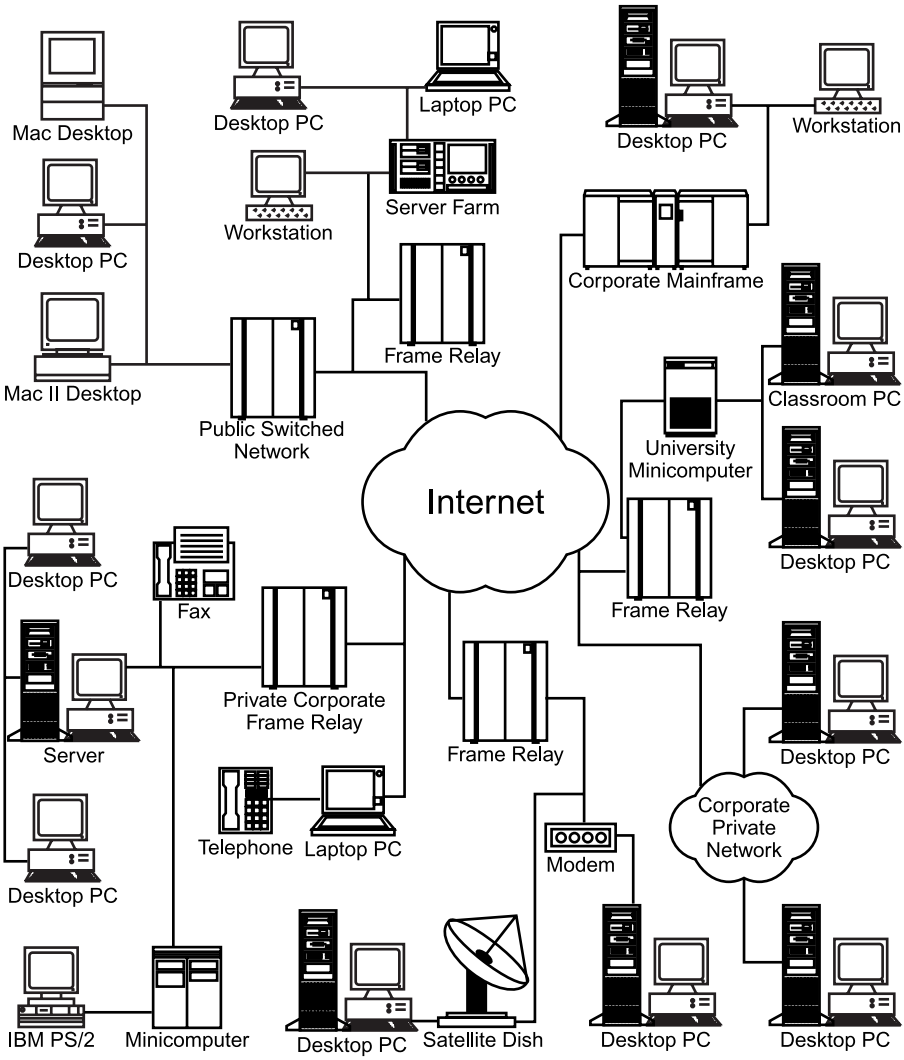

Exhibit 3-1. Internet connectivity.

Chat rooms on the Internet are really modified e-mail sites that allow multiple parties to read the mail simultaneously, similar to looking at a note stuck on a bulletin board. These services allow users to "post" a message to a board that allows several people to view it at once. This type of communication represents a whole new level of risk. There is controlling who has access to the site, where the site is hosted, how people gain access to the site, and many other issues that are created by any type of shared communications. The best example of a chat room is a conference call that has a publicly available phone number that can be looked up in

any phone book. The difference is that when someone joins the conference, the phone usually has a tone indicating the arrival of a new individual or group. With many chat rooms, no such protocol exists and users may not know who is watching or listening to any particular session if there is no specific user authentication method in use.

Today, e-mail is a trusted form of corporate communications that just about every major government and corporation in the world are using. Internal networks move communications in cleartext with sometimes little to no authentication. These business-critical messages are moved across public phone lines that are utilized for internal communications. This traffic in most cases is never even questioned as to authenticity and data can be listened to and intercepted.

Messages are presumed to be from the original author although there is no certificate or signature verifying it. By today's standards, e-mail has become a de facto trusted type of communications that is considered legal and binding in many cases. Even today, for a document to be considered legal and binding, it must contain a third-party certificate of authenticity, or some form of binding notary. However, in the case of e-mail, people consider this a form of electronic signature although it is so easy to change the senders' names without much effort. It is possible for the most untrained person to quickly figure out how to change their identity in the message and the recipient quickly gets information that may cause major damage, both financially or reputationally.

What makes matters even worse is the sue-happy attitude that is prevalent in the United States and is quickly spreading around the globe. There have already been several cases that have tested these waters and proven fatal to the recipient of the message as well as the falsified sender. These cases have taken to task system administrators to prove where electronic information has come from and where it went. Questions like who actually sent it, when was it sent, and how can one prove it, became impossible to answer without auditing tools being in place that cover entire networks with long-term report or audit data retention.

Today, e-mail traffic is sharing communications lines with voice, video, audio, and just about anything else that can be moved through wire and fiber optics. Despite the best frame relay systems, tied to the cleanest wires with the best filters, there is still going to be bleed over of communications in most wired types of systems (note that the author has seen fiber-optic lines tapped). This is not as much an issue in fiber optic as it is in copper wire. System administrators must watch for capacity issues and failures. They must be able to determine how much traffic will flow and when are the time-critical paths for information. For example, as a system administrator, one cannot take down a mail server during regular business times. However, with a global network, what is business time, and when is traffic

flow needed the most? These and many other questions must be asked before any mail system can be implemented, serviced, and relied upon by the specified user community.

Once the system administrator has answered all their questions about number of users, and the amount of disk space to be allocated to each user for the storage of e-mail, a system requirement can be put together. Now the administrative procedures can be completed and the configuration of the system can be put together. The administrator needs to figure out how to protect it without impacting the operational functionality of the system. The amount of security applied to any system will directly impact the operational functionality and speed at which the system can function.

Protection of the mail server becomes even more important as the data that moves through it becomes more and more mission critical. There is also the issue of protecting internal services from the mail server that may be handling traffic that contains viruses and Trojan horses. Viruses and Trojan horses as simple attachments to mail can be the cause for anything from simple annoyances or unwanted screen displays, all the way to complete destruction of computing facilities. Executives expect their mail to be "clean" of any type of malicious type of attachment. They expect the mail to always be delivered and always come from where the "FROM" in the message box states it came from.

The author notes that no virus can hurt any system until it is activated today. This may change as new programs are written in the future. This means that if a virus is going to do anything, the person receiving it via mail must open the mail message and then attempt to view or run the attachment. Simply receiving a message with an attached virus will not do anything to an individual's system. This hoax about a virus that will harm one's machine in this fashion is urban legend in this author's opinion.

Cookies or applets received over the Internet are a completely different subject matter that is not be discussed here. Users, however, must be aware of them and know how to deal with them. From a certain perspective, these can be considered a form of mail; however, by traditional definition, they are not.

TYPES OF MAIL SERVICES

Ever since that first message was sent across a wire using electricity, humanity has been coming up with better ways to communicate and faster ways to move that data in greater volume in smaller space. The first mainframe mail was based on simple SNA protocols and only used ASCII formatted text. The author contends that it was probably something as simple as a person leaving a note in another person's directory (like a Post-It on your computer monitor). Today, there is IP-based traffic that is moved through

many types of networks using many different systems of communications and carries multiple fonts, graphics, and sound and other messages as attachments to the original message.

With all the different types of mail systems that exist on all the different types of operating systems, choosing which e-mail service to use is like picking a car. The only environment that utilizes one primary mail type is Mac OS. However, even in this environment, one can use Netscape or Eudora to read and create mail. With the advent of Internet mail, the possibility of integration of e-mail types has become enormous. Putting multiple mail servers of differing types on the same network is now a networking and security nightmare that must be overcome.

Sendmail

Originally developed by Eric Allman in 1981, Sendmail is a standard product that is used across multiple systems. Regardless of what e-mail program is used to create e-mail, any mail that goes beyond the local site is generally routed via a mail transport agent. Given the number of "hops" any given Internet mail message takes to reach its destination, it is likely that every piece of Internet e-mail is handled by a Sendmail server somewhere along it's route.

The commercially available version of Sendmail began in 1997 when Eric Allman and Greg Olson formed Sendmail, Inc. The company still continues to enhance and release the product with source code and the right to modify and redistribute. The new commercial product line focuses on cost-effectiveness with Web-based administration and management tools, and automated binary installation.

Sendmail is used by most Internet service providers (ISPs) and shipped as the standard solution by all major UNIX vendors, including Sun, HP, IBM, DEC, SGI, SCO, and others. This makes the Sendmail application very important in today's Internet operations.

The Sendmail program was connected to the ARPAnet, and was home to the INGRES project. Another machine was home to the Berkeley UNIX project and had recently started using UUCP. Software existed to move mail within ARPAnet, INGRES, and BerkNet, but none existed to move mail between these networks. For this reason, Sendmail was created to connect the individual mail programs with a common protocol.

The first Sendmail program was shipped with version 4.1c of the Berkeley Software Distribution or BSD (the first version of Berkeley UNIX to include TCP/IP). From that first release to the present (with one long gap between 1982 and 1990), Sendmail was continuously improved by its authors. Today, version 8 is a major rewrite that includes many bug fixes and significant enhancements that take this application far beyond its original conception.

Other people and companies have worked on their versions of the Sendmail programs and injected a number of improvements, such as support for database management (dbm) files and separate rewriting of headers and envelopes. As time and usage of this application have continued, many of the original problems with the application and other related functions have been repaired or replaced with more efficient working utilities.

Today, there are major offshoots from many vendors that have modified Sendmail to suit their particular needs. Sun Microsystems has made many modifications and enhancements to Sendmail, including support for Network Information Service (NIS) and NIS+ maps. Hewlett-Packard also contributed many fine enhancements, including 8BITMIME (multi-purpose Internet mail extensions that worked with 8-bit machines limited naming controls, which do not exist in the UNIX environment) support.

This explosion of Sendmail versions led to a great deal of confusion. Solutions to problems that work for one version of Sendmail fail miserably with others. Beyond this, configuration files are not portable, and some features cannot be shared. Misconfiguration occurs as administrators work with differing types of products, thus creating further problems with control and security.

Version 8.7 of Sendmail introduced multicharacter options and macro names, new interactive commands. Many of the new fixes resolved the problems and limitations of earlier releases. More importantly, V8.7 has officially adopted most of the good features from IDA, KJS, Sun, and HP's Sendmail, and kept abreast of the latest standards from the Internet Engineering Task Force (IETF). Sendmail is a much more developed and user-friendly tool that has an international following and complies with much needed e-mail standards.

From that basic architecture, there are many programs today that allow users to read mail — Eudora, MSmail, Lotus Notes, and Netscape Mail are some of the more common ones. The less familiar ones are BatiMail or Easymail for UNIX, and others. These products will take an electronically formatted message and display it on the screen after it has been written and sent from another location. This allows humans to read, write, and send electronic mail using linked computers systems.

Protecting E-mail

Protecting e-mail is no easy task and every administrator will have his own interpretation as to what constitutes strong protection of communication. The author contends that strong protection is only that protection needed to keep the information secured for as long as it has value. If the information will be forever critical to the organization's operation, then it will need to be protected at layer two (the data-link level) of the IP stack.

This will need to be done in a location that will not be accessible to outsiders, except by specific approval and with proper authentication.

The other side of that coin is when the information has a very short valued life. An example would be that the data becomes useless once is has been received. In this case, the information does not need to be protected any longer than it takes for it to be transmitted. The actual transmission time and speed at which this occurs may be enough to ensure security. The author assumes that this type of mail will not be sent on a regular basis or at predetermined times. Mail that is sent on a scheduled basis or very often is easier to identify and intercept than mail sent out at random times. Thieves have learned that credit card companies send out their plastic on a specific date of every month and know when to look for it; this same logic can be applied to electronic mail as well.

Which ever side one's data is on, it is this author's conviction that all data should be protected to one level of effort or one layer of communication below what is determined to be needed to ensure sufficient security. This will ensure that should one's system ever be compromised, it will not be due to a flaw in one's mail service, and the source of the problem will be determined to have come from elsewhere. The assumption is that the hardware or tapes that hold the data will be physically accessible. Therefore, it is incumbent on the data to be able to protect itself to a level that will not allow the needed data to be compromised.

The lowest level of protection is the same as the highest level of weakness. If one protects the physical layer (layer 1 of the IP stack) within a facility, but does not encrypt communications, then when one's data crosses public phone lines, it is exposed to inspection or interception by outside sources.

When the time comes to actually develop the security model for a mail system, the security person will need to look at the entire system. This means that one must include all the communications that are under one's control, as well as that which is not. This will include public phone lines, third-party communications systems, and everything else that is not under one's physical and logical control.

IDENTIFYING THE MAILER

Marion just received an electronic message from her boss via e-mail. Marion knows this because in the "FROM" section is her boss' name. Marion absolutely knows this because who could possibly copy the boss' name into their own mailbox for the purpose of transmitting a false identity? The answer: anyone who goes into their preferences and changes the identity of the user and then restarts their specific mail application.

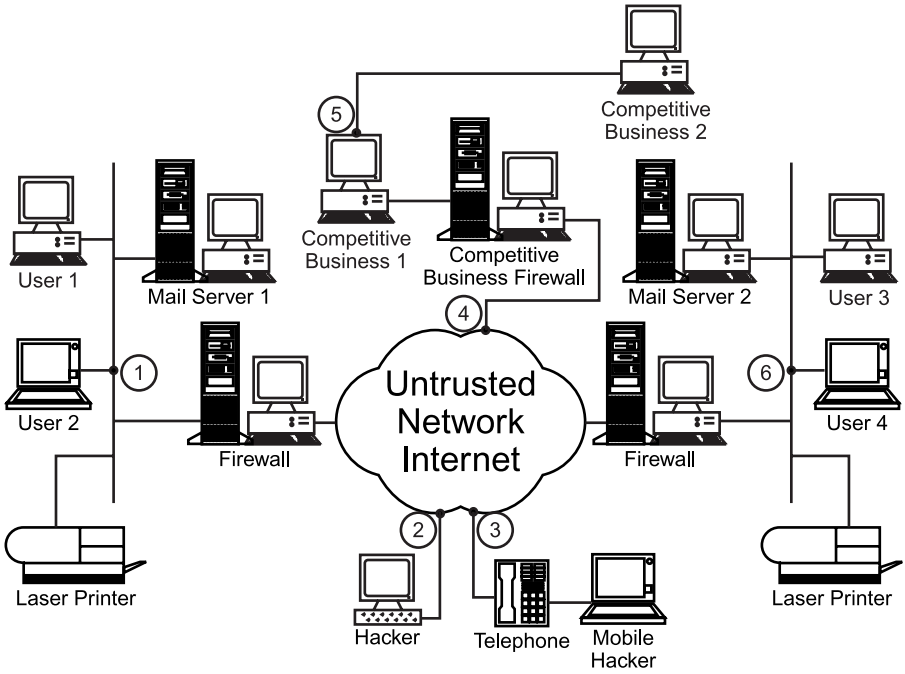

Exhibit 3-2. Unsecured network.

Whether talking about physical mail or electronic mail, the issue of authentication is an important subject. Authenticating the source of the communication and securing the information while in transit is critical to the overall security and reliability of the information being sent. In the physical world, a letter sent in a sealed, certified, bonded envelope with no openings is much safer and more reliable than a postcard with a mass mail stamp on it. So it goes with electronic mail as well.

Spoofing or faking an ID in mail is a fairly easy thing to do. Thankfully, not too many people know how to do it yet, and most will not consider it. To understand all the points of risk, one needs to understand how mail is actually sent. Not just what program has been implemented — but also the physical architecture of what is happening when one sends it.

In Exhibit 3-2, there are several points of intercept where a message can be infiltrated. Each point of contact represents another point of interception and risk. This includes the sender's PC which may store an original copy of the message in the sent box.

Network Architecture for Mail

User 1 wants to send an e-mail to User 4. If user 4 is connected to their network, then the mail will travel directly from User 1 to User 4 if all systems

between the two users are functioning correctly. If User 4 is not connected, then the mail will be stored on User 4's mail server for later pickup. If any mail server in the path is not functioning correctly, the message may stop in transit until such time as it can be retransmitted, depending on the configuration of the particular mail servers.

For mail to go from one user to another, it will go through User 1's mail server. Then it will be routed out through the corporate firewall and off to User 4's firewall via the magic of IP addressing. For the purpose of this chapter, one assumes that all of the routing protocols and configuration parameters have been properly configured to go from point User 1 to point User 4. As a user, it is presumed that one's mail is sent across a wire that is connected from one point to another with no intercepting points. The truth is that it is multiple wires with many connections and many points of intercept exist, even in the simplest of mail systems.

With the structure of our communications systems being what it is today, and the nature of the environment and conditions under which people work, that assumption is dangerously wrong. With the use of electronic frame relay connections, multi-server connections, intelligent routers and bridges, a message crosses many places where it could be tapped into by intruders or fail in transmission all together.

Bad E-mail Scenario

One scenario that has played out many times and continues today looks like this (see Exhibit 3-2):

1. User 1 writes and sends a message to User 4.
2. The message leaves User 1's mailbox and goes to the mail server, where it is recorded and readied for transmission by having the proper Internet packet information added to its header.
3. Then the mail server transmits the data out onto the Internet through the corporate firewall.
4. A hacker who is listening to the Internet traffic copies the data as it moves across a shared link using a sniffer (an NT workstation in promiscuous mode will do the same thing).
5. Your competition is actively monitoring the Internet with a sniffer and also sees your traffic and copies it onto their own network.
6. Unbeknownst to your competition, they have been hacked into and now share that data with a third party without even knowing about it.
7. The mail arrives at the recipient's firewall where it is inspected (recorded maybe) and sent onto the mail server.
8. The recipient goes out and gathers his mail and downloads it to his local machine without deleting the message from the mail server.

This message has now been shared with at least three people who can openly read it and has been copied onto at least two other points where it can be retrieved at a later date. There are well-known court cases where this model has been utilized to get old copies of mail traffic that have not been properly deleted and then became a focal point in the case.

As a security officer, it will be your job to determine the points of weakness and also the points of data gathering, potentially, even after the fact. How will one protect these areas; who has access to them; and how are they maintained are all questions that must be answered. To be able to do that, one needs to understand how e-mail works and what its intended use really was yesterday and how it is used today.

This form of communication was originally intended to just link users for the purpose of communicating simple items. It is the author's belief that the original creators of e-mail never initially intended for it to be used in so many different ways for so many different types of communications and information protocols.

Intercept point 1 in Exhibit 3-2 represents the biggest and most common weakness. In 1998, the Federal Bureau of Investigation reported that most intercepted mail and computer problems were created internally to the company. This means that one's risk by internal employees is greater than outside forces. The author does not advocate paranoia internally, but common sense and good practice. Properly filtering traffic through routers and bridges and basic network protection and monitoring of systems should greatly reduce this problem.

Intercept points 2 through 4 all share the same risk — the Internet. Although this is considered by some to be a known form of communications, it is not a secure one. It is a well-known fact that communications can be listened in on and recorded by anyone with the most basic of tools. Data can be retransmitted, copied, or just stopped, depending on the intent of the hacker or intruder.

Intercept points 5 and 6 are tougher to spot and there may be no way to have knowledge of or about if they are compromised. This scenario has an intruder listening from an unknown point that one has no way of seeing. This is to say, one cannot monitor the network they are connected to or may not see their connection on one's monitoring systems. The recipient does not know about them and is as blind to their presence as you are. Although this may be one of the most unlikely problems, it will be the most difficult to resolve. The author contends that the worst-case scenario is when the recipients' mail is intercepted inside their own network, and they do not know about a problem.

It is now the job of the security officer to come up with a solution — not only to protect the mail, but to also be able to determine if and when that

system of communications is working properly. It is also the security officer's responsibility to be able to quickly identify when a system has been compromised and what it will take to return it to a protected state. This requires continuous monitoring and ongoing auditing of all related systems.

HOW E-MAIL WORKS

The basic principle behind e-mail and its functionality is to send an electronic piece of information from one place to another with as little interference as possible. Today's e-mail has to be implemented very carefully and utilize controls that are well-defined to meet the clients need and at the same time protect the communications efficiently.

Today, there are some general mail terms that one must understand when discussing e-mail. They are Multipurpose Internet Mail Extensions (MIME), which was standardized with RFC 822 that defines the mail header and type of mail content; and RFC 1521, which is designed to provide facilities to include multiple objects in a single message, to represent body text in character sets other than US-ASCII, to represent formatted multi-font text messages, to represent nontextual material such as images and audio fragments, and generally to facilitate later extensions defining new types of Internet mail for use by cooperating mail agents.

Then there is the Internet Message Access Protocol (IMAP) format of mail messages that is on the rise. This is a method of accessing electronic mail or bulletin board data. Finally, there is POP, which in some places means Point of Presence (when dealing with an Internet provider); but for the purpose of this book means Post Office Protocol.

IP Traffic Control

Before going any further with the explanation of e-mail and how to protect it, the reader needs to understand the TCP/IP protocol. Although to many this may seem like a simple concept, it may be new to others. In short, the TCP/IP protocol is broken into five layers (see Exhibit 3-3). Each layer of the stack has a specific purpose and performs a specific function in the movement of data. The layers the author is concerned about are layers three and above (the network layer). Layers one and two require physical access to the connections and therefore become more difficult to compromise.

TCP/IP Five-Layer Stack:

1. The e-mail program sends the e-mail document down the protocol stack to the transport layer.
2. The transport layer attaches its own header to the file and sends the document to the network layer.

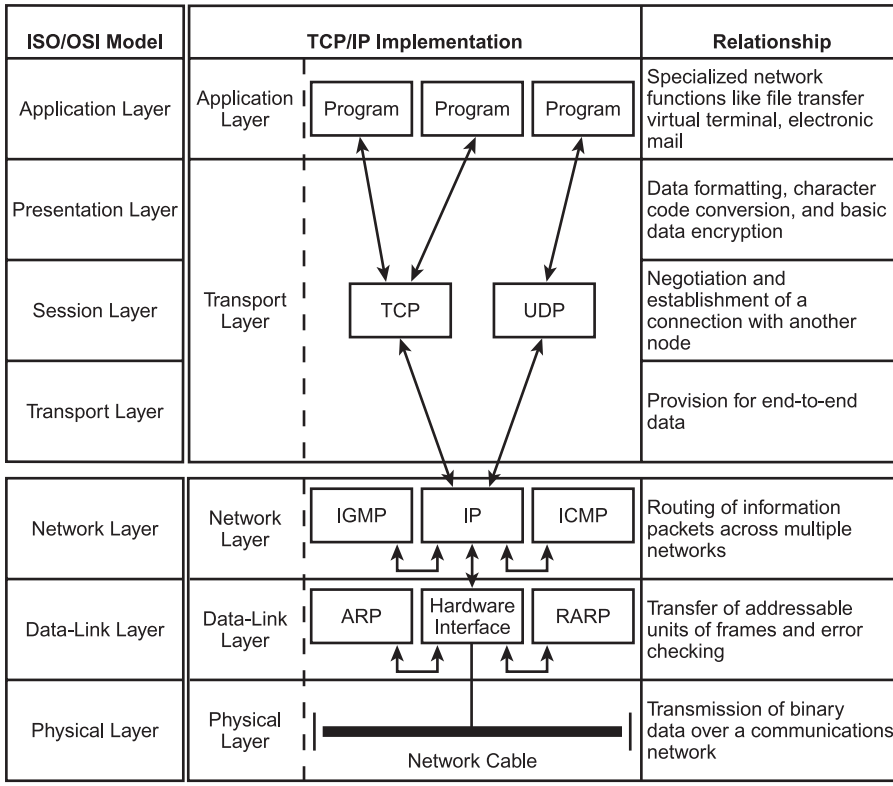

Exhibit 3-3. The five layers of the TCP/IP protocol.

3. The network layer breaks the data frames into packets, attaches additional header information to the packet, and sends the packets down to the data-link layer.
4. The data-link layer sends the packets to the physical layer.
5. The physical layer transmits the file across the network as a series of electrical bursts.
6. The electrical bursts pass through computers, routers, repeaters, and other network equipment between the transmitting computer and the receiving computer. Each computer checks the packet address and sends the packet onward to its destination.
7. At the destination computer, the physical layer passes the packets back to the data-link layer.
8. The data-link layer passes the information back to the network layer.
9. The network layer puts the physical information back together into a packet, verifies the address within the packet header, and verifies that the computer is the packet's destination. If the computer is the

packet's destination, the network layer passes the packet upward to the transport layer.
10. The transport layer, together with the network layer, puts together all the file's transmitted pieces and passes the information up to the application layer.
11. At the application layer, the e-mail program displays the data to the user.

The purpose of understanding how data is moved by the TCP/IP protocol is to understand all the different places that one's data can be copied, corrupted, or modified by an outsider. Due to the complexity of this potential for intrusion, critical data needs to be encrypted and or digitally signed. This is done so that the recipient knows who sent, and can validate the authenticity of, a message that they receive.

Encryption and digital signatures need to authenticate the mail from layer two (the data-link layer) up, at a minimum in this author's opinion. Below that level will require physical access; if one's physical security is good, this should not be an area of issue or concern.

Multipurpose Internet Mail Extensions (MIME)

Multipurpose Internet Mail Extensions (MIME) is usually one of the formats available for use with POP or e-mail clients (Pine, Eudora), Usenet News clients (WinVN, NewsWatcher), and WWW clients (Netscape, MS-IE). MIME extends the format of Internet mail.

STD 11, RFC 822, defines a message representation protocol specifying considerable detail about US-ASCII message headers, and leaves the message content, or message body, as flat US-ASCII text. This set of documents, collectively called the Multipurpose Internet Mail Extensions, or MIME, redefines the format of messages to allow:

- textual message bodies in character sets other than US-ASCII
- an extensible set of different formats for nontextual message bodies
- multi-part message bodies
- textual header information in character sets other than US-ASCII

These documents are based on earlier work documented in RFC 934, STD 11, and RFC 1049; however, it extends and revises them to be more inclusive. Because RFC 822 said so little about message bodies, these documents are largely not a revision of RFC 822 but are new requirements that allow mail to contain a broader type of data and data format.

The initial document specifies the various headers used to describe the structure of MIME messages. The second document, RFC 2046, defines the general structure of the MIME media typing system and also defines an initial

set of media types. The third document, RFC 2047, describes extensions to RFC 822 to allow non-US-ASCII text data in Internet mail header fields. The fourth document, RFC 2048, specifies various Internet Assigned Numbers Authority (IANA) registration procedures for MIME-related facilities. The fifth and final document, RFC 2049, describes the MIME conformance criteria as well as providing some illustrative examples of MIME message formats, acknowledgments, and the bibliography.

Since its publication in 1982, RFC 822 has defined the standard format of textual mail messages on the Internet. Its success has been such that the RFC 822 format has been adopted, wholly or partially, well beyond the confines of the Internet and the Internet SMTP transport defined by RFC 821. As the format has seen wider use, a number of limitations have been found to be increasingly restrictive for the user community.

RFC 822 was intended to specify a format for text messages. As such, nontextual messages, such as multimedia messages that might include audio or images, are simply not mentioned. Even in the case of text, however, RFC 822 is inadequate for the needs of mail users whose languages require the use of character sets with far greater size than US-ASCII. Because RFC 822 does not specify mechanisms for mail containing audio, video, Asian language text, or even text in most European and Middle Eastern languages, additional specifications were needed, thus forcing other RFCs to include the other types of data.

One of the notable limitations of RFC 821/822 based mail systems is the fact that they limit the contents of electronic mail messages to relatively short lines (i.e., 1000 characters or less) of seven-bit US-ASCII. This forces users to convert any nontextual data that they may wish to send into seven-bit bytes representable as printable US-ASCII characters before invoking a local mail user agent (UA). The UA is another name for the program with which people send and receive their individual mail.

The limitations of RFC 822 mail becomes even more apparent as gateways were being designed to allow for the exchange of mail messages between RFC 822 hosts and X.400 hosts. The X.400 requirement also specifies mechanisms for the inclusion of nontextual material within electronic mail messages. The current standards for the mapping of X.400 messages to RFC 822 messages specify either that X.400 nontextual material must be converted to (not encoded in) IA5Text format, or that they must be discarded from the mail message, notifying the RFC 822 user that discarding has occurred. This is clearly undesirable, as information that a user may wish to receive is then potentially lost if the original transmission is not recorded appropriately. Although a user agent may not have the capability of dealing with the nontextual material, the user might have some mechanism external to the UA that can extract useful information from the material after the message is received by the hosting computer.

There are several mechanisms that combine to solve some of these problems without introducing any serious incompatibilities with the existing world of RFC 822 mail, including:

- *A MIME-Version header field,* which uses a version number to declare a message to be in conformance with MIME. This field allows mail processing agents to distinguish between such messages and those generated by older or nonconforming software, which are presumed to lack such a field.
- *A Content-Type header field,* generalized from RFC 1049, which can be used to specify the media type and subtype of data in the body of a message and to fully specify the native representation (canonical form) of such data.
- *A Content-Transfer-Encoding header field,* which can be used to specify both the encoding transformations that were applied to the body and the domain of the result. Encoding transformations other than the identity transformation are usually applied to data to allow it to pass through mail transport mechanisms that may have data or character set limitations.
- Two additional header fields that can be used to further describe the data in a body include the *Content-ID* and *Content-Description header fields.*

All of the header fields defined are subject to the general syntactic rules for header fields specified in RFC 822. In particular, all these header fields except for Content-Disposition can include RFC 822 comments, which have no semantic contents and should be ignored during MIME processing.

Internet Message Access Protocol (IMAP)

IMAP is the acronym for Internet Message Access Protocol. This is a method of accessing electronic mail or bulletin board messages that are kept on a (possibly shared) mail server. In other words, it permits a "client" e-mail program to access remote message stores as if they were local. For example, e-mail stored on an IMAP server can be manipulated from a desktop computer at home, a workstation at the office, and a notebook computer while traveling to different physical locations using different equipment. This is done without the need to transfer messages or files back and forth between these computers.

The ability of IMAP to access messages (both new and saved) from more than one computer has become extremely important as reliance on electronic messaging and use of multiple computers increase. However, this functionality should not be taken for granted and can be a real security risk if the IMAP server is not appropriately secured.

The IMAP includes operations for creating, deleting, and renaming mailboxes; checking for new messages; permanently removing messages; setting and clearing flags; server-based RFC-822 and MIME, and searching; and selective fetching of message attributes, texts, and portions thereof.

IMAP was originally developed in 1986 at Stanford University. However, it did not command the attention of mainstream e-mail vendors until a decade later. It is still not as well-known as earlier and less-capable alternatives such as using POP mail. This is rapidly changing, as articles in the trade press and the implementation of the IMAP are becoming more and more commonplace in the business world.

Post Office Protocol (POP)

The Post Office Protocol, version 3 (POP-3) is used to pick up e-mail across a network. Not all computer systems that use e-mail are connected to the Internet 24 hours a day, 7 days a week. Some users dial into a service provider on an as-needed basis. Others may be connected to a LAN with a permanent connection but may not always be powered on (not logged into the network). Other systems may simply not have the available resources to run a full e-mail server. Mail servers may be shielded from direct connection to the Internet by a firewall security system, or it may be against organization policy to have mail delivered directly to user systems. In the case where e-mail must be directly mailed to users, the e-mail is sent to a central e-mail server where it is held for pickup when the user connects at a later time. POP-3 allows a user to logon to an e-mail post office system across the network and validates the user by ID and password. Then it will allow mail to be downloaded, and optionally allow the user to delete the mail from the server.

The widely used POP works best when one has only a single computer. POP e-mail was designed to support "offline" message access to increase network usability and efficiency. This means that messages can be downloaded and then deleted from the mail server if so configured. This mode of access is not compatible with access from multiple computers because it tends to sprinkle messages across all of the computers used for mail access. Thus, unless all of those machines share a common file system, the offline mode of access that is using POP effectively ties the user to one computer for message storage and manipulation. POP further complicates access by placing user-specific information in several locations as the data is stored as well.

The pop3d command is a POP-3 server and supports the POP-3 remote mail access protocol. Also, it accepts commands on its standard input and responds on its standard output. One normally invokes the pop3d command with the inetd daemon with those descriptors attached to a remote client connection.

The pop3d command works with the existing mail infrastructure consisting of sendmail and bellmail.

```
Net::POP3 - Post Office Protocol 3 Client class
          (RFC1081)
```

IMAP is a server for the POP and IMAP mail protocols. POP allows a "post office" machine to collect mail for users and have that mail downloaded to the user's local machine for reading. IMAP provides the functionality of POP, and allows a user to read mail on a remote machine without moving it to the user's local mailbox.

The popd server implements POP, as described in RFC1081 and RFC1082. Basically, the server listens on the TCP port named pop for connections. When it receives a connection request from a client, it performs the following functions:

- checks for client authentication by searching the POP password file in /usr/spool/pop
- sends the client any mail messages it is holding for the client (the server holds the messages in /usr/spool/pop)
- for historical reasons, the MH POP defaults to using the port named pop (port 109) instead of its newly assigned port named pop3 (port 110)

To determine which port MH POP, check the value of the POPSERVICE configuration option. One can display the POPSERVICE configuration option by issuing any MH command with the -help option. To find the port number, look in the /etc/services file for the service port name assigned to the POPSERVICE configuration option. The port number appears beside the service port name.

The POP database contains the following entry for each POP subscriber:

```
name::primary_file:encrypted_passwd::
          user@<client_address>::::0
```

The fields represent the following:

- name — the POP subscriber's username
- primary_file — the mail drop for the POP subscriber (relative to the POP directory)
- encrypted_passwd — the POP subscriber's password generated by popwrd(8)
- user@<client_address> — the remote user allowed to make remote POP (RPOP) connections

This database is an ASCII file and each field within each POP subscriber's entry is separated from the next by a colon. Each POP subscriber is separated from the next by a new line. If the password field is null, then no password is

valid; therefore, always check to see that a password is required to further enhance the security of your mail services.

To add a new POP subscriber, edit the file by adding a line such as the following:

```
bruce:: bruce:::::::0i
```

Then, use popwrd to set the password for the POP subscriber. To allow POP subscribers to access their maildrops without supplying a password (by using privileged ports), fill in the network address field, as in:

```
bruce:: bruce::: bruce@filteringisim.edu::::0
```

which permits "bruce@filteringisim.edu" to access the maildrop for the POP subscriber "bruce." Multiple network addresses can be specified by separating them with commas, as in:

```
bruce::bruce:9X5/m4yWHvhCc::bruce@filteringisim.edu,
          bruce@rsch.isim.edu::::
```

To disable a POP subscriber from receiving mail, set the primary file name to the empty string. To prevent a POP subscriber from picking up mail, set the encrypted password to "*" and set the network address to the empty string. This file resides in home directory of the login "pop." Because of the encrypted passwords, it can and does have general read permission.

Encryption and Authentication

Having determined what your e-mail needs are, one will have to determine how and when one will need to protect the information being sent. The "when" part is fairly straightforward, as this is set by corporate policy. If the security officer does not have the proper documentation and description of the controls that will need to be in place for electronic data transfer, then now is the time to put it together, as later will be too late. Suffice it to say that this author presumes that all the proper detail exists already. This needs to be done so the security officer will be able to determine the classification of the information that he or she will be working with for traffic to move successfully.

Encryption is a process whereby the sender and the receiver will share an encryption and decryption key that will protect the data from someone reading the data while it is in transit. This will also protect the data when it is backed up on tape or when it is temporarily stored on a mail server. This is not to say that encryption cannot be broken — it can, and has been done to several levels. What is being said is that the encryption used will protect the information long enough that the data is no longer of value to the person who intercepts it or has value to anyone else. This is important

to remember, to ensure that too much encryption is not used while, at the same time, enough is used to sufficiently protect the data.

Authentication is meant to verify the sender to the recipient. When the sender sends the message to the other party, they electronically sign the document that verifies to the person receiving the document the authenticity of it. It also verifies what the person sent is what the person received. It does not however protect the data while in transit, which is a distinct difference from encryption and is often a misconception on the part of the general user community.

Encryption

There are many books outlining encryption methodology and the tools that are available for this function. Therefore, this chapter does not go into great detail about the tools. However, the weaknesses as well as the strengths of such methods are discussed. All statements are those of the author and therefore are arguable; however, they are not conditional.

All mail can be seen at multiple points during its transmission. Whether it be from the sendmail server across the Internet, via a firewall to another corporation's firewall, or to their sendmail server, all mail will have multiple hops when it transits from sender to recipient. Every point in that transmission process is a point where the data can be intercepted, copied, modified, or deleted completely.

There are three basic types of encryption generally available today. They are private key (symmetric or single key) encryption, pretty good privacy (PGP) or public key encryption, and privacy enhanced mail (PEM). Each of these types of protection systems has strengths and flaws. However, fundamentally they all work the same way and if properly configured and used will sufficiently protect one's information (maybe).

Encryption takes the message that can be sent, turns it into unreadable text, and transmits it across a network where it is decrypted for the reader. This is a greatly simplified explanation of what occurs and does not contain nearly the detail needed to understand this functionality. Security professionals should understand the inner workings of encryption and how and when to best apply it to their environment. More importantly, they must understand the methods of encryption and decryption and the level at which encryption occurs.

Private key encryption is the least secure method of sending and receiving messages. This is due to a dependency on the preliminary setup that involves the sharing of keys between parties. It requires that these keys be transmitted either electronically or physically on a disk to the other party and that every person who communicates with this person potentially has a separate key. The person who supplies the encryption key must then

manage them so that two different recipients of data do not share keys and data is not improperly encrypted before transmission. With each new mail recipient the user has, there could potentially be two more encryption keys to manage.

This being the problem that it is, today there is public key encryption available. This type of encryption is better known as pretty good privacy (or PGP). The basic model for this system is to maintain a public key on a server that everyone has access. User 1, on the other hand, protects his private key so that he is the only one who can decrypt the message that is encrypted with his public key. The reverse is also true in that if a person has User 1's public key, and User 1 encrypts using his private key, then only a person with User 1's public key will be able to decrypt the message. The flaw here is that potentially anyone could have User 1's public key and could decrypt his message if they manage to intercept it.

With this method, the user can use the second party's public key to encrypt the private (single or symmetric) key and thereby transmit the key to the person in a secured fashion. Now users are using both the PGP technology and the private key technology. This is still a complicated method. To make it easy, everyone should have a public key that they maintain in a public place for anyone to pick up. Then they encrypt the message to the recipient and only the recipient can decrypt the message. The original recipient then gets the original sender's public key and uses that to send the reply.

As a user, PGP is the easiest form of encryption to use. User 1 simply stores a public key on a public server. This server can be accessed by anyone and if the key is ever changed, User 1's decryption will not work and User 1 will know that something is amiss. For the system administrator, it is merely a matter of maintaining the public key server and keeping it properly secured.

There are several different algorithms that can be applied to this type of technology. If the reader would like to know more about how to build the keys or development of these systems, there are several books available that thoroughly describe them.

Digital Certificates

Like a written signature, the purpose of a digital signature is to guarantee that the individual sending the message really is who he or she claims to be. Digital signatures are especially important for electronic commerce and are a key component of most authentication schemes. A digital signature is an attachment to an electronic message used for security purposes. The most common use of a digital certificate is to verify that a user sending a message is who he or she claims to be, and to provide the receiver with the means to encode a reply.

The actual signature is a quantity associated with a message that only someone with knowledge of an entity's private key could have generated, but which can be verified through knowledge of that entity's public key. In plain terms, this means that an e-mail message will have a verifiable number generated and attached to it that can be authenticated by the recipient.

Digital signatures perform three very important functions:

1. *Integrity:* A digital signature allows the recipient of a given file or message to detect whether that file or message has been modified.
2. *Authentication:* A digital signature makes it possible to verify cryptographically the identity of the person who signed a given message.
3. *Nonrepudiation:* A digital signature prevents the sender of a message from later claiming that they did not send the message.

The process of generating a digital signature for a particular document type involves two steps. First, the sender uses a one-way hash function to generate a message digest. This hash function can take a message of any length and return a fixed-length (e.g., 128 bits) number (the message digest). The characteristics that make this kind of function valuable are fairly obvious. With a given message, it is easy to compute the associated message digest. It is difficult to determine the message from the message digest, and it is difficult to find another message for which the function would produce the same message digest.

Second, the sender uses its private key to encrypt the message digest. Thus, to sign something, in this context, means to create a message digest and encrypt it with a private key.

The receiver of a message can verify that message via a comparable two-step process:

1. Apply the same one-way hash function that the sender used to the body of the received message. This will result in a message digest.
2. Use the sender's public key to decrypt the received message digest.

If the newly computed message digest matches the one that was transmitted, the message was not altered in transit, and the receiver can be certain that it came from the expected sender. If, on the other hand, the number does not match, then something is amiss and the recipient should be suspect of the message and its content.

The particular intent of a message digest, on the other hand, is to protect against human tampering by relying on functions that are computationally infeasible to spoof. A message digest should also be much longer than a simple checksum so that any given message may be assumed to result in a unique value. To be effective, digital signatures must be unforgeable; this means that the value cannot be easily replaced, modified, or copied.

A digital signature is formed by encrypting a message digest using the private key of a public key encryption pair. A later decryption using the corresponding public key guarantees that the signature could only have been generated by the holder of the private key. The message digest uniquely identifies the e-mail message that was signed. Support for digital signatures could be added to the Flexible Image Transport System, or FITS, by defining a FITS extension format to contain the digital signature certificates, or perhaps by simply embedding them in an appended FITS table extension.

There is a trade-off between the error detection capability of these algorithms and their speed. The overhead of a digital signature can be prohibitive for multi-megabyte files, but may be essential for certain purposes (e.g., archival storage) in the future. The checksum defined by this proposal provides a way to verify FITS data against likely random errors. On the other hand, a full digital signature may be required to protect the same data against systematic errors, especially human tampering.

An individual wishing to send a digitally signed message applies for a digital certificate from a certificate authority (CA). The CA issues an encrypted digital certificate containing the applicant's public key and a variety of other identification information. The CA makes its own public key readily available through print publicity or perhaps on the Internet.

The recipient of an encrypted digital certificate uses the CA's public key to decode the digital certificate attached to the message. Then they verify it as issued by the CA and obtain the sender's public key and identification information held within the certificate. With this information, the recipient can verify the owner of a public key.

A certificate authority is a trusted third-party organization or company that issues digital certificates used to verify the owner of a public key and create public-private key pairs. The role of the CA in this process is to guarantee that the individual granted the unique certificate is who he or she claims to be. Usually, this means that the CA has an arrangement with a financial institution, such as a credit card company, which provides it with information to confirm an individual's claimed identity. CAs are a critical component in data security and electronic commerce because they guarantee that the two parties exchanging information are really who they claim to be.

The most widely used standard for digital certificates is X.509. X.509 is actually an ITU Recommendation, which means that has not yet been officially defined or approved. As a result, companies have implemented the standard in different ways. For example, both Netscape and Microsoft use X.509 certificates to implement SSL in their Web servers and browsers. However, an X.509 certificate generated by Netscape may not be readable by Microsoft products, and vice versa.

Secure Sockets Layer (SSL)

Short for Secure Sockets Layer, SSL is a protocol developed by Netscape for transmitting private documents via the Internet. SSL works using a private key to encrypt data that is transferred over the SSL connection. Both Netscape Navigator and Internet Explorer support SSL, and many Web sites use the protocol to obtain confidential user information, such as credit card numbers. By convention, Web pages that require an SSL connection start with https: instead of http:.

The other protocol for transmitting data securely over the World Wide Web is Secure HTTP (S-HTTP). Whereas SSL creates a secure connection between a client and a server, over which any amount of data can be sent securely, S-HTTP is designed to securely transmit individual messages. SSL and S-HTTP, therefore, can be seen as complementary rather than competing technologies. Both protocols have been approved by the Internet Engineering Task Force (IETF) as a standard.

However, fully understanding what SSL is means that one must also understand HTTP (HyperText Transfer Protocol), the underlying protocol used by the World Wide Web (WWW). HTTP defines how messages are formatted and transmitted, and what actions Web servers and browsers should take in response to various commands. For example, when one enters a URL in the browser, this actually sends an HTTP command to the Web server directing it to fetch and transmit the requested Web page.

HTTP is called a stateless protocol because each command is executed independently, without any knowledge of the commands that came before it. This is the main reason why it is difficult to implement Web sites that react intelligently to user input. This shortcoming of HTTP is being addressed in a number of new technologies, including ActiveX, Java, JavaScript, and cookies.

S-HTTP is an extension to the HTTP protocol to support sending data securely over the World Wide Web. Not all Web browsers and servers support S-HTTP and, in the United States and other countries, there are laws controlling the exportation of encryption that can impact this functionality as well. Another technology for transmitting secure communications over the World Wide Web — Secure Sockets Layer (SSL) — is more prevalent. However, SSL and S-HTTP have very different designs and goals, so it is possible to use the two protocols together. Whereas SSL is designed to establish a secure connection between two computers, S-HTTP is designed to send individual messages securely.

The other main standard that controls how the World Wide Web works is HTML, which covers how Web pages are formatted and displayed.

Good Mail Scenario

Combining everything discussed thus far and a few practical principles involved in networking, one now has the ability to put together a much

more secure mail system. This will allow one to authenticate internal and external mail users. The internal requirements will only add one server and a router/filter outside the firewall, and the external requirements will require that there be a publicly available certificate authority (CA) for the world to access.

Now a system has been created that will allow users to segregate internally encrypted messages from externally. Each person will have two public keys to maintain:

- one that resides on the internally installed public key server
- one that resides on the external public key server

The private part of the public key pair will be a privately held key that the user will use to decrypt all incoming messages. Outside the firewall resides a server that will specifically handle all mail and will scan it for viruses and to be sure that all inbound mail is properly encrypted. If it is not, it will forward the message to a separate server that will authenticate the message to a specific user and will then scan and forward it after it has been properly accepted.

Now as we walk through the model of sending a message, no matter who intercepts it, or where it may be copied while in transit, the only place it can be understood will be at the final location of the keys. This method of PGP will not only secure the message, but it will act like a digital certificate in that the user will know limited information about the sender. If a digital signature is added to the model, then the recipient will know the source of the encryption session key. This will include the source of the digital signature and the senders' authentication information sufficiently enough to ensure that they are who they say they are.

There are many other components not discussed above that should be in place; these are outlined in the following steps. For more information, there are many books on router protocol and systems security that can be obtained at the local library.

Mail Sent Securely. The following steps break down the path with which a secure message can be sent (see Exhibit 3-4). This is a recommended method of securing all one's internal and external mail.

1. Before sending or receiving any messages, the author of the message gets a private encryption key from his private network.
2. Then the author places two public keys out on the networks. One is placed on his internal key ring and the second is placed on a public key ring. The purpose of this is to keep his internal mail private and still be able to use public-private key encryption of messages. This will also allow the author to separate mail traffic relevant to its origin.

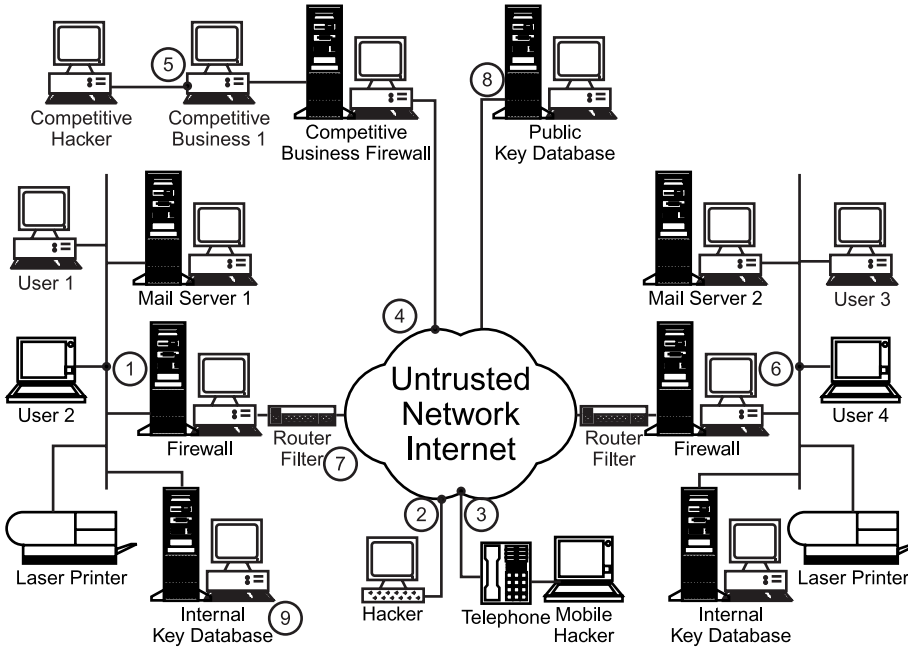

Exhibit 3-4. Secured network.

3. The author of an e-mail message logs on to his personal network and is also authenticated by the mail server via usage of a password to get ready to send electronic mail.
4. They the author composes the message using his personal mail utility that has been preconfigured with the following settings.
   a. all messages will be sent with a digital signature
   b. all messages will have receipt notice automatically sent
   c. private key encryption will be automatically utilized
5. The author signs and sends the document to a secure server. The message is encrypted and digitally signed before it leaves the author's machine.
6. The author's mail server is connected to the network with hardware-level encrypting routers that protect all internal communications. Note that the latency created by hardware-level encryption is nominal enough that most users will not notice a delay in transmission of data which is any different than already occurs.
7. The mail server determines whether the traffic is internal or external and forwards appropriately. This particular message is determined to be outbound and is therefore sent to the firewall and out to the Internet via an automated hardware encryption device.

8. In front of the firewall on the recipient's end is a hardware device that decrypts the traffic at layer three, but leaves it encrypted and signed as it was originally sent. Loss of this level of encryption is noted by the author. However, unless the outside recipient of this message has the proper hardware to decrypt the message, this level of protection will impede the communications and the recipient will not be able to read the message.
9. The message travels over the Internet. At this point, any interception that records the transmission will not assist another party in obtaining the information. To do so, they will have to:
   a. be in the line of traffic at the proper time to intercept the message
   b. have the decryption tools with which the message was encrypted
   c. have a copy or method of recreating the digital certificate if they want to modify the message and retransmit it
10. The message is then received by the recipient's firewall and allowed in based on the addressing of the message.
11. The firewall forwards the message to a mail server that quickly scans the message for viruses (this will slow down mail traffic considerably in a high traffic environment). To determine if this level of security is needed, one must determine the damage a virus or Trojan horse can do to the individual or systems to which the individual is connected.
12. The message is stored on the mail server until the recipient logs on to the network and authenticates himself to that particular server. The mail server is password protected and all data contained there will also be encrypted.
13. The mail recipient goes out to the appropriate public key server (internal for internal users and off the public key for external users) and retrieves the sender's public key before trying to open the sender's message.
14. The mail server then forwards the message to the individual user, who then opens the message after it is decrypted and verifies the signature based matching message digests.
15. Notification of receipt is automatically created and transmitted back to the original author via a reverse process that will include the recipient's signature.

The author recognizes that in a perfect world, the level of encryption that is used would not be breakable by brute force or other type of attack. The certificate and signature that are used cannot be copied or recreated. However, this is not true; it is believed that with 128-bit encryption, with an attached digital signature, the message's information will be secure enough that it will take longer to decrypt than the information would be viable or useful.

This methodology will slow down the communication of all e-mail. The return is the increased security that is placed on the message itself. There

are several layers of protection and validation that show that the message is authentic. The sender and the recipient both know who the message is from and to whom it is being sent, and both parties have confirmation of receipt.

If senders are not concerned about protecting the content of their individual messages, then the encryption part could be skipped, thereby speeding up the process of delivery. It is this author's opinion that digital signatures should always be used to authenticate any business-related or personal message to another party.

CONCLUSION

From the beginning of time, people have tried to communicate over long distances — efficiently and effectively. The biggest concern then and today is that the message sent is the message received and that the enemy (e.g., corporate competition) does not intercept a message.

From the time that the first electronic message was sent to today's megabit communications systems, people have been trying to figure out new ways to copy, intercept, or just disrupt that messaging system. The value of getting one's data is proportionately equal to the value that data has if private, and is far greater if in the corporate world.

Our challenge in today's world of computer communications — voice, video, and audio communications — is to protect it: to make sure that when it is transmitted from one specific medium to another it is received in a fashion that the recipient will be able to hear it, read it, or see it. Both the author and the recipient are confident enough that the communications are secure and reliable enough that they do not have to worry about the message not getting to where it should.

Setting up a system of checks and balances to verify transmission, to authenticate users, to authenticate messages and protect them from prying eyes becomes the task at hand for the systems administrator and the security officer. Effective implementation of encryption, digital certificates, and configuration of mail servers placed in the proper areas of a network are all components of making this happen efficiently enough that users will not try to bypass the controls.

The security officer is responsible for the information in the corporation, and becomes a security consultant by default when the architecture of a mail system is to be built. The security officer will be asked how to, when to, and where to implement security, all the while keeping in mind that one must inflict as little impact on the user community as possible. The security officer will be asked to come up with solutions to control access to e-mail and for authentication methods.

To be able to do this, the security officer needs to understand the protocols that drive e-mail, as well as the corporate standards for classification

and protecting information and the associated policies. If the policies do not exist, the security officer will need to write them. Then once they are written, one will need to get executive management to accept those polices and enforce them. The security officer will also need to make sure that all employees know and understand those standards and know how to follow them.

Most importantly, whenever something does not feel or look write, question it. Remember that even if something looks as if it is put together perfectly, one should verify it and test it. If everything tests out correctly and the messages are sent in a protected format, with a digital signature of some kind, and there is enough redundancy for high availability and disaster recovery, then all one has left to do is listen to the user community complain about the latency of the system and the complexity of successfully sending messages.

E-Mail Security

Clay Randall

THE FIRST E-MAIL APPLICATIONS WERE CREATED BEFORE ANY TYPE OF COMPUTER NETWORKS WERE IN ORDINARY USE, and thus were limited to communications between different users of a single multi-user computer system. E-mail was invented to fulfill a need for a standard, organized, and functional communications process and to prevent security problems.

Prior to e-mail applications, users would grant public access to a portion of their space so that other users could "drop off" messages and files. Users who lacked the necessary technical savvy created both non-operable conditions (insufficient privileges) and security problems (excessive privilege).

Because it was both widely desirable and applicable, some basic form of e-mail application was soon supplied as a standard component of nearly every multi-user computer operating system. As soon as computer networks became widely available, e-mail applications were adapted to be capable of exchanging e-mail between (like) systems.

The first commercially viable and widely deployed public computer networks were based on the ITU X.25 packet switching network standards. As more companies gained connectivity between sites, it quickly became useful for e-mail applications to have the ability to transport messages between computer systems over these networks — although initially the traffic was nearly exclusively intra-organizational. The early applications were not standardized to allow message transfer between different vendor's systems, and lacked appropriate management and security controls for multi-organizational environments.

The first international standard for e-mail systems using these networks was also an ITU creation: X.400 (1984, "Red Book"), and it became widely adopted among large commercial and governmental entities. (Although a smaller, more primitive form of the Internet was in existence, and had already developed e-mail standards that are still the foundation of Internet e-mail today, at the time, the public "Internet," NFSnet, specifically prohibited commercial use.)

The authors of the X.400 standard recognized the need for multiple layers of control, security, and operational organization and created a robust design hierarchically defined by country, ADMD (public operator), PRMD (private entity), organization, and organizational units. The authors of X.400 also recognized the need for minutely detailed standards to ensure interoperability between different software vendors, protocols for message format, communications between servers, communications between clients and servers, and additional features such as the ability to attach nontextual components (facsimile images, audio, video, etc.).

In addition to addressing certain weaknesses and flaws in the original version, the second iteration of the X.400 standard (1988, "Blue Book") added a vast array of optional features and a separate but related directory standard: X.500 (of which LDAP is basically a subset).

Before the newer ITU standards were widely deployed, the Internet "went commercial" and quickly overtook the established X.25 networks as the computer network of choice. For a few years, the two systems interoperated through gateway systems that translated between the two formats. Strangely, the relatively primitive and simple e-mail standards of the Internet quickly replaced the advanced and complex X.400 standard although the more sophisticated X.400 was capable of utilizing TCP/IP for transport.

The current Internet e-mail standards involve four primary areas.

SMTP (Simple Mail Transfer Protocol). Originally specified in RFC-821, and as extended with dozens of other RFCs, this protocol specifies the method for transferring messages between e-mail servers. Initially, it also specified some aspects of traffic routing, but the features of DNS as described below have replaced traffic routing. Of particular importance to security is the ASMTP (Authenticated SMTP) extension, RFC-2554, which provides a method to authenticate users submitting messages from client workstations.

"Standard for the Format of ARPA Internet Text Messages." Originally specified in RFC-822, and as extended and modified by dozens of other RFCs, this standard defines the format of the messages to be exchanged. Particularly important are the MIME (Multipurpose Internet Mail Extensions) that specify a standard method to encode multi-part message bodies, including nontextual information.

DNS (Domain Name System). The original purpose of DNS was to relate Internet IP addresses with computer names. This system was extended to aid SMTP e-mail routing. Currently, the second e-mail routing extension is in use over the Internet: MX (Mail eXchanger) records. These extensions have replaced the routing originally defined in SMTP.

S/MIME (Secure/MIME), PEM (Privacy Enhancement for Internet Electronic Mail). These standards allow for a variety of security features, including encryption and decryption of e-mail content, message integrity protection, and nonrepudiation of origin.

In addition, two standards were created to allow e-mail clients to retrieve mail from servers:

IMAP (Interactive Mail Access Protocol). This protocol defines a standard for client/server interaction between e-mail clients and servers. It is currently the *de facto* standard for open-standards e-mail systems but is also available as an alternate access method for many proprietary e-mail server systems. IMAP is designed to allow clients extensive control over the client's e-mail message store: retrieval, deletion, server-based searches, refiling messages between folders, message status, shared public (multi-user) folders, etc.

POP (Post Office Protocol). This protocol defines a standard for how e-mail clients can retrieve headers or messages from a server, and how it can request messages to be deleted from the server. While still in widespread use, it is currently relegated to minimal client and server implementations, and is being overtaken in robust systems by IMAP.

Importantly, neither of these protocols provides a method for submitting new messages for delivery. E-mail clients based on these standards utilize SMTP for submission of new messages.

GOALS AND NON-GOALS

It is important to consider what basic design goals are important to an effective e-mail system so that the security policies, plans, techniques, and devices do not unduly limit the functionality or prevent ease of use of the application.

Obviously, e-mail is intended to provide communication between users; and, as with any application, ease of use and reliability are important. From the very earliest, e-mail applications included three basic elements still found in all current e-mail applications:

- *Standard format*. A standard message format allows any user to exchange messages with any other user.
- *Organization*. All messages include fields such as originator (from), recipients (to, and possibly cc or bcc), submission date, and subject.
- *Security*. Users can only read their own mail, and messages they create are identified as originating from their accounts.

Current e-mail systems improve the three original elements in many ways, and have added only two new basic elements:

- *Interoperability*: The ability to exchange messages between networks of individual computer systems.
- *Transport of nontextual information*: The capability to include or attach computer data types such as audio, video, static images, databases, spreadsheets, executable files or scripts, etc.

Unfortunately, these last two goals are often in direct conflict with security.

To begin the list of security goals, there are common elements with most computer security areas:

- Control access to computer resources so that only legitimate users can access systems and services.
- Prevent loss of or damage to data.
- Prevent theft of data or services.
- Prevent inappropriate dissemination of data.
- Monitor for compliance with law or organizational policies.

RISKS AND PROBLEMS SPECIFIC TO E-MAIL COMMUNICATIONS

In general, e-mail systems need to allow the users in an organization to communicate with users in other organizations over the Internet. While this will ultimately require communications of e-mail messages between the Internet and the organization's e-mail servers, it does not require direct network connectivity between those e-mail servers and the Internet.

To limit network connectivity from the Internet to an organization's e-mail servers, one will have to have a standard "bastion" network between the Internet (or other insecure network) and the organization's internal network, and a mail relay device will need to be installed on the bastion network (see Exhibit 13-1).

While the exterior firewall will provide some protection to the e-mail relay system, it must allow some communications between the e-mail relay and external servers. Hackers will have the opportunity to attempt attacks through the e-mail channels provided. The protections provided by implementing the relay system in the bastion network include the following:

- Because it is the only system that can be directly attacked from the Internet, intrusion detection efforts can be focused on that system, while there may be multiple e-mail servers on the internal network.
- If compromised, the relay system contains only transient messages.
- Denial-of-service attacks launched against the relay may not prevent intra-organizational traffic from functioning normally.

In general, the attacker will only be able to do limited damage and disrupt service between internal users and external users. The hacker will need to have the ability to fully compromise the relay server, and will need

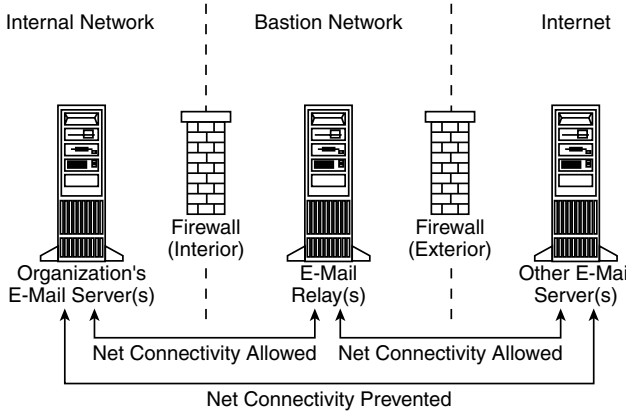

Exhibit 13-1. Limiting network connectivity from the Internet to e-mail servers.

to spend the time and effort to do so before being able to use it as a platform to directly attack the internal mail servers.

Some firewall vendors provide a similar functionality within a single firewall. When this capability is implemented, the firewall itself assumes the role of the e-mail relay. While not as robust a solution as a functionally separate relay system residing within a bastion network, it is quite superior to allowing direct network communications between the insecure network and the internal mail servers.

In many cases, e-mail messages traveling over the Internet will involve sensitive information that will need to be protected from third-party monitoring. With Internet connectivity, there is only one ready solution: encryption. Unfortunately, there exist multiple competing standards for e-mail encryption, and none of the standards are currently widely deployed. Depending on the amount of information and the distribution of affected users, there are several approaches to performing the encryption.

The greatest security can be achieved by utilizing encryption that occurs within each user's e-mail client software. As shown in Exhibit 13-2, each message is encrypted within the sender's system, and remains encrypted until it reaches the client software of the receiver's system. Unfortunately, there are many problems associated with this approach:

- Encryption only occurs when the sender remembers to activate the feature.
- The users of the different organizations must agree on utilizing the same encryption schemes (S/MIME, PGP, etc.).
- The user's and client software at each end must be able to exchange information about the encryption key(s) to use.

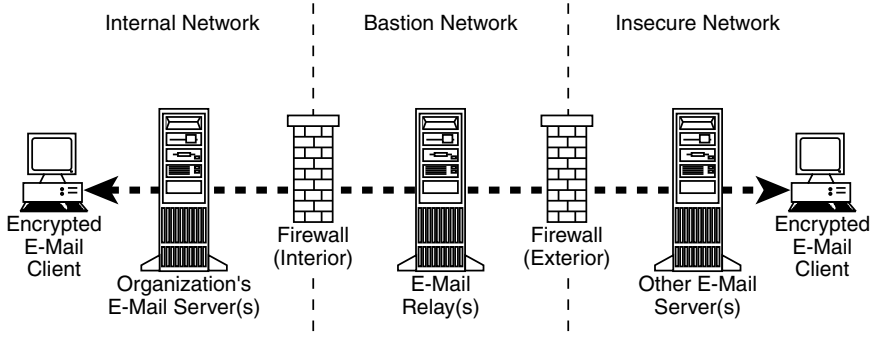

Exhibit 13-2. Encryption.

In cases where the Internet is used to provide network connectivity between geographically separate offices of the same or related organizations, an encrypted VPN can provide the protection necessary for intra-organizational traffic. It then simply becomes necessary to ensure that the routing of the e-mail traffic between the sites occurs through the VPN.

In cases where communications between two business partners' systems require the protection of encryption, but where for some reason it is impractical to implement a VPN, a mail encrypting appliance can be installed between the internal mail servers and the insecure networks, as shown in Exhibit 13-3. Once installed, the appliance is configured to encrypt/decrypt traffic exchanged with specific configured sites, while allowing traffic to pass through nonencrypted to nonconfigured sites.

In addition to the messages passing between the servers, the security of traffic passing between the servers and the users' workstations needs to be considered. Most e-mail application software systems have the ability to encrypt the communications channel between the client and server software. Because the use of encryption significantly increases the load on the server platforms, it is generally disabled by default. Some systems utilize proprietary encryption schemes, while others make use of existing encryption standards such as SSL/TLS.

Special attention should be given to the connectivity security for users accessing e-mail from home or while traveling. While some large organizations can economically provide private, secure remote access systems to internal network resources, organizations are increasingly utilizing the Internet as connectivity for remote users. All access methods in use (proprietary, SMTP, POP, IMAP, webmail, etc.) need to be considered when planning this encryption.

An alternative to encrypting e-mail client to server communications for remote users is the use of encryption-capable remote access servers (see

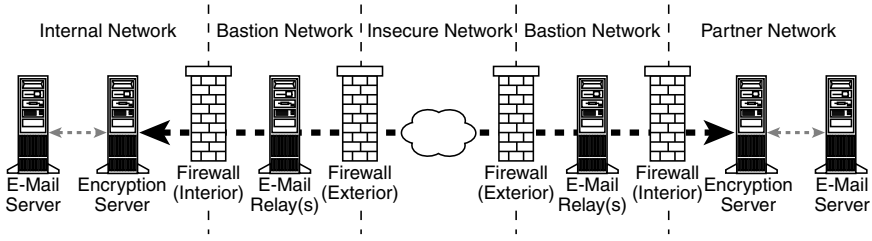

Exhibit 13-3. Installing a mail encrypting appliance.

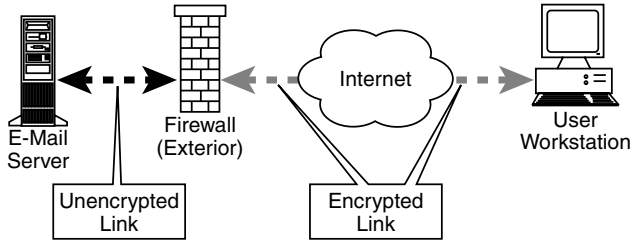

Exhibit 13-4. Encryption-capable remote access servers.

Exhibit 13-4). These devices are typically used to form encrypted tunnels directly to software installed on the user's workstation. Forming VPN tunnels to remote workstations requires the addition of remote access servers, installation and configuration of the VPN software on the clients' workstations, and the maintenance of the authentication schemes used for VPN tunnels setups. Once installed, however, it provides more than e-mail connectivity, as the remote users may then be granted access to any internal network resources.

The primary e-mail protocol utilized for exchange of traffic over the Internet is generally referred to as SMTP (Simple Mail Transfer Protocol). Originally developed in 1982, it was intended to be especially easy to implement, and was expected to be used on the (then) innocent Internet (mostly academic use). While numerous extensions and upgrades to the base protocol have become available over the years, the legacy of the original design created many security problems.

To begin with, SMTP has no mechanism for determining the validity of the originator of the message. In many systems, the indicated originator of the message is whatever the user has typed into their client software. If the user enters "George.Washington@whitehouse.gov," then that is what their client software places in the originator field. If the server receiving the message from the client system does not reject the orignator's identity,

it will probably not be rejected at any other point during the relay and delivery process. Server software should be configured to:

- *Require that the originating address of submitted messages match the identity authenticated during connection establishment from local users.* Sadly, most open systems do not do so by default, and some are completely incapable of doing so. The proprietary systems (Microsoft Exchange, Lotus Notes Domino, etc.) typically enforce the correct originating e-mail address for the user authenticated if utilizing the proprietary submission method (MAPI, etc.), but may not do so when allowing open-standards clients (SMTP/POP/IMAP) to connect.
- *Require session authentication if the originator's address of the message represents a local user.* Unless carefully configured to do so, most systems receiving messages via SMTP do not perform this check.

The answer to these specific problems it to require the use of ASMTP (Authenticated SMTP) and to verify that once enabled, the authenticated user may not submit messages with originating addresses that do not map to the user authenticated. (It is not safe to assume that one implies the other.)

Be forewarned that it may be necessary to disable the ASMTP requirement for specific IP addresses, typically for application servers that generate e-mail traffic without being able to authenticate. In these cases, the IP address of the server attempting to submit the traffic is considered to be "authentication."

While the use of ASMTP prevents the counterfeiting of messages within an organization's domain, it cannot be used to check the validity of messages being received from external organizations. In general, the most that can be done is to verify that the IP address or hostname of the server attempting to submit the traffic to one's server is "appropriate" for the domain of the message's originating address. Without prior arrangement and agreement between the organizations, any attempt to evaluate inbound message validity would be based on guesswork.

One of the best available solutions to this problem is to educate users of this situation, and to appropriately evaluate all e-mail messages received from outside domains. Even if all internal e-mail requires authentication, the credentials (typically a username/password combination) can be guessed, stolen, or otherwise compromised. (Proper user training in the use of e-mail is also discussed in several chapter sections below.)

It is also important to configure one's mail servers to prevent a condition known as "open relay." An e-mail server that functions as an open relay will accept messages with any originating address for delivery to

any recipient address. From the Internet's historical perspective, the open relay was a good samaritan that would route other organization's messages. In modern context, the open relay is an irresponsible bad citizen that allows "spammers" to operate. If allowed to continue unchecked, an organization's mail servers may become "blacklisted" and be unable to communicate to many other organizations. (More correctly known as UBE, Unsolicited Bulk E-mail, the subject of "spam" far exceeds the dimensions of this chapter.) From a security standpoint, there are three primary considerations:

- Spammers can utilize an organization's processing power and connectivity bandwidth without permission or compensation or simply "theft of service."
- If such usage remains unchecked, an organization's e-mail systems and bandwidth will be utilized to the point where the organization's use of e-mail will be degraded or become useless.
- Allowing one's systems to process the traffic causes others to hold one's organization in lower esteem and may cause public relations problems.
- To "close" one's e-mail servers as relays, they should be configured to accept traffic under only two basic conditions:
  - The system attempting to submit the message has properly authenticated as a user of one's system, and the originating address of the message matches the authenticated identity. (Unfortunately, the null originating address, "< >" is" valid for any authenticated identity as it is used for receipts, delivery notifications, etc.)
  - The system attempting to submit the message has not authenticated as a user, the originating address is from an outside domain, and all recipients of the message are inside the organization's domain.

It is not only important that the e-mail system be configured as advised by the manufacturer to close the relay capabilities, but also that the relay status of the server be tested after configuration to ensure that the recommended configuration actually closes the relay. (There are several major e-mail products currently marketed that are still partially open relays when configured as recommended. The best source of up-to-date information for the configuration necessary to close relays is available online from a variety of anti-spam organizations, such as MAPS, ORBS, and CAUCE.)

RISKS AND PROBLEMS SPECIFIC TO E-MAIL CONTENT

Certainly the most visible single e-mail security issue would be the transmission of viruses. Prior to the widespread use of e-mail, a computer

virus would often take weeks, months, or even years to cause widespread infestation. Thanks to certain automatic features of many recent e-mail clients and a little clever "social engineering" by some virus perpetrators, several recent viruses have spread worldwide in less than a day and taken down large-scale e-mail systems in minutes. Preventing the spread of viruses through e-mail systems clearly needs to be a high priority, carefully planned and implemented. (Included in this category are other programs and scripts that are not technically viruses such as Trojan horses.)

Traditionally, the approach to antivirus protection was through the installation of antivirus software on all workstations. While this is still very important, it cannot protect against all current forms of e-mail viruses. In particular, many e-mail client software packages have internal script processing and execution environments (JavaScript, VBS, etc.). Several virus varieties have exploited these capabilities within the e-mail realm in such a way as to prevent traditional antivirus software from intervening. The first large-scale example of such a virus was the "ILoveYou" virus. Through a combination of clever programming and social engineering, it triggered e-mail clients into sending copies of itself to every entry in the local user's address book. Indirectly, the volume of e-mail generated overwhelmed many e-mail servers to the level that it created a denial-of-service attack.

Another traditional approach to combating e-mail viruses has been to place a virus-scanning e-mail relay between the internal e-mail systems and the Internet. This is still an important step in a layered defense to protect e-mail systems from viral attack; it can be susceptible to the multi-server e-mail client. Most current e-mail clients, particularly those designed for open standards (SMTP/IMAP/POP) are designed to be able to interoperate with multiple accounts on multiple servers. Users often utilize this feature to cause their client to interact with both their organizational e-mail account and one or more personal accounts (home ISP, clubs, alumni, etc.). Because the client utilizes IMAP or POP to reach the remote servers, an SMTP relay with antivirus capability cannot protect these transactions. Once a virus-infected message reaches the user's workstation, it can then replicate freely inside the internal networks.

To circumvent this possibility, there are two approaches. First, the firewalls can be configured to prevent clients in the internal network from reaching external e-mail servers by blocking IMAP and POP TCP ports. This has limited effectiveness due to laptops and other portable computing devices. (A user takes his laptop home, and through his ISP connection reaches unprotected mail servers. If a virus-infected message is received, it can be triggered at a later time when the laptop is again brought into the office and reconnected to the internal network.)

The second approach is to install antivirus software that is designed to work directly with the e-mail server on every internal server. This software scans every message being submitted, preventing e-mail viruses from spreading, even after they reach the internal network. (This software scans for all virus types, not just e-mail-specific viruses.)

Because of the speed at which e-mail viruses are capable of spreading (ILoveYou spread worldwide in less than a day, and crippled some e-mail servers in minutes), it becomes necessary to find an antivirus package that can be updated with new antivirus definitions in near-real-time, preferably automatically. In evaluating antivirus solutions, it is most important to ensure that the systems intended for the e-mail servers and relays are capable of being upgraded quickly. If possible, try to select a server antivirus solution that is automatically upgraded, where the antivirus solution vendor transmits the new virus definitions to the servers. (Trying to download updates from vendor sites immediately after a major new virus strike can be problematic.)

The best approach to providing virus protection involves a layered approach:

- Workstations should have antivirus software installed and properly upgraded. While these packages may not protect against some e-mail-specific viruses, they do protect against other virus propagation methods (portable media, transmission through shared storage, etc.), and prevent some major forms of damage (formatting disks, deletion of files, etc.).
- E-mail servers within the internal network should have antivirus software designed to scan all e-mail messages (including all attachments) to protect these servers from viruses that enter into the internal networks due to portable computing and clients accessing remote e-mail accounts. It is important that this software be kept up to date with the latest virus definitions in near-real-time.
- E-mail relays passing traffic between the internal network and the Internet (or any untrusted network) should have antivirus systems to control virus transmission between internal systems and untrusted external systems. It is critically important that this system be kept updated with the latest antivirus definitions in near-real-time. In instances where there is a "storm" of virus transmission on the Internet, this system will prevent the internal e-mail servers from becoming overwhelmed with the handling (rejecting or disposing of) inbound virus-infected messages. (The relay system may become bogged down, but intra-organizational e-mail remains operable.)
- All e-mail client software used by internal users should be configured to maximal security settings to prevent autonomous virus transmission and be kept up to date with the latest security patches available

from the vendor. In many cases, the default configuration at installation is highly insecure.
- E-mail users should be trained in the various forms of e-mail viruses, and the precautions they need to employ when working with e-mail. This is particularly important in preventing the transmission of Trojan horse programs. (Never open attachments of e-mails from unknown or untrusted sources. Be suspicious of unexpected e-mail attachments from known sources. Know how to obtain assistance if a suspicious message is received.)

There is another nontechnological form of virus: the denial-of-service (hoax) virus. Typically, these consist of a detailed message describing a brand-new virus that is spread through e-mail. While the virus described may be entirely fictitious, the message is carefully crafted to strike fear in the recipient, and typically requests the reader to spread the word. Several of these hoax virus warnings have been so convincing that large numbers of users, in the interest of helping their associates, forward the message to large numbers of recipients. In effect, e-mail systems may become overloaded with the volume of these messages such that an effective denial-of-service attack is created. It is important that users know how they should react in these situations:

- Do not propagate such a virus warning to multiple recipients. If desired, instruct users to forward a single copy to a responsible party within the organization who will then evaluate the threat. (If it is a real threat, that person or organization becomes responsible for notification.)
- The user should expect to receive any real virus threat warning from a specific address within the organization, and trust only those messages.

In addition to the handling of virus-infected messages and virus warnings, users should be trained in several other aspects of e-mail. In the previous chapter section, recommendations were made to help prevent the counterfeiting of e-mail messages (also commonly known as spoofing). Typical users are usually unaware of how simple it can be to counterfeit e-mail. Users should be trained not to implicitly trust everything they receive. If they receive an e-mail that is in any way outside normal practices and procedures, the content needs to be confirmed through other channels. The implicit trust some users have otherwise placed in the validity of e-mail has caused a range of problems. Some real examples are startling.

- A cruel joke perpetrated by a fellow employee. An employee receives an e-mail addressed from their manager saying that "You're fired. Have your personal belongings removed from your desk and office and be out of the building by 5 p.m." In another case, a spoofed e-mail is sent to the corporate security department indicating that

an employee appears to be stealing office supplies, apparently originating from the employee's manager.
- A disgruntled employee creating trouble. The order fulfillment manager receives an e-mail addressed from a VP in finance indicating that all orders being shipped to a major customer should be halted until further notice due to lack of payment.
- A dishonest person (outside the company) fakes an e-mail to appear to be from a high-level marketing executive. The e-mail instructs another employee to ship 100 samples of a product to an address in another country for an upcoming trade show to be given out as samples to prospective clients. Due to an oversight, the samples need to be shipped immediately, with the usual paperwork following thereafter.

Would a manager really fire an employee via e-mail? Are these instructions/orders normally communicated with e-mail? Users need to be instructed as to which matters are routinely handled through e-mail, and when and how they should question or confirm such messages. If the receiver of the message implicitly trusts these types of messages, disastrous situations can result.

Because e-mail messages often travel in near-real-time, and most e-mail systems have very limited archiving and logging capabilities, systems and procedures will be needed for the ongoing or after-the-fact investigations. The previous chapter section gave samples of unpleasant actions involving jokes, sabotage, and theft. There are also issues of corporate espionage, sexual harassment, threats, contraband, etc. enacted through e-mail. While most major corporations have active compliance programs in place to keep users trained in appropriate behavior and usage, those problems that still occur will need to be investigated.

The reader should be aware that the following information needs to be considered in the context of possible laws regarding privacy, data retention, and encryption, which are discussed in a later chapter section.

At the very minimum, policy and procedure should be established to retain the logs of the e-mail systems for an "appropriate" time period. Any e-mail system will normally log the originator, recipients, size, and time of receipt and delivery of each message. Many e-mail servers have optional logging configurations that control the amount and types of information recorded. If applicable, the following settings should be examined and set to record the most critical information to allow investigation.

- Indication of the actual, original source of any message (independent of the "From" field). If possible, include the authenticated user. The name or network address of the workstation or server that submitted the message is important as an alternate indication or as data

corroborating originator authentication. If the submitting computer is multi-user, what account was used to submit the message?
- Subject or other headers from the message can be crucial in identifying individual messages and what route they took through various e-mail servers and systems.
- Content types and names for attachments ("customers.doc" — application/ms-word, "nudie.jpg" — image/jpeg, etc.) may be helpful.

In addition, some e-mail systems allow for archival copies of messages to be made. Where applicable, these copies retain the complete content. Some systems archive all messages transferred through a system, while others have controls that indicate which messages to archive by originator/recipient address or domain, priority, size, or other factors. If archiving features are available, they may impart a large additional storage requirement on the e-mail systems, so it will be necessary to determine organizational needs, priorities, and budgets and balance them with potential security requirements.

Where archival features are not available, systems may allow copies of messages to be automatically created and sent to (unintended) recipients. (Typically, these are BCC or auto-forward features.) These features are not typically efficient enough to be left enabled for all users, so they are generally only useful for new investigations.

If investigation is required, whether searching server logs or archived messages, it may be impractical to sift through the collected information without effective search or reporting tools. It is highly advisable to acquire and test the necessary tools ahead of time. The functionality of the tools should be verified and the resultant familiarity with the tools will save valuable time.

Within some organizations, personal use of e-mail is considered nothing more than an employee perk. If the organizational policy indicates that the use of e-mail is limited to official business, then personal use may be considered theft of service. Where this is the case, a need is created to be able to detect users' usage patterns (correspondence with non-business partners; receiving messages from entertainment, sports, or joke lists; etc.) or content types (multimedia — images, videos, audio, games, etc.). Unfortunately, e-mail server systems are typically designed for functionality and flexibility and are not designed to limit content. The ability to observe usage patterns is typically limited to post-processing of server log files. The ability to observe, filter, log, or archive traffic by content type is not available.

E-mail relay products and services designed to provide these features are available. Generally described as e-mail firewalls, their processing occurs at the application level as opposed to the network level of ordinary

firewalls. (The various features they typically supply are described in a later chapter section.) Where used, these e-mail firewalls can be effective in several areas, but are generally limited to messages passing between servers and are typically installed at the boundary between the internal e-mail systems and the Internet. Messages passing between different users of the same server are typically processed entirely internally and cannot be investigated by these devices.

WIRELESS SECURITY

Among the latest new developments in e-mail connectivity is wireless data communications. While the term "wireless" is often discussed as a single category, the various devices operate in different ways on different types of data networks, with multiple technologies for interconnecting to the Internet. The primary security concern is that the e-mail data will be intercepted either over the wireless link or over an Internet link during transfer. With the exception of pagers, most wireless data devices have some form of encryption over the wireless link. Due to the large variety of services and the quickly changing market, it will be necessary to check the specific service in question. All of these devices use the Internet for some portion of the message routing, and that portion of the routing does not inherently support encryption.

Among the current crop of wireless devices are cell phones, Internet modems, PDAs, LAN cards, and pagers.

Digital Cell Phones. While there are variations in the specifics of the network technology, these devices all utilize the networks originally designed for carrying digitally encoded two-way voice telephone calls. For data network use, once the signal reaches the cell tower, various methods are used to interconnect with the Internet. E-mail service is provided on the phone by two different methods:

- First, the cell phone can access e-mail through either HTML or WAP Webmail. In this access mode, it is functionally the same as ordinary Internet access, with the exception that it is likely that this Web access will not support SSL encryption for the connection.
- Second, some cellular service providers supply an e-mail account with the phone. In this case, the cellular provider operates the e-mail server. Normally, this is independent of an organization's e-mail security, except for the likelihood that users with these devices will want to set up auto-forwarding of some or all of their e-mail from their local account to their cell phone account. Bear in mind that the auto-forwarded messages are routed across the Internet unencrypted.

Wireless Internet Modems for Laptops and PDAs (WAN), PDAs with Built-In Wireless Modems, and Digital Cell Phones with Integral PDAs. These devices use either an independent wireless network or a digital cell phone network. Once the data passes through the wireless network onto the Internet, the data is not encrypted. Laptops can overcome this problem by utilizing SSL encryption for the connection, but the client software for PDAs is often not capable of SSL.

Wireless LAN Cards. There are a variety of these devices that use a number of different technologies. The vendor's documentation will be required to determine whether or not the transmissions are encrypted and whether or not they must be configured to enable or enforce encryption on links.

Wireless E-Mail-Specific Devices. While some other functions are typically included, their primary function is to be able to send and receive e-mail messages, and may use encrypted wireless data networks or unencrypted pager networks. All of these devices use proprietary protocols to communicate between the wireless device and the service provider. They operate in two modes:

- First, the service provider may provide a gateway that translates between the proprietary protocol of the device and open-standard protocols (SMTP/POP/IMAP) to a preconfigured Internet e-mail host. The service may or may not support SSL for the Internet connection, and may or may not have the ability to submit messages via ASMTP.
- Second, the service provider may supply a separate e-mail account for the device on an e-mail server operated by the service provider. Again, users within an organization may wish to auto-forward some or all of their e-mail to this account. The auto-forwarded mail would then travel unencrypted over the Internet to the server for this account.

Alphanumeric Pagers and Two-Way Pagers. For these devices, the paging service provider provides an e-mail address associated with the pager. When the service provider's server receives e-mail for that address, the message is typically stripped down to a minimal textual form and then transmitted to the pager. The wireless communication is typically not encrypted. Two-way pagers usually have a method to send simple reply messages.

For those devices with access methods that require that an e-mail account be forwarded to the service provider's e-mail server, care should be taken not to allow sensitive information to be auto-forwarded because it will be sent unencrypted over the Internet. If auto-forwarding cannot be configured to be selective enough, it may be necessary to disable auto-forwarding to the Internet.

Where the wireless device accesses the organization's e-mail server through the Internet and where the protection of SSL session encryption is not available, it becomes necessary to decide whether to prevent the access or to trust the user not to remotely access the e-mail server from the Internet.

E-MAIL SECURITY TOOLS

At the time of this writing (early 2001), there are primarily three categories of tools directly applicable to e-mail security:

E-Mail Encryption Systems. These devices are generally available in the form of e-mail relay devices that encrypt and decrypt traffic between configured e-mail servers. Some utilize proprietary encryption schemes, although most now utilize one of a variety of competing e-mail encryption standards (primarily S/MIME and PGP).

Due to the lack of wide-scale acceptance, the lack of a clear single standard for e-mail encryption, and various problems with the PKI infrastructure, these devices are generally only usable between systems under common control or between cooperating organizations.

Antivirus Systems Designed to Interoperate with E-Mail Servers. The vendors of e-mail servers have recognized the need for antivirus protection, but are generally not proficient in the antivirus arena. In most cases, the makers of the server software provide a published API for message processing between the acceptance and delivery phases of message processing, which one or more antivirus vendors utilize to provide server-specific products. There are also some e-mail antivirus server products designed for inline placement with the message acceptance protocol of open-standard (SMTP) systems.

E-Mail Firewall Products and Services. Both products and services may include any of a number of combinations of functions, including antivirus, anti-spam, content filtering (content search), content type filtering (attachment name or type detection), message archiving, usage pattern reporting, disclaimer notices, load limiting for defense against denial-of-service attacks, encryption, anti-counterfeiting, anti-spoofing, and user monitoring.

When planning to utilize either an encryption or firewall product or service, it will also be necessary to evaluate how it will be positioned between the affected e-mail servers. For organizations with only one server, it can be positioned between the e-mail server and the Internet as a relay. If the organization has multiple servers to be protected, then it will be necessary to determine how it can be positioned to provide the services for multiple servers while not interfering with e-mail routing.

KEEPING UP-TO-DATE

The electronic messaging environment generally changes rapidly. Every few months, vendors release new server and client software with new features that can affect security. Hackers and security experts regularly find new exploits and weaknesses of existing products, and vendors produce patches and new versions to close the gaps. Untold miscreants are actively working on the next new virus. Those individuals trying to keep up with these developments need to regularly update their knowledge in the field.

The best source of information about the most recent security and virus issues can generally be found on the Internet in the form of Web sites and mailing lists. (Of course, it is important for the surfer to evaluate the sources.) Some of the most important are:

- CERT (Computer Emergency Response Team); for general computer security issues, CERT regularly issues bulletins that include those related to e-mail and viruses.
- The vendors of e-mail client and server software are important sources of information about security issues.
- The rootshell Web site regularly has important information about hacks that can be perpetrated against services.

The vendors of antivirus software are good sources of timely information about new viruses. Be sure to check with your vendor, as many have limited access portions on their Web sites or mailing lists restricted to their customers.

SUMMARY

This chapter has focused on providing a general overview of e-mail and the security challenges it brings when used in a corporate environment. Beginning with a historical profile of electronic communications, the text investigated numerous enterprise e-mail risks, detailed the technical and operational concepts behind them, and revealed the tools and applications IT organizations can use to combat them. The text has also provided strategies for dealing with wireless e-mail security in the enterprise.

GLOSSARY

ARPAnet *Advanced Research Projects Agency NETwork* is the research network funded by the U.S. Advanced Research Projects Agency (ARPA). The precursor to today's Internet.

DNS *Domain Name System* Name resolution software that lets users locate computers on a UNIX network or the Internet (TCP/IP network) by domain name.

IMAP *Internet Messaging Access Protocol* A standard mail server expected to be widely used on the Internet. It provides a message store that holds incoming e-mail until users log on and download it. IMAP4 is the latest version.

MAPS *Mail Abuse Prevention System* A California-based, nonprofit organization dedicated to eliminating spamming by maintaining the RBL (Real-time Blackhole List). The RBL contains the IP addresses of spammers, and companies and ISPs can use the list to reject incoming mail.

ORBS *Open Relay Behavior modification System* A database for tracking SMTP servers that have been confirmed to permit third-party (open) relay of bulk e-mail messages. ORBS is a competitor of MAPS.

PEM *Privacy Enhanced Mail* A standard for secure e-mail on the Internet. It supports encryption, digital signatures, and digital certificates, as well as both private and public key methods.

POP3 *Post Office Protocol 3* A standard mail server commonly used on the Internet. It provides a message store that holds incoming e-mail until users log on and download it. POP3 is a simple system with little selectivity. All pending messages and attachments are downloaded at the same time. POP3 uses the SMTP messaging protocol.

S/MIME *Secure Multipurpose Internet Mail Extensions* A common method for transmitting non-text files via Internet e-mail, which was originally designed for ASCII text. S/MIME is a version of MIME that adds RSA encryption for secure transmission.

SMTP *Simple Mail Transfer Protocol* The standard e-mail protocol on the Internet, it is a TCP/IP protocol that defines the message format and the message transfer agent (MTA), which stores and forwards the mail.

SSL *Secure Sockets Layer* The leading security protocol on the Internet. When an SSL session is started, the server sends its public key to the browser, which the browser uses to send a randomly generated secret key back to the server in order to have a secret key exchange for that session.

TLS *Transport Layer Security* A security protocol from the IETF that is a merger of SSL and other protocols. It is expected to become a major security standard on the Internet, eventually superseding SSL. TLS is backward compatible with SSL and uses Triple DES encryption.

UBE *Unsolicited Bulk E-mail* E-mail sent to a large number of recipients without their solicitation or permission; otherwise known as spam.

VPN *Virtual Private Network* A private network that is configured within a public network that enjoys the security of a private network via access

control and encryption, while taking advantage of the economies of scale and built-in management facilities of large public networks.

X.25 The first international standard packet switching network developed in the early 1970s and published in 1976 by the CCITT (now ITU). X.25 was designed to become a worldwide public data network similar to the global telephone system for voice, but it never came to pass due to incompatibilities and the lack of interest within the United States.

X.400 An OSI and ITU standard messaging protocol that is an application layer protocol (layer 7 in the OSI model). X.400 has been defined to run over various network transports, including Ethernet, X.25, TCP/IP, and dialup lines.

PROTECTING AGAINST DIAL-IN HAZARDS: E-MAIL AND DATA COMMUNICATIONS

Leo A. Wrobel

INSIDE

The Telecommunications Privacy Policy, Tailgating, Dial-Back Modems, Securing the Mainframe, Vendor Solutions, Internet Security, Firewalls, Backup T1s

PROBLEMS ADDRESSED

With the advent of nomadic and home office environments, remote access security is once again taking its place at the forefront of security planning activities. Everyone wants an Internet presence and Internet access. Telecommuting is gaining in popularity. Sales agents armed with laptops roam the countryside.

Opening up systems to casual access by nomadic and home office workers requires the implementation of security procedures before the systems become mission critical and revenue producing. This article presents an overview of considerations to be addressed regarding dial-in and Internet access systems. Tips on how to ensure that standards for both physical equipment and privacy policies for today's mobile data world are also included. For information on protecting against dial-in hazards involving voice systems, see article 5-04-41.

PAYOFF IDEA

As more workers use E-mail and data communications, the importance of security grows, and should be firmly established before the systems are used to generate revenue. Beginning with a sound telecommunications privacy policy, organizations should implement protective measures ranging from paging systems, dialback modems, and comprehensive after-market equipment to test firewalls, fully redundant configurations, and backup T1s.

THE TELECOMMUNICATIONS PRIVACY POLICY

What happens if you read someone else's confidential E-mail? Can the company read yours? Does an employee have an absolute right to privacy? Many individuals and companies have no idea how to answer these questions.

For example, it is a violation of federal law to listen to a telephone conversation without the knowledge of the participants. We all know from television shows that there is a rigid process to secure a wire tap on a phone line. Do similar protections exist for E-mail?

Generally, a company's employee policy on E-mail privacy, usually in a telecommunications privacy document, sets the standard. Unfortunately, many organizations do not have such a document.

Every so often, a story in the paper underscores the vulnerability of E-mail far better than thousands of words by experts. The following is one example.

An office romance was blooming between two employees of a major service company. The company depended heavily on electronic mail in the conduct of daily business, and employees had every reason to believe this E-mail was secure. The young lady involved apparently thought it would be romantic to send a graphic E-mail letter, with an attached photograph, to her suitor. This would have been well and good if she had not clicked on the "All Users" button when sending the message. Suffice it to say this made for good office gossip and sent a clear message to everyone about the use of E-mail systems.

Notwithstanding such human errors, are E-mail systems really secure? Can an employer read E-mail? Do employees have a right to privacy? Article 5-04-41 discussed other forms of communication such as fax transmissions. Is a person breaking the law when he or she receives and reads a fax or E-mail intended for someone else? The answers may surprise you, and could call for a thorough review of security procedures for these systems.

A policy on telecommunications privacy should be broad enough in scope to cover not only E-mail, but voice mail and other mediums. Policies generally fit in between the following two ends of the spectrum:

- "Employees work for the company, and it owns the system. The company will listen to or monitor whatever we feel like monitoring or listening to," or
- "ABC Company is committed to absolute privacy of communications and each employee has the right to not have their communications monitored."

Which approach is right? That depends on your company. We usually opt for the latter, with a caveat, as follows:

- "ABC Company is committed to absolute privacy of communications, and each employee has the right to not have their communications monitored. However, if in the course of normal maintenance activity we inadvertently discover illegal activity, we reserve the right to report this activity to the responsible authorities."

Once again, it is wise to contact legal counsel when writing these policies. I was purposely casual in these illustrations to illustrate the range of options, but also because failure to contact legal counsel can leave organizations exposed to risk. An example of this is an employee who ran an illegal bookmaking operation out of a company system. He was fired but then reinstated because the company had no policy on privacy on which to base the dismissal. It is important to contact the corporate legal department, outside counsel, or an internal audit department for further details.

In addition to the establishment of the privacy policy, an evaluation of protective measures for dial-in lines should begin with an overview of their hazards. Any proposed solutions must address the types of intrusion discussed in the following sections if they are to ensure even a minimum level of protection.

HACKERS

Hackers are unauthorized users, often juveniles, who attempt to break into a system for kicks. They may or may not be lethal, but some rudimentary precautions can prevent these break-ins. Because these individuals often use demon dialers, which dial every number in a prefix to find modem lines (e.g., 555-0000, 555-0001, and so on), it is often not difficult for them to find numbers, especially if they are front ended with an identifying script. Therefore, security precautions must be evaluated to prevent this occurrence. These include:

- Modems that dial back the user.
- Modems that screen the CALLER ID of the calling party.
- Modems or equipment that answer initially with silence, rather than with a modem tone.
- Equipment that does not paint an initial screen, such as "Welcome to ABC Widget Company," which can serve to further encourage an unauthorized user.
- Equipment that logs and tracks unsuccessful log-in attempts.
- Equipment that requires a special hardware key to allow access.

Although none of these provides a definitive solution, several or all of these methods can provide a nearly impenetrable defense against unauthorized access.

SABOTEURS

The most unsettling types of attacks come from those who are knowledgeable of the environment. Disgruntled employees, for example, can cause more damage than anyone else, because they know exactly what attack can be the most damaging. Many organizations have a high level of employee trust, and have an established policy of allowing employees

a high degree of system access. This is commendable, but care should be taken because even the most close-knit firms can never be sure when an employee will destroy a critical system because of a personal gripe.

Recommended minimum precautions include:

- A simple process for eliminating log in access when an employee leaves the company.
- A mandatory process for eliminating log in access when any employee is terminated.

TAILGATING

Tailgating is an old ploy used to gain access to a system. It goes like this:

1. A super user or system administrator dials into a remote system.
2. The hacker dials the number (obtained through a demon dialer) and gets a busy signal.
3. The hacker dials 0 and asks the local telephone operator to verify the line.
4. The operator interrupts the line, which usually drops the authorized super user.
5. The hacker is meanwhile dialing out at the same time on another line. If timed perfectly, the modem sees the drop of carrier as a temporary line hit and reestablishes the session with the hacker's modem.
6. The hacker is online with super user access; the super user in turn oftentimes does not even know he has been dropped and instead thinks the system has simply locked up.
7. Working quickly, the hacker grabs the password files and compromises the system for his next attempt later, before the super user realizes anything was amiss. When security logs are checked, only the super user is logged because his session was never terminated.

Sounds rather ingenious? Actually, compared with some of the other tricks, this one is elementary. It underscores that any additional security precautions implemented provide greater peace of mind and protection to organizational assets. Remember, security is a major concern when dozens or hundreds of employees are accessing mission-critical systems through the public telephone network. Careful planning can avoid major difficulties later.

PREVENTIVE MEASURES

Inbound Call Accounting Systems

Each proposed solution should provide an accounting record of all call attempts to make a paper trail of dial-in access. Strength in screening, reporting, and presentation of this information must be a principal selec-

tion criterion in any protective system. A system showing 350 unsuccessful log-in attempts one night is sending a clear signal.

Paging Systems

Some systems that require a high degree of security provide automatic pager notification. When a user logs in, a system administrator's pager goes off. These can be combined with procedures for reporting mysterious login attempts that cannot otherwise be accounted for. They are not terribly expensive considering that a system administrator is instantly notified of anomalies.

Hardware Keys

Hardware devices such as hardware keys should be included in any security recommendations for mission-critical systems. Ease of use, such as plugging into a parallel port, and low cost should be both overriding criteria in the use of these devices.

The keys are a hardware device that usually plugs into a parallel port of a laptop computer. In conjunction with the attendant software, they provide a fairly bulletproof solution because an intruder would have to have both the encryption software, and the hardware key, to get even close to accessing a system.

Caller ID

Caller ID is available in many cities. Even in telephone wire centers where it is available, there are limitations. Caller ID is useful for more than just identification of annoying calls during dinnertime. Properly used, it can identify unauthorized users by their telephone number and often by name. Even nicer, caller ID is a built-in feature for many modems and ISDN (integrated services digital network) terminal adapters. The numbers can be logged on a call-by-call basis as part of the dial-in log described earlier.

Owing to the nonavailability of caller ID service in many areas, modems or other equipment that use this service as the sole underlying basis of a protective system may not be considered. Even if caller ID is available, there are still security concerns, namely:

- Caller ID data may not always be passed by interexchange carriers like AT&T, MCI, and Sprint. Your company would in a sense be vulnerable to long distance callers using carriers who do not pass this data. (This is rapidly changing as carriers comply with FCC regulations to pass caller ID data whenever possible.)
- Even if interexchange carriers were equipped to pass this data, the distant local central office might not be. A company would still be open to intrusion unless other methods were employed.

- Many local central offices in parts of the country are not caller ID capable for either local or long-distance calls.

Therefore, at least a few calls will still slip through with the "out of area" disclaimer on the modem or display device. Caller ID alternatives should be carefully considered as an exclusive security precaution until the service becomes more ubiquitous. Even after universal deployment, it is recommended that this service is used only to augment existing security measures and not as a solution. Even where caller ID is available, the user can in many cases dial the override code to block it. This demands another level of protection on a modem: rejection of users where the incoming data indicates that the caller ID information was deliberately blocked.

Dial-Back Modems

Many dial-back modems are available on the market today. These devices require that users login, and then hang up and call the incoming caller back at a predetermined number. These are fairly foolproof, but inconvenient. A nomadic user in a hotel will not have an authorized number and will not be able to dial into a call-back modem bank. Nonetheless, special modem banks and numbers can be set up for this purpose with special emphasis and screening for potential intruders.

Securing the Mainframe

Many users are stuck trying to protect legacy mainframe environments where security options for dial-in are marginal at best. While IBM has no graceful and simple solution for the mainframe, it can provide an additional level of security by front ending the protocol converter with a dial-in server. The IBM 8235 dial-in server is one candidate. It provides the necessary accounting, dial-back capability, and with an eight port maximum capacity, it seems sized correctly for any future growth. However, it is somewhat expensive.

More common are solutions where distributed devices are hung off the mainframe through the use of bridges and LAN switches. A PC-based system with appropriate protocol conversion software will often suffice in a pinch as a secure dial-in medium for the mainframe.

Software-Based Solutions

Because transparency for dial-in users is an issue (different departments often use a variety of software packages when dialing in), you may not want to consider a wholesale change of dial-in software emulation packages. This might prove disruptive to your present operating environment.

Software alternatives that augment or enhance the current hardware package in use are most preferable because the need for training on new packages is minimal.

After-Market Equipment

Often, the only way to provide acceptable security across a broad range of installed equipment and large cross-section of users is to adapt some sort of outboard solution. Naturally, the potential exists to black box a company to death by over-broadening the range of installed equipment. It pays to evaluate carefully. Following are several effective alternatives:

- A line of equipment distributed by CDI Incorporated of Clifton, NJ. This equipment seems to most adequately reflect pressing security concerns presented by most users. Although I have not had direct experience with this equipment, on paper it certainly seems to provide a most comprehensive solution to the dial-in security issue and should be carefully considered.
- Another cost-effective solution is brokered by LeeMah Data Comm Security Corp. of Hayward CA. It also appears to meet criteria for transparency and accommodation of diverse remote users.

When evaluating these or another product, look for the following features:

1. The unit should serve as security device and modem manager. Anyone who has ever repeatedly hit a "ring-no-answer" when dialing a modem pool can appreciate this feature. Make sure the system can automatically busy these lines out, then alert you to the problem.
2. The unit should provide response time information by modem, by phone line, and by port. For example, it should interface to a personal computer for effective performance management. This makes a good source of information to a help desk for when users call in to report trouble connecting.
3. The product should offer effective upgradeability. For additional security, the product should offer token hardware devices that interfaces to a user's parallel port. Software token should also be available. DOS or Windows software both should be supported.
4. Software and hardware keys. Because transparency of equipment for users is usually an issue, try not to consider major changes in hardware used by remote users. This might prove too disruptive to the present operating environment. This may cost more later in maintenance and training.

An unbiased opinion makes LeeMah the favorite in terms of flexibility and cost-effectiveness. Some of the features offered provide effective evaluation criteria for whatever system you decide to acquire. These include:

- The unit is a multiple port challenge-response unit.
- It supports up to 32 modems (Traq-Net 2032).

- The unit installs between the phone line and modem, allowing for use of present modems.
- The product allows for use of (optional) proprietary LeeMah Security Modems for additional protection.
- The product employs either a hardware or software token at user request.
- It provides a full audit trail.
- The product meets DES security standard.
- The product operates transparently, allowing for use of all present emulation software.
- It offers reasonably priced software (Infodisk).
- The product supports, for example, Procomm, Qmodem, Crosstalk, PCAnywhere, and Smartcom.

LeeMah DataComm provides a standards-based, virtually impenetrable, flexible, and configurable, security solution for the protection of remote access to telecommunications and data communications network information and resources. LeeMah's remote access security solutions consist of three elements: access control systems, personal authentication devices, and security administration software.

The LeeMah system represents one of the most adaptable and feature-rich solutions to protect dial-in services over a wide variety of equipment types from mainframes to local area networks (LANs). However, it is still wise to evaluate several vendors and base a decision on each unique environment. An Internet search will probably uncover numerous other choices with similar capabilities.

INTERNET SECURITY RESPONSIBILITIES

No discussion of unauthorized data access is complete without mentioning the Internet. The Internet is a relatively new phenomenon for many companies, at least as a revenue generating system, and many companies have unresolved organizational issues about security responsibilities. Who maintains the equipment used for Internet access? Historically, these types of operations often have fallen under a special unit in the IS department, such as midrange computer services. However, today many companies have a separate group of technologists responsible for the actual operation of the Internet firewall and other components. There is not always a clear business unit responsible for Internet security.

Many clients have reported minor snafus (i.e., holes or vulnerabilities left temporarily exposed in the system) due to lack of a clear policy outlining who is responsible for which system and under what circumstances. Although this responsibility will ultimately gravitate to an IT security group (much like the LAN and mainframe services of today), vulnerabilities will

continue in the immediate term, while the technology is in the "tweaking and tinkering" stage.

Another issue includes staffing and resource allocation. Many companies should consider a nominal increase in manpower to avoid creating too small a pool of specialists and provide better depth. When Internet access is established and any possible security breeches or holes are closed, organization changes may be readdressed. If a company has one person who is readily identified as the Internet guru, take note. These folks are in high demand and could leave you holding the bag if they accept other employment. Besides, outgunned and undermanned staffs have little time to probe for security violations.

Installation of Test Firewall

Many companies do not have firewall platform exclusively earmarked for testing and backup. For all intents and purposes, the present technology is single threaded in almost every way. This is not a major concern yet, but will be when the firewall goes into full operation, and the system becomes revenue producing.

Just as in mainframes and local area networks, it is important to establish a protocol and procedure that does not directly introduce new applications into a production environment. This lesson became apparent during 25 years of mainframe operations, and even the most renegade LAN managers have learned to adopt it as a gospel of prudent operation. Like many new technologies, these protocols have yet to catch up in the Internet arena for many firms.

A test firewall also can double as a backup in the event of a major equipment failure in the primary configuration. This will be important again when the system becomes fully revenue generating.

Because the Internet is a relatively new technology for many firms, staff should be encouraged to dabble. Although it is not prudent to experiment on a production platform, the backup firewall configuration can provide a practical option. The backup can be justified further by encouraging the staff to experiment, improve, and refine without jeopardizing operation of the enterprise. In summary, the extra expense of a backup firewall capability can be justified for the resiliency it provides the network and because it shortens the educational curve when principal technologists are encouraged to try new processes.

Upgrading to a Fully Redundant Configuration

The issue of redundant physical componentry of the Internet firewall raises several items of concern. Again, these will not be major concerns until the Internet and firewalls go into full production and become revenue-generating systems, but they will demand increased attention in the

future. The first is in the area of general fault tolerance on the physical components.

Many routers in use, such as the CISCO 4000 series, have no redundancy. The CISCO 5000 series has redundant power and a redundant CPU, which will be required later. Every other component in other systems generally has a redundant backplane, power supply, CPU, and other common logic. As usual in the world of technology, the newer systems play catch-up for a couple of years with regard to redundancy. CISCO appears to have responded commendably to user demands for such backup systems, as have other vendors. Organizations should explore these options and use them as soon as Internet access is about to become revenue generating or otherwise mission critical.

Backup T1s

Another issue to consider is that most large users install only one T1 to the Internet Service Provider (ISP), which creates a point of vulnerability. A wiser approach is to consider adding a second T1 along with "Round Robin DNS" for greater resiliency on the wide area network connectivity to the ISP. Many local telephone companies offer services designed to diversify T1 access as well. In Southwestern Bell territory, the service is called SecureNet™, which offers a completely diverse T1 circuit at a significantly reduced rate. Other components, such as CSUs and DSUs, are single threaded without redundancy. Spares should be kept or depot arrangements should be made with vendors to ensure that failed components can be replaced quickly, minimizing the impact on the business.

As the Internet becomes more and more of an integral part of a company's operations (as defined by impact on revenue or other valid measurement), storing of spare components, including hard drives, redundant controller cards, spare tape drives, and power supplies should be considered.

In summary, to ensure a system up to par with revenue-generating applications, companies should upgrade to series 5000 or 6000 routers (or equivalent), combined with dual connections to the ISP and "Round Robin DNS" at the same juncture. Depot arrangements should be established for spare parts, and services such as Southwestern Bell SecureNet and other methods for diversifying T1 access should be considered. Such precautions will provide cheap insurance for what will fast become a revenue-producing system.

RECOMMENDED COURSE OF ACTION

Although revenue-generating dial-in systems may seem to be far away for many companies, experience shows that systems like these have a way of catching on. Insurance companies love the idea of roving claims adjusters with dial-in laptop computers. Everyone wants to work at home.

Commerce is blossoming on the Internet. Waiting until there is a revenue impact after a failure resigns an organization to be almost perpetually in the reactive mode of trying to keep up with the protection of a potentially business debilitating system. The alternative is to start now, while these systems are still relatively immature and design the protective systems in before the Internet becomes a fully functional business system.

Leo A. Wrobel is president and CEO of Premiere Network Services, Inc., in DeSoto, TX. An active author, national and international lecturer, and technical futurist, he has published 10 books and over 100 trade articles on a variety of technical subjects, including *Writing Disaster Recovery Plans for Telecommunications and LANS* (Artech House, 1993) and *Business Resumption Planning* (Auerbach Publications, 1997). His experience of nearly two decades includes assignments at AT&T, a major mortgage banking company, and a host of other firms engaged in banking, brokerage, heavy manufacturing, telecommunications services and government, as well as the design and regulatory approval of a LATA-wide OC-12/ATM network for a $10 billion manufacturing giant, the first of its kind. A three-term city councilman and previous mayor, Leo Wrobel is a knowledgeable and effective communicator known for his entertaining presentation style on a wide variety of technical topics. E-mail Security Using Pretty Good Privacy

William Stallings

Payoff

Many users are unaware that their E-mail messages are completely public and can be monitored by someone else. This article describes Pretty Good Privacy, an E-mail security package that allows users to send messages that are secure from eavesdropping and guaranteed to be authentic.

Introduction

Users who rely on electronic mail for business or personal communications should beware. Messages sent over a network are subject to eavesdropping.If the messages are stored in a file, they are subject to perusal months or even years later. There is also the threat of impersonation and that a message may not be from the party it claims to be from. Protection is available in the form of Pretty Good Privacy (PGP), an E-mail security package developed by Phil Zimmermann that combines confidentiality and digital signature capabilities to provide a powerful, virtually unbreakable, and easy-to-use package.

PGP Defined

The most notable features of this E-mail security program are that it:

- Enables people to send E-mail messages that are secure from eavesdropping. Only the intended recipient can read a Pretty Good Privacy message.
- Enables people to send E-mail messages that are guaranteed authentic. The recipient is ensured that the PGP message was created by the person who claims to have created it and that no one has altered the message since it was created.
- Is available as freeware on the Internet, many electronic bulletin boards, and most commercial services such as CompuServe.
- Is available in versions for Disk Operating System, Macintosh, UNIX, Amiga, OS/2 , VMS, and other operating systems.
- Works with any E-mail package to create secure E-mail messages.

E-Mail Risks

PGP provides protection from the threat of eavesdropping. A message sent over the Internet can pass through a handful of mail forwarders and dozens of packet-switching nodes. A systems administrator or someone who has gained privileged access to any of these transfer points is in a position to read those messages.

Although E-mail users may feel they have nothing to hide, they may someday want to correspond with their lawyers or accountants using the Internet, or they may work for companies that want to send proprietary information over the Internet. Many people already use the Internet for sending highly personal or sensitive messages.

There is also a civil liberties issue to be concerned about. The police, intelligence, and other security forces of the government can easily monitor digital and computerized E-

mail messages, looking for key words, names, and patterns of exchanges. Any user could be innocently caught up in such a net.

Authenticity of messages poses another potential risk. It is not difficult to spoof the network into sending a message with an incorrect return address, enabling impersonation. It is also relatively easy to trap a message along its path, alter the contents, and then send it on its way.

For example, if a user is on a shared system, such as a UNIX system, that hooks into the Internet, then the impersonator could be someone with “superuser” privileges on the system. Such a person could divert all incoming and outgoing traffic from an unsuspecting mailbox to a special file. The impersonator could also have access to a router, mail bridge, or other type of gateway through which all traffic between the user and a correspondent must pass. Such impersonators could use their privileged status on the gateway to intercept mail and to create and send mail with a fraudulent return address.

PGP's History: Privacy At Issue

PGP is a legitimate tool that can be used for legitimate reasons by ordinary citizens, although some users consider it slightly suspect.

Phil Zimmerman began working on Pretty Good Privacy in the 1980s and released the first version in 1991. One of the key motivating factors for PGP's development was an effort by the FBI to secure passage of a law that would ban certain forms of security algorithms and force computer manufacturers to implement security features for E-mail that could be bypassed by government agencies. Zimmerman saw this as a threat to privacy and freedom. Thus, PGP was conceived as a package that could be used by the average person on a small system to provide E-mail privacy and authenticity. Zimmerman accomplished this by:

- Selecting the best available security algorithms as building blocks.
- Integrating these algorithms into a general-purpose application that is independent of the operating system and processor and that is based on a small set of easy-to-use commands.
- Making the package and its documentation, including the source code, free and widely available.

Because PGP uses encryption algorithm, it was subject to export controls. An encryption algorithms lets users scramble a message in such a way that allows only the intended recipient to unscramble it.

Encryption algorithms are classified by the US government as armaments and fall under the International Trafficking in Armaments Regulations (ITAR). ITAR requires that users get an export license from the State Department to export armaments. In practice, the State Department will not grant any such license for strong encryption algorithms, and PGP uses two of the strongest.

This problem does not need to concern the average user because there is no law against using PGP in the US. There is also no law outside the US to prevent use of a product that was illegally exported from the US. Furthermore, some of the more recent versions of PGP actually originated outside the US, eliminating the problem altogether.

A second problem has to do with patents. One of the two encryption algorithms in PGP is known as Rivest-Shamir-Adleman (RSA). Anyone using PGP inside the US was, for a time, potentially subject to a lawsuit for Rivest_Shamir-Adleman patent infringement.

A new release of PGP, known as version 2.6, which was developed at MIT with the supervision of Phil Zimmermann, has patent approval from the RSA patent holders. Like the original PGP, this version has also made its way onto bulletin boards and Internet sites outside the US. In addition, a compatible non-US version 2.6was created outside the US. As long as a user chooses any of the flavors of version 2.6, there is no infringement on any patents.

Conventional Encryption

PGP exploits two powerful security functions: conventional encryption and public-key encryption. Conventional encryption is the classic approach to secret codes that dates back to ancient Rome and even earlier. A conventional encryption scheme (see Exhibit 1) includes the following five ingredients:

- **Plaintext.** This is the readable message or data that is fed into the algorithm as input.
- **Encryption algorithm.** The encryption algorithm performs various substitutions and transformations on the plaintext.
- **Secret key.** The secret key is also input to the algorithm. The exact substitutions and transformations performed by the algorithm depend on the key.
- **Ciphertext.** This is the scrambled message produced as output. It depends on the plaintext and the secret key.
- **Decryption algorithm.** This is essentially the encryption algorithms run in reverse. It takes the ciphertext and the same secret key and produces the original plaintext.

Conventional Encryption

The Caesar cipher, used by Julius Caesar, is a simple example of encryption. The Caesar cipher replaces each letter of the alphabet with the letter standing three places further down the alphabet, for example:

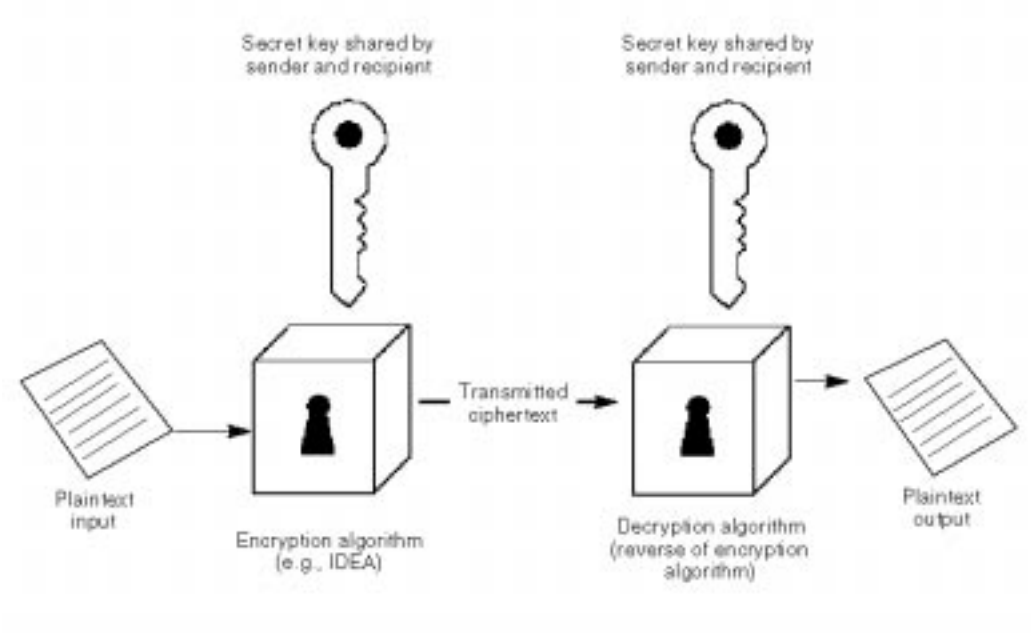
```
plain:  meet me after the toga party
cipher: phhw ph diwhu wkh wrjd sduwb
```

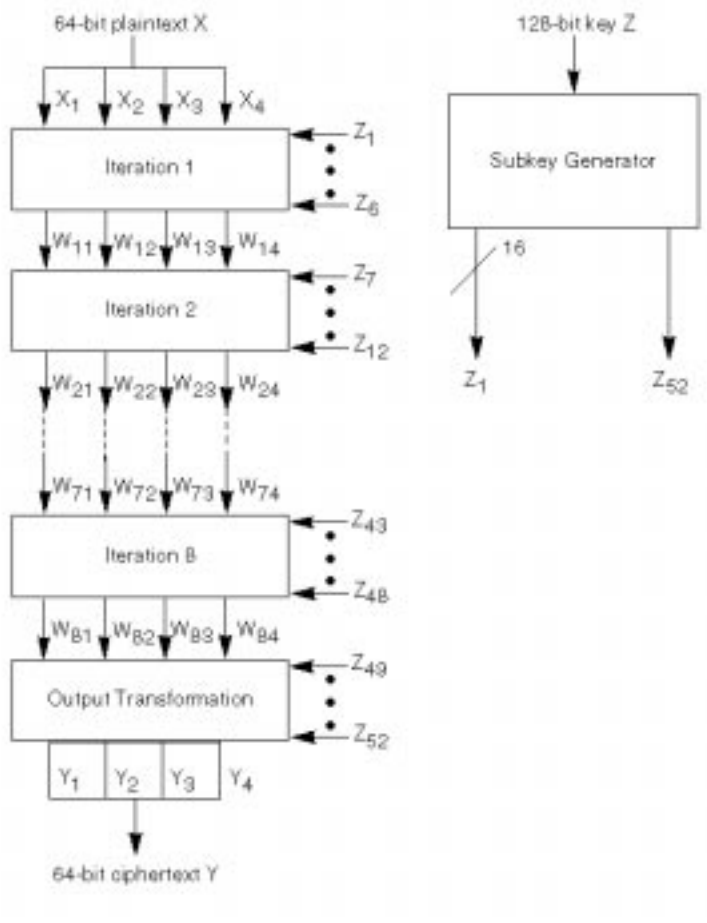
The alphabet is wrapped around so that the letter following Z is A. The decryption algorithm simply takes the ciphertext and replaces each letter with the letter standing three places earlier on in the alphabet. A general Caesar cipher involves a shift of *k* letters, where *k* ranges from 1 through 25. In this case, *k* is the secret key to the algorithm.

The Caesar cipher is not very secure. Anyone who wanted to decipher the code could simply try every possible shift from 1 to 25. Pretty Good Privacy uses a much stronger algorithm known as the International Data Encryption Algorithm, or Interactive Data Extraction and Analysis.

The International Data Encryption Algorithm

IDEA is a block-oriented conventional encryption algorithms developed in 1990 by Xuejia Lai and James Massey of the Swiss Federal Institute of Technology. The overall scheme for IDEA encryption is illustrated in Exhibit 2. IDEA uses a 128-bit key to encrypt data in blocks of 64 bits.





Overall IDEA Structure

The IDEA algorithm consists of eight rounds, or iterations, followed by a final transformation function. The algorithm breaks the input into four 16-bit subblocks. Each of the iteration rounds takes four 16-bit subblocks as input and produces four 16-bit output blocks. The final transformation also produces four 16-bit blocks, which are concatenated to form the 64-bit ciphertext. Each of the iterations also uses six 16-bit subkeys, whereas the final transformation uses four subkeys, for a total of 52 subkeys. The right-hand portion of the exhibit indicates that these 52 subkeys are all generated from the original 128-bit key.

Each iteration of IDEA uses three different mathematical operations. Each operation is performed on two 16-bit inputs to produce a single 16-bit output. The operations are:

- Bit-by-bit exclusive-OR, denoted as ∞.
- Addition of integers modulo 2^{16} (modulo 65536), with input and output treated as unsigned 16-bit integers. This operation is denoted as §
- Multiplication of integers modulo 216 + 1 (modulo 65537), with input and output treated as unsigned 16-bit integers, except that a block of all zeros is treated as representing 2^{16}. This operation is denoted as [Theta].

For example,

0000000000000000 [Theta]1000000000000000 = 1000000000000001

because

$$2^{16} * 2^{15} \bmod (2^{16} + 1) = 2^{15} + 1$$

These three operations are incompatible because no pair of the three operations satisfies a distributive law. For example:

a§b[Theta]c≠(a§b)[Theta](a§c)

They are also incompatible because no pair of the three operations satisfies an associative law. For example:

a§(b∞c)≠a§b)∞c

The use of these three separate operations in combination provides for a complex transformation of the input, making cryptanalysis very difficult.

Exhibit 3 illustrates the algorithm for a single iteration. In fact, this exhibit shows the first iteration. Subsequent iterations have the same structure, but with different subkey and plaintext-derived input. The iteration begins with a transformation that combines the four input subblocks with four subkeys, using the addition and multiplication operations. This transformation is highlighted as the upper shaded rectangle. The four output blocks of this transformation are then combined using the XOR operation to form two 16-bit blocks that are input to the lower shaded rectangle, which also takes two subkeys as input and combines these inputs to produce two 16-bit outputs.

Single Iteration of IDEA (First Iteration)

Finally, the four output blocks from the upper transformation are combined with the two output blocks of the MA structure using XOR to produce the four output blocks for this iteration. The two outputs that are partially generated by the second and third inputs (X_2 and X_3) are interchanged to produce the second and third outputs (W_{12} and W_{13}), thus increasing the mixing of the bits being processed and making the algorithm more resistant to cryptanalysis.

The ninth stage of the algorithm, labeled the output transformation stage in Exhibit 2, has the same structure as the upper shaded portion of the preceding iterations (see Exhibit 3). The only difference is that the second and third inputs are interchanged before being applied to the operational units. This has the effect of undoing the interchange at the end of the eighth iteration. This extra interchange is done so that decryption has the same structure as encryption. This ninth stage requires only four subkey inputs, compared to six subkey inputs for each of the first eight stages. The subkeys for each iteration are generated by a series of shifts on the original 128-bit key.

IDEA has advantages over older conventional encryption techniques. The key length of 128 bits makes it resistant to brute-force key search attacks. IDEA is also highly resistant to cryptanalysis and was designed to facilitate both software and hardware implementations.

Public-Key Encryption

One essential characteristic of Interactive Data Extraction and Analysis and all conventional encryption algorithm is the need for the two parties to share a secret key that is not known to anyone else. This is a tremendous limitation, especially for an E-mail application.

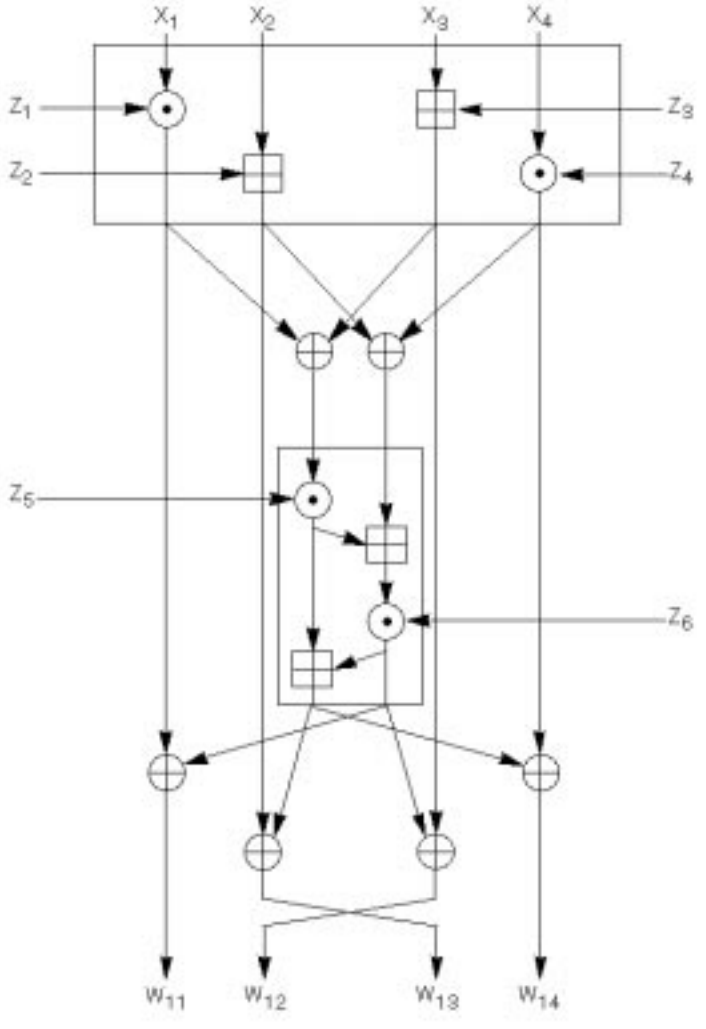
If Pretty Good Privacy depended solely on the use of IDEA, before a user could correspond with anyone, that user would somehow have to arrange to share a secret 128-bit number with the message recipient. If there is no way to communicate securely, it becomes difficult to send the key.

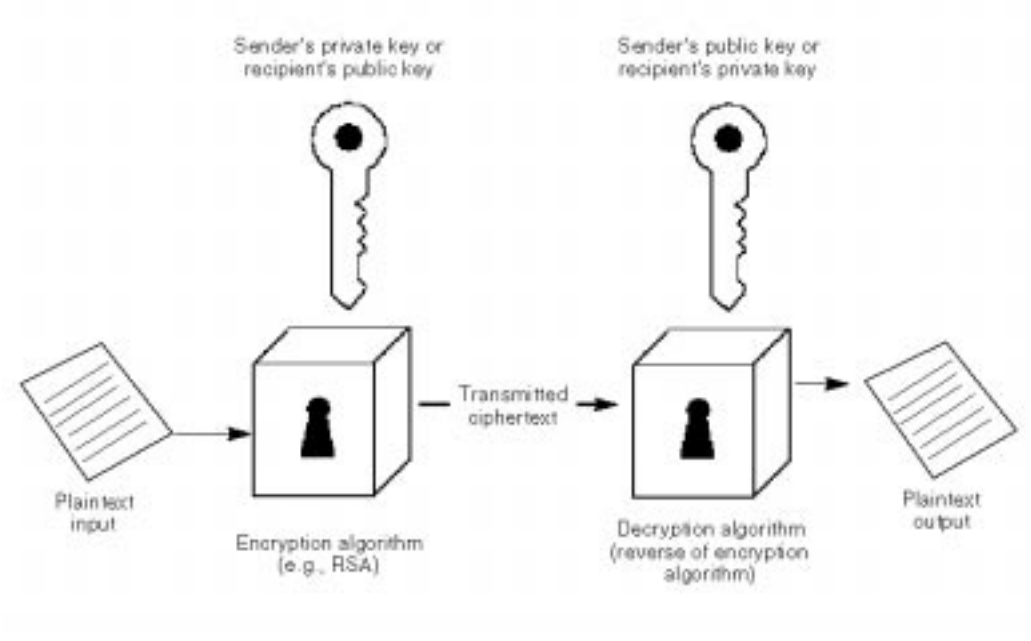
A new approach to encryption known as public-key encryption offers a solution to this problem. With this method, developed in 1976 by Whitfield Diffie, there is no need to convey a secret key. Instead, each person has a private key and a matching public key. Encryption is done with one of these two keys and decryption uses the other. The private key is kept secret, known only to its holder. The matching public key is just that—public. The private key holder can broadcast the matching public key.

Public-key encryption can be used to ensure privacy in much the same way as IDEA (see Exhibit 4). Users put plaintext and the intended recipient's public key in the encryption algorithms. The algorithm uses the plaintext and the public key to produce ciphertext. At the receiving end, the decryption algorithm, which is the reverse of the encryption algorithms, is used. In this case, the input is the ciphertext and the receiver's private key. This message is secure from eavesdropping because only the receiver has the private key necessary for decryption. Anyone who has a copy of the recipient's public key can create a message that can be read only by this recipient.

Public-Key Encryption

Authentication can also be performed by putting plaintext and the sender's private key in the encryption algorithms. The algorithm uses the plaintext and the private key to produce ciphertext. At the receiving end, the decryption algorithm, which is the reverse of the





encryption algorithms, is used. In this case, the input is the ciphertext and the sender's public key.

This message is guaranteed to be authentic because only the sender has the private key necessary for encryption. Anyone who has a copy of the sender's public key can read the message and verify that it must have come from the alleged sender.

The public-key scheme used for PGP is the Rivest_Shamir-Adleman algorithm. RSA takes variable-length keys. Typically, the key size for both the private and public keys is 512 bits.

The RSA Algorithm

One of the first public-key schemes was developed in 1977 by Ron Rivest, Adi Shamir, and Len Adleman at MIT and first published in 1978. Named for its creators, the Rivest-Shamir-Adleman (RSA) scheme has since reigned as the only widely accepted and implemented approach to public-key encryption. RSA is a block cipher in which the plaintext and ciphertext are integers between 0 and n - 1 for some n. Encryption and decryption take the following form for some plaintext block M and ciphertext block C:

$C = M^e \bmod n$

$M = C^d \bmod n = (M^e)^d \bmod n = M^{ed} \bmod n$

Both sender and receiver must know the value of n. The sender knows the value of e, and only the receiver knows the value of d. Thus, this is a public-key encryption algorithms with a public key of KU = {e, n} and a private key of KR = {d, n}. For this algorithm to be satisfactory for public-key encryption, the following requirements must be met:

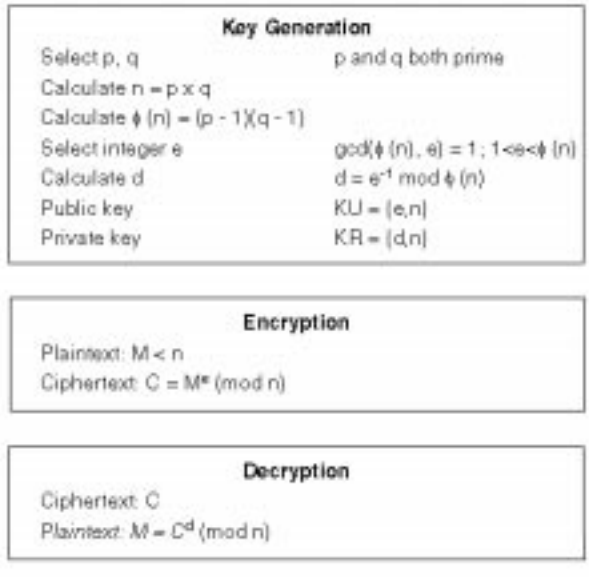
- It should be possible to find values of e, d, n such that $M^{ed} = M \bmod n$ for all $M < n$.
- It should be relatively easy to calculate M^e and C^d for all values of $M < n$.
- It should be infeasible to determine d given e and n.

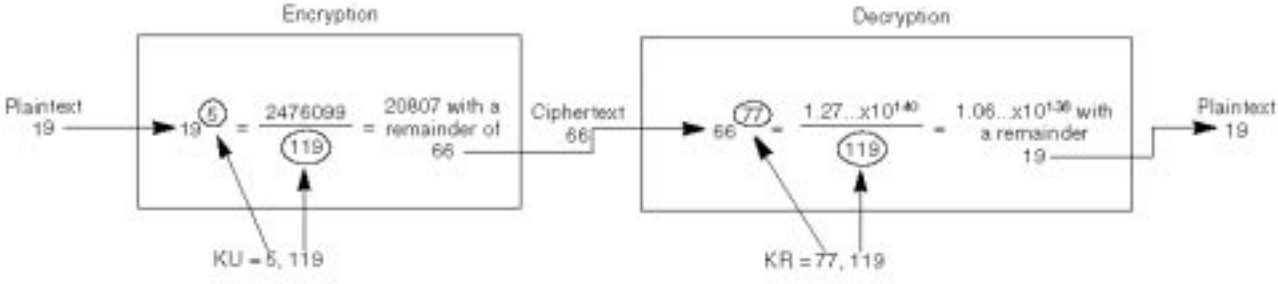
Exhibit 5 summarizes the RSA algorithm. To understand the algorithm, users should begin by selecting two prime numbers, p and q, and calculating their product n, which is the modulus for encryption and decryption. Next, the quantity $\phi(n)$, which is referred to as the Euler totient of n, which is the number of positive integers less than n and relatively prime to n should be determined. Then an integer d, that is relatively prime to f (n), (i.e., the greatest common divisor of d and $\phi(n)$ is 1), should be selected. Finally, $e$should be calculated as the multiplicative inverse of d, modulo $\phi(n)$. It can be shown that d and e have the desired properties.

The private key consists of {d, n} and the public key consists of {e, n}. Suppose that user A has published its public key and that user B wishes to send the message M to A. Then, B calculates $C = M^e \pmod n$ and transmits C. On receipt of this ciphertext, user A decrypts by calculating $M = C^d \pmod n$.

An example is shown in Exhibit 6. For this example, the keys are generated as follows:

- Two prime numbers, p = 7 and q = 17, are selected.
- Calculate $n = pq = 7 \times 17 = 119$.





Key:
KU public key
KR private key

- Calculate f (n) = (p-1)(q-1) = 96.
- Select e such that e is relatively prime to f (n) = 96 and less than f (n);in this case, e = 5.
- Determine d such that de =1 mod 96 and d < 96. The correct value is d = 77, because 77 x 5 = 385 = 4 x 96 + 1.

The resulting keys are public key KU = {5, 119} and private key KR = {77,119}. The example shows the use of these keys for a plaintext input of M = 19.For encryption, 19 is raised to the fifth power, yielding 2,476,099. Upon division by 119, the remainder is determined to be 66. Therefore, 195 [equiv]66 mod 119, and the ciphertext is 66. For decryption, it is determined that 66^{77} [equiv]19 mod 119.

How Hard Is It to Break the Code?

There are two possible approaches to defeating the RSA algorithm. The first is the brute-force approach: trying all possible private keys. Thus the larger the number of bits in $e$and d, the more secure the algorithm. However, because the calculations involved, both in key generation and in encryption/decryption, are complex, the larger the size of the key, the slower the system will run.

Most discussions of the cryptanalysis of RSA have focused on the task of factoring p into its two prime factors. Until recently, this was considered infeasible for numbers in the range of 100 decimal digits, which is about 300 or more bits. To demonstrate the strength of Rivest-Shamir-Adleman, its three developers, issued a challenge to decrypt a message that was encrypted using a 129-decimal-digit number as their public modulus. The authors predicted that it would take 40 quadrillion years with current technology to crack the code. Recently, the code was cracked by a worldwide team cooperating over the Internet and using more than 1,600 computers after only eight months of work. This result does not invalidate the use of RSA; it simply means that larger key sizes must be used. Currently, a 1,024-bit key size (about 300 decimal digits), is considered strong enough for virtually all applications.

How PGP Works

Digital Signature

It may seem that Rivest-Shamir-Adleman is all that is needed for a secure E-mail facility. Everyone who wants to use Pretty Good Privacy can create a matching pair of keys (PGP will do the necessary calculation) and then distribute the public key. To send a message, it must first be encrypted with the private key to guarantee its authenticity. Next, the result of step one must be encrypted with the recipient's public key to guarantee that no one else can read the message.

This scheme is technically valid but impractical. The problem is that RSA, and all other public-key schemes, are very slow. To double-encrypt messages of arbitrary length is far too time-consuming. Users could experience delays of minutes or even hours waiting for their PCs to do the number-crunching.

Instead, PGP exploits the strengths of conventional and public-key encryption. When a message is sent, it goes through two security-related stages of processing: digital signature and encryption.

The digital signature is one of the most clever innovations to come out of the work on public-key encryption. To use digital signature, users take the message that they want to send and map it into a fixed-length code of 128 bits. The algorithm for doing this is called MD5 (message digest version 5). The 128-bit message digest is unique for this message. It would be virtually impossible for someone to alter this message or substitute another message and still come up with the same digest.

PGP then encrypts the digest using RSA and the sender's private key. The result is the digital signature, which is attached to the message. Anyone who gets this message can re-compute the message digest and then decrypt the signature using RSA and the sender's public key. If the message digest in the signature matches the message digest that was calculated, then the signature is valid. Because this operation only involves encrypting and decrypting a 128-bit block, it takes little time.

For the encryption stage, PGP randomly generates a 128-bit secret key and uses Interactive Data Extraction and Analysis to encrypt the message plus the attached signature. The recipient can discover the secret key by using RSA. PGP takes the secret key as input to RSA, using the receiver's public key, and produces an encrypted secret key that is attached to the message. On the receiving end, PGP uses the receiver's private key to recover the secret key and then uses the secret key and IDEA to recover the plaintext message plus signature.

Getting Public Keys

Public-key encryption techniques make use of two keys for each user: a private key that is known only to one user, and a corresponding public key that is made known to all users. With these two keys, it is possible to create digital signatures that guarantee the authenticity of a message and to support the encryption of a message in such a way that only the intended recipient can read it.

There is, however, a common misconception that each user simply keeps his or her private key private and publishes the corresponding public key. Unfortunately, this is not a simple solution. An impostor can generate a public- and private-key pair and disseminate the public key as if it were someone else's. For example, suppose that user A wishes to send a secure message to user B. Meanwhile, user C has generated a public- and private-key pair, attached user B's name and an E-mail address that user C can access, and published this key widely. User A has picked this key up, uses the key to prepare her message for user B, and uses the attached E-mail address to send the message. Result: user C receives and can decrypt the message; user B either never receives the message or cannot read it without holding the required private key.

One way around this problem is to insist on the secure exchange of public keys. For example, if user B and user A know each other personally and live near each other, they could physically exchange keys on diskettes. But for PGP to be useful as a general-purpose E-mail security utility, it must be possible for people in widely distributed sites to exchange keys with others that they have never met and may not even know.

Public-Key Certificates and Distributed Security

The basic tool that permits widespread use of PGP is the public-key certificate. The essential elements of a public-key certificate are:

- The public key itself.

- A user ID consisting of the name and E-mail address of the owner of the key.

- One or more digital signatures for the public key and user ID.

The signer testifies that the user ID associated with this public key is valid. The digital signature is formed using the private key of the signer. Anyone in possession of the corresponding public key can verify that the signature is valid. If any change is made, either to the public key or the user ID, the signature will no longer compute as valid.
Public-key certificates are used in several security applications that require public-key cryptography. In fact, it is the public-key certificate that makes distributed security applications using public keys practical.

One approach that might be taken to use public-key certificates is to create a central certifying authority. This is the approach recommended for use with the privacy-enhanced mail (PEM) scheme. Each user must register with the central authority and engage in a secure exchange that includes independent techniques for verifying user identity. Once the central authority is convinced of the identity of a key holder, it signs that key. If everyone who uses this scheme trusts the central authority, then a key signed by the authority is automatically accepted as valid.

There is nothing inherent in the PGP formats or protocols to prevent the use of a centralized certifying authority. However, PGP is intended as an E-mail security scheme for the masses. It can be used in a variety of informal and formal environments. Accordingly, Pretty Good Privacy is designed to support a so-called web of trust, in which individuals sign each other's keys and create an interconnected community of public-key users.

If user B has physically passed a public key to user A, then user A knows that this key belongs to user B and signs it. User A keeps a copy of the signed key and also returns a copy to user B. Later, user B wishes to communicate with user D and sends this person the public key, with user A's signature attached. User D is in possession of user A's public key and also trusts user A to certify the keys of others. User D verifies user A's signature on user B's key and accepts user B's key as valid.

Computing Trust

Although Pretty Good Privacy does not include any specification for establishing certifying authorities or for establishing trust, it does provide a convenient means of using trust, associating trust with public keys, and exploiting trust information.

Each user can collect a number of signed keys and store them in a PGP file known as a public-key ring. Associated with each entry is a key legitimacy field that indicates the extent to which PGP will trust that this is a valid public key for this user; the higher the level of trust, the stronger is the binding of this user ID to this key. This field is computed by Pretty Good Privacy. Also associated with the entry are zero or more signatures that the key ring owner has collected that sign this certificate. In turn, each signature has associated with it a signature trust field that indicates the degree to which this PGP user trusts the signer to certify public keys. The key legitimacy field is derived from the collection of signature trust fields in the entry. Finally, each entry defines a public key associated with a particular owner, and an owner trust field is included that indicates the degree to which this public key is trusted to sign other public-key certificates; this level of trust is assigned by the user. The signature trust fields can be thought of as cached copies of the owner trust field from another entry.

Trust Processing

If user A inserts a new public key on the public-key ring, PGP must assign a value to the trust flag that is associated with the owner of this public key. If the owner is in fact A, and this public key also appears in the private-key ring, then a value of ultimate trust is automatically assigned to the trust field. Otherwise, PGP asks user A for an assessment of the trust to be assigned to the owner of this key, and user A must enter the desired level. The user can specify that this owner is unknown, untrusted, marginally trusted, or completely trusted.

When the new public key is entered, one or more signatures may be attached to it. More signatures may be added later on. When a signature is inserted into the entry, PGP searches the public-key ring to see if the author of this signature is among the known public-key owners. If so, the OWNERTRUST value for this owner is assigned to the SIGTRUST field for this signature. If not, an unknown user value is assigned.

The value of the key legitimacy field is calculated on the basis of the signature trust fields present in this entry. If at least one signature has a signature trust value of ultimate, then the key legitimacy value is set to complete. Otherwise, PGP computes a weighted sum of the trust values. A weight of 1/X is given to signatures that are always trusted and 1/Y to signatures that are usually trusted, where* and Y are user-configurable parameters. When the total of weights of the introducers of a key/user ID combination reaches 1, the binding is considered to be trustworthy, and the key legitimacy value is set to complete. Thus, in the absence of ultimate trust, at least X signatures that are always trusted or Y signatures that are usually trusted or some combination, is needed.

Signature Trust and Key Legitimacy

Periodically, PGP processes the public-key ring to achieve consistency. In essence, this is a top-down process. For each OWNERTRUST field, PGP scans the ring for all signatures authored by that owner and updates the SIGTRUST field to equal the OWNERTRUST field. This process starts with keys for which there is ultimate trust. Then, all KEYLEGIT fields are computed on the basis of the attached signatures.

Exhibit 7 provides an example of the way in which signature trust and key legitimacy are related. The exhibit shows the structure of a public-key ring. The user has acquired a number of public keys, some directly from their owners and some from a third party such as a key server.

PGP Trust Model Example

The node labeled “You” refers to the entry in the public-key ring corresponding to this user. This key is valid and the OWNERTRUST value is ultimate trust. Each other node in the key ring has an OWNERTRUST value of undefined unless some other value is assigned by the user. In this example, the user has specified that it always trusts users D, E, F, and L to sign other keys. This user also partially trusts users A and B to sign other keys.

The shading, or lack thereof, of the nodes in Exhibit 7 indicates the level of trust assigned by this user. The tree structure indicates which keys have been signed by which other users. If a key is signed by a user whose key is also in this key ring, the arrow joins the signed key to the signer. If the key is signed by a user whose key is not present in this key ring, the arrow joins the signed key to a question mark, indicating that the signer is unknown to the user.

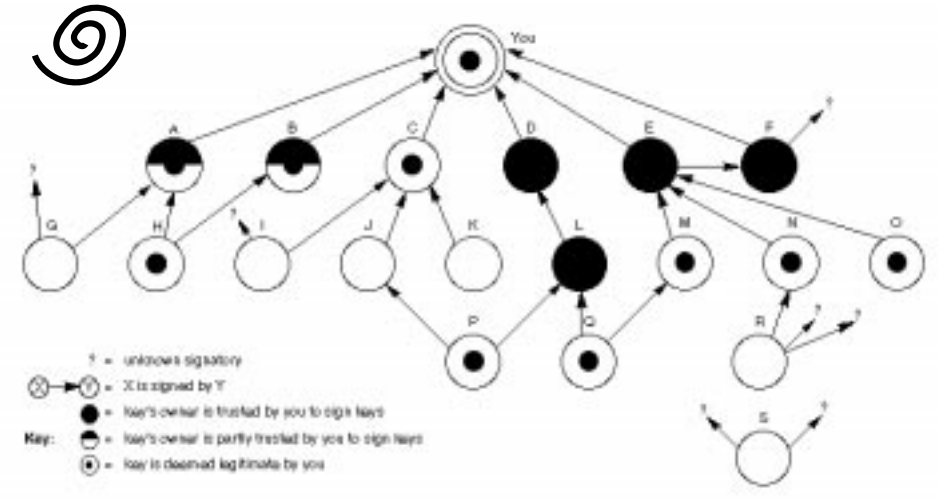


Exhibit 7 illustrates that all keys whose owners are fully or partially trusted by the user have been signed by this user, with the exception of node L. Such a user signature is not always necessary, as the presence of node L indicates, but in practice most users are likely to sign the keys for most owners that they trust. So, for example, even though E's key is already signed by trusted introducer F, the user chose to sign E's key directly.
It can be assumed that two partially trusted signatures are sufficient to certify a key. Hence, the key for user H is deemed valid by PGP because it is signed by A and B, both of whom are partially trusted.

A key may be determined to be valid because it is signed by one fully trusted or two partially trusted signers, but its user may not be trusted to sign other keys. For example, N's key is valid because it is signed by E, whom this user trusts, but N is not trusted to sign other keys because this user has not assigned N that trust value. Therefore, although R's key is signed by N, PGP does not consider R's key valid. This situation makes perfect sense. If a user wants to send a secret message to an individual, it is not necessary that the user trust that individual in any respect. It is only necessary to ensure use of the correct public key for that individual.

Exhibit 7 also shows a detached orphan node S, with two unknown signatures. Such a key may have been acquired from a key server. PGP cannot assume that this key is valid simply because it came from a reputable server. The user must declare the key valid by signing it or by telling PGP that it is willing to fully trust one of the key's signers.
It is the PGP web of trust that makes it practical as a universal E-mail security utility. Any group, however informal and however dispersed, can build up the web of trust needed for secure communications.

Conclusion

PGP is already widely used. Pretty Good Privacy has become essential to those struggling for freedom in former Communist countries. Ordinary people throughout the world are active participants in the alt.security.PGP USENET newsgroup. Because PGP fills a widespread need, and because there is no reasonable alternative, its future is secure. One of the best lists of locations for obtaining PGP, with the file name getpgp.asc, is maintained at two File Transfer Protocol sites on the Internet: ftp.csn.net/mpj and ftp.netcom.com/pub/mp/mpj.

PROTECTING AGAINST DIAL-IN HAZARDS: VOICE SYSTEMS

Leo A. Wrobel

INSIDE

Voice-Mail Breaches and Preventive Measures, Facsimile Breaches and Preventive Measures, Cellular Phone Security and Preventive Measures, Cracking Voice Systems, Precautions for Telephone Fraud

INTRODUCTION

"Hello, this is Carl. I can't take your call right now, but if you leave your name and number, I'll return your call as soon as I can. If your call is urgent, press zero for the operator."

Sounds familiar enough, doesn't it? Just suppose, this time, it is not a customer or employee, but rather a hacker attempting to compromise your system. This is not difficult to do. In fact, it is as easy in many cases as dialing one number: zero. In this case, the hacker exercises the "press-zero) option, and when the operator answers, he proceeds to jump down her throat:

Hacker: "Where the HELL is Carl! I've been trying him all day and he's supposed to be at this desk! That lowlife is in big trouble! Oh, never mind, just give me an outside line so I can track him down!"

The hacker's objective is to intimidate and frazzle the receptionist, so the abusive language is common. The receptionist has one more hostile caller, who appears to be calling from inside the building, after all, who's number is lighting up on her switchboard? Why Carl's, of course (remember, the hacker transferred from Carl's line). So what happens next? More often than not, the receptionist will give the caller an outside line. Once connected to the local Bell operator, and the receptionist has disconnected and moved on to the next caller, the hacker continues:

PAYOFF IDEA

Dial-in voice technologies, including voice mail, facsimile machines, and cellular phones, provide fertile ground for fraud that is easily accomplished but difficult to recover. The targeted suggestions presented for each of these technologies provide practical and cost-effective solutions that can save organizations tens of thousands of dollars and a career or two along the way.

Hacker: "Operator, I would like to place a call to Bombay, India, please."

Operator: "How would you like to pay for that call?"

Hacker: "Oh, just bill it to this number."

This example shows one of the easiest ways a hacker can compromise a network. Voice mail systems are common targets, but compared to some of the more sophisticated tricks, this scenario is the technological equivalent of stone knives and bear claws. Thousands of companies fall victim each year, and when it happens to them, they get stuck with the bill. One feature that can help protect against these operator "splash-backs" is called line screening. It is generally used to tip the operator off that the call is coming from a hotel or pay phone. It is typically used on hotel and pay phone trunks to avoid the situation just described. However, most businesses have never heard of it, let alone ordered it. Absent this precaution, procedures prohibiting any transfer (except 911) and mandatory operator training are a must.

EXAMPLES OF VOICE MAIL SECURITY BREACHES

An astute hacker can tell from listening to the automated voice on a company's voice mail the type of system the company uses. This can be disastrous, because hackers will also usually know what the factory default codes are for the system, which will allow them to dial into the operating system. This could mean they could make outgoing international calls. It also makes for some other interesting situations, as the following example indicates.

One user I met at a seminar said his voice mail system was used for several months to run a call girl operation. The hackers were able to break in and set up special voice mailboxes (using the authorized users boxes) after hours. They were always careful to delete all of these messages before the employees came in at 8 a.m. One day, however, the call girl operation was either raided, moved, or just lost interest in the voice mail system. All the messages to the "clients" were still there when the shifts came in on Monday morning! The content of these messages was not elaborated on by the telecom manager, but I am told many of the surprising messages found that morning are still legendary within the company. This is comical, especially because there was no real cost to the company other than to raise the office gossip a notch or two.

What was unsettling for everyone involved, however, was that it went undetected for so long. Does your company change these codes frequently? Does it monitor for unsuccessful attempts? Would it know if it were being hacked right now?

A second company was not so lucky. This company had a formal policy to block all operator transfers from voice mail to outside lines, except for 911. The operators were trained and signed off on the new proce-

dure. One Thanksgiving weekend, when the operators were off and the phones rolled to the security guard (who was not trained), a friendly caller identified himself as "Bill at AT&T" asked for an outside transfer to test the phones. "Bill" spent all Thanksgiving Day and the next three days, hacking the company. Each time, the guard made an entry in the log "Assissted AT&T." On Monday morning, a security supervisor saw dozens of entries, got suspicious, and called the telecom manager. The result? A five-digit telephone bill to Pakistan! Would you know if this was happening right now in your organization? Has everyone been trained?

PREVENTATIVE MEASURES FOR VOICE MAIL

What can a user do to protect against abuse on these systems? The following activities provide a prevention checklist:

1. Implement policy that prohibits transfers to outside lines in all cases, except for the possible exception of a 911 emergency transfer.
2. Disconnect DISA (direct inward system access). Hackers refer to it as Dial In/Steal Away. It is used by nomadic or homebound workers to access PBX dial tone from a remote location. The caller dials in, gets a dial tone back, enters an access code, then completes a call on the company switch. These systems literally cry out to the world, "Please hack me!" If this system is necessary, use long, complicated access codes, and consider having the system answer with silence, not a dial tone, until after the caller enters the code.
3. Monitor systems for suspicious activity. If 300 unsuccessful attempts were made on DISA or dial-in modem ports last night, would the company know it?
4. Are the dial-in ports to multiplexers, routers, and PBX monitored for suspicious activity? Are the original factory codes changed? Besides vendors, who may be dialing in right now?
5. Watch for dumpster divers. Many people go through the company's trash looking for credit card receipts and long distance access codes!
6. Hire bonded maintenance workers. Do you know the cleaning crews? Are users instructed to not leave sensitive access codes out on desks where crews can find them? One client of mine actually had a high-end fax machine stolen from a 17th floor office! It would found in a nearby pawn shop a few days later.
7. Does the company have a telecommunications privacy policy? This should be implemented and be broad enough in scope to cover E-mail, voice mail, and other mediums.

For example:

"ABC Company is committed to absolute privacy of communications, and each employee has the right to not have their communications mon-

itored. However, if in the course of normal maintenance activity we inadvertently discover illegal activity, we reserve the right to report this activity to the responsible authorities."

This would give some recourse if a situation required monitoring. One manufacturing company's employees came in on a Monday morning after a holiday (hackers love long weekends) to find three T1's worth of traffic into U.S. Sprint, all filled with people speaking Spanish: 72 channels of people speaking a foreign tongue to a faraway land on the company's nickel. The company did not have any Spanish-speaking clients, employees, or overseas branches. Most of the people on the calls probably did not know it was illegal. Scam artists constantly work the immigrant communities, and lines of new immigrants at pay phones waiting for "discount calls" from disreputable thieves is a common sight in many cities.

FACSIMILE SECURITY BREACHES

What about other internal compromises of security, such as the fax machine? Because the security of information is paramount in business, and unauthorized access of information is becoming more prevalent, facsimile transmissions should not be neglected. The fax machine is widely accepts and heavily used, yet security precautions for these devices often do not exist.

Fax security concerns not only fax machines but fax boards in workstations. A company must know how much proprietary information might be leaving your organization this very instant from a $79 fax board. This has a direct bearing on LAN (local area network) standards, which every company must have. What is the company's liability if it receives a fax intended for another company, or even more ominously, if an employee or employees use the information learned from the fax for personal gain? It could be significant.

Even more disturbing, however, are people who are deliberately trying to obtain proprietary information from a company. For example, is the wastebasket next to the fax machine routinely shredded, or are these materials simply thrown away? Is the machine in a visible area? Is it checked frequently for incoming messages to avoid confidential correspondence from being in open view for extended periods of time? Is the fax machine used at any time for truly proprietary data? If so, additional precautions are necessary. All too often, the major cause of facsimile interception (or any type of confidential information) is from internal sources. Companies often ignore the threat from inquisitive or disgruntled employees. These employees may read fax traffic. The negative effect of unauthorized access to payroll, force reduction, or financial information through unsecured fax machines is self evident.

PREVENTIVE MEASURES FOR FAX SECURITY

To prevent unwanted access to fax machines, a company can take several proactive steps. Rather than name specific makes and models of equipment (which become quickly outdated), the specific features desirable for securing a fax machine, the operating environment surrounding the machine, or both, are described in the following sections.

Use a High-End Fax Machine

These machines receive fax transmissions into memory and store them on a hard drive in a confidential mail box. The addressing scheme should require the use of extended dialing by the sender to store the fax in the confidential mailbox. A user with an appropriate security code must then enter this code into the machine in order to retrieve the fax from the hard drive. The fax will then be printed and the file simultaneously deleted from the hard drive.

Use a Low-End Desktop Machine

For users who consistently send or receive confidential or sensitive information, use of a low-end desk top machine may be advisable. This can be controlled in the area where needed. As a point of need machine, it can be used by a specific department for sending confidential information. For routine administrative traffic, the normal centralized fax machine can be used. This separates the traffic, providing an additional level of security. It is also inexpensive because the cost of these desktop machines is often under $400, depending on features required, plus telephone line costs.

Store-and-Forward Fax and Fax Servers on LANs

Here, a computer sends from memory and receives into memory. The use of confidential long-on procedures to send and receive messages is similar to that of high-end fax machines. Local area networks now employ fax servers on the networks. These are actually computers that receive faxes from users and store them until transmission can take place. Original documents must be scanned into the system, which adds a level of complexity. Further, inbound traffic must be capable of being directed to a confidential mail box, similar to high-end stand-alone fax machines. If this is not implemented, security is violated because a systems administrator would have to read the fax, then direct it to the intended individual either on the network or in paper form.

Front-End with a Voice Mail System

Similar to some of the schemes just described, a voice mail system can be often modified to provide storage and password protection for incom-

ing faxes. The system would be programmed to answer with a message such as: "You have two messages and one fax." The user would then retrieve the voice messages from any phone but would be forced to dial from a fax machine to retrieve the fax. The alternative to moving to a fax machine is to enter a code and have the voice mail system dial out to a common fax machine; however, this is considered more risky. An employee could enter his code, then immediately receive another incoming call or have something else distract his attention. In the meantime, the fax comes in, unprotected, to an unattended machine. Built-in safeguards and procedures that force employees to be at the machine to retrieve a fax are preferable for this reason.

Because interception and monitoring is possible on almost any kind of phone line, lines serving especially sensitive fax machines can be made secure through the use of an encryption device. These devices, which can be expensive, scramble the data before it is sent. Some work for both fax machines and conversations. This means that both ends have comparable equipment for encryption/decryption of the information. Otherwise, fax traffic must be shipped in an unsecured mode.

Educating Users

Users with lap-top computers or fax cards in personal computers must be educated about the risks associated with the transmission and reception of faxes across these systems. Appropriate audit and security controls will help to avoid confidential files and information from being faxed out of the company directly from a PC without being saved on paper.

Hotel Faxes

The best approach is to avoid sending confidential information to or through a hotel fax machine. Hotel clerks usually make copies of the fax traffic in case there is an inquiry about the status. It also is not uncommon for hotel staff to deliver a fax to the wrong party.

CELLULAR PHONE SECURITY

Another frequently abused armament of the road warrior is the cellular phone. A multi-billion manufacturing company was arranging financing for the company. Each day, the CEO would discuss the most intimate details of the transaction on his cellular phone. Only as the deal neared a close did he question whether someone could monitor his conversations. Luckily, things went smoothly. Nonetheless, the CEO was shocked to learn that anyone with a $200 bear scanner could have monitored his entire conversation with ease.

CLONING CELL PHONES

Thieves also have become adept at cloning bogus authorization numbers into cellular phones. In the past, cellular providers have been hit hard by hackers cloning phones, then calling overseas. Now, most block calls of this type unless the provider is certain the user is authorized. However, this often can mean inconvenience for authorized users who happen to be roaming in another service area, where their identity cannot always be guaranteed with certainty.

This problem can also involve domestic calls. I was recently in an area of New York City (which has the dubious distinction of being the telephone fraud capital of the world) where I could not roam with my cell phone at all. All calls were directed to an operator, who would only complete a telephone credit card call. I found this preposterous because hundreds of hackers were probably standing by using their $200 bear scanners, just waiting for me to read my credit card number to the operator so they could steal it and beat it to death calling overseas locales. I instead chose to find a pay phone.

Precautions for Cellular Phones

The following list is designed to help secure cellular voice systems.

1. Never give a credit card or telephone credit card number over a cellular phone.
2. Never say anything over any wireless phone that you would not mind the whole world knowing.
3. Try to dial 800 numbers whenever possible when on the road rather than making credit card calls. An astute hacker can capture your touch tone digits when you make an automated credit card call, even if the number is not read to an operator.
4. Monitor your cellular bill closely and report any unusual calling activity (indicating your number may be been cloned) to your cellular provider immediately.
5. Consider upgrading to digital cellular service. Although not foolproof, digital technologies require more sophisticated equipment to monitor and are thus more difficult to intercept by hackers.

CRACKING VOICE SYSTEMS

It is easy for a potential hacker to download a "War Games" auto dialer from the Internet. The system need not be one that caters to hackers, because these programs are commonly available from lots of sites. These are designed specifically to find DISA and modem lines. The programs sequentially dial every number in a NXX (within a given three-digit pre-

fix) logging every number that answers with a carrier (modem) tone or dial tone. This is done while the hacker sleeps. For example, if the hacker knows your company has a 755 prefix for its telephone numbers, the program is set up to dial sequentially, 775-0000, 775-0001, 775-0002 … up to 775-9999. At some point they will hit, and log, every one of the numbers that answers with a dial tone or carrier. After a good night's rest, the hacker has a list of numbers to use.

Once the hacker has a list of possible candidates, he first screens them with a regular modem program to see what they are. Some are naturally metering circuits, credit card authorization lines, or other numbers only of marginal interest to the hacker.

Recommended Telephone Fraud Precautions

Organizations should take several precautions to prevent this type of abuse. These include:

- Disconnecting DISA lines if at all possible. This is the only guaranteed solution. If disconnection is not possible, consider the remaining suggestions.
- Using longer access codes. Do not use a three-digit access code; rather, use a 7, 8, or 9 digit code. The odds increase exponentially for each number you add to the code. If your system is too difficult to crack, the hacker is likely to move on to an easier mark.
- Optioning a DISA to answer with silence. The dial tone that most DISA lines put out when answering is a dead give away and an open invitation to hackers and the curious. By answering the line with silence, the automated equipment used by the hacker will see the line as a voice call, and will not flag it as useful.
- Monitoring traffic. Several warning signs of impending disaster include:
  1. Increased traffic volume on 1-800 lines
  2. Increased traffic volume on outgoing trunks
  3. Increased access to 950

  By monitoring this traffic, it may be possible to identify fraud before it is too late. Similarly, carriers can aid in this pursuit. Most now offer fraud insurance at a monthly fee, which provides traffic monitoring and reporting of any unusual circumstances or traffic loads.
- Blocking 011, 1-900, 976 access. If the company does not have Caribbean offices, disable the 809 area code, along with all the recently assigned, new Caribbean area codes. These are a high source of fraudulent calls and are a source of anguish and exposure for many a telecom manager.

Remember, if a company is defrauded, the FCC has ruled that carriers are not responsible for toll fraud and are entitled to collect the full amount owed regardless of whether the calls were due to theft of services. Also keep in mind, although federal authorities are supposed to investigate instances of toll fraud, cases of less than $100,000 in loss get little or no attention, owing to the huge workload generated by thousands of hackers. While toll fraud in itself does not necessarily represent a disaster, a $100,000 telephone bill can be disastrous to a career.

CONCLUSION

The areas in which a company can pay a significant financial penalty for lack of vigilance are too numerous to be covered in just one article. It pays to keep an eye on even the most mundane systems, to ensure that these minor conveniences of the office do not become a major strain on another important system — your cardiovascular system. Article 5-04-42 will discuss the other side of the coin, namely, securing your data carrier from the unauthorized intruder.

Leo A. Wrobel is president and CEO of Premiere Network Services, Inc., in DeSoto, TX. An active author, national and international lecturer, and technical futurist, he has published 10 books and over 100 trade articles on a variety of technical subjects, including *Writing Disaster Recovery Plans for Telecommunications and LANS* (Artech House Books, 1993) and *Business Resumption Planning* (Auerbach Publications, 1997). His experience of nearly two decades including assignments at AT&T, a major mortgage banking company, and a host of other firms engaged in baking, brokerage, heavy manufacturing, telecommunications services, and government, including the design and regulatory approval of a LATA-wide OC-12/ATM network for a $10 billion manufacturing giant, the first of its kind. 51

Voice Security

Chris Hare, CISSP, CISA

Most security professionals in today's enterprise spend much of their time working to secure access to corporate electronic information. However, voice and telecommunications fraud still costs the corporate business communities millions of dollars each year. Most losses in the telecommunications arena stem from toll fraud, which is perpetrated by many different methods.

Millions of people rely upon the telecommunication infrastructure for their voice and data needs on a daily basis. This dependence has resulted in the telecommunications system being classed as a critical infrastructure component. Without the telephone, many of our daily activities would be more difficult, if not almost impossible.

When many security professionals think of voice security, they automatically think of encrypted telephones, fax machines, and the like. However, voice security can be much simpler and start right at the device to which your telephone is connected. This chapter looks at how the telephone system works, toll fraud, voice communications security concerns, and applicable techniques for any enterprise to protect its telecommunication infrastructure. Explanations of commonly used telephony terms are found throughout the chapter.

POTS: Plain Old Telephone Service

Most people refer to it as "the phone." They pick up the receiver, hear the dial tone, and make their calls. They use it to call their families, conduct business, purchase goods, and get help or emergency assistance. And they expect it to work all the time.

The telephone service we use on a daily basis in our homes is known in the telephony industry as POTS, or plain old telephone service. POTS is delivered to the subscriber through several components (see Exhibit 51.1):

- The telephone handset
- Cabling
- A line card
- A switching device

The telephone handset, or station, is the component with which the public is most familiar. When the customer picks up the handset, the circuit is closed and established to the switch. The line card signals to the processor in the switch that the phone is off the hook, and a dial tone is generated.

The switch collects the digits dialed by the subscriber, whether the subscriber is using a pulse phone or Touch-Tone®. A pulse phone alters the voltage on the phone line, which opens and closes a relay at the switch. This is the cause of the clicks or pulses heard on the line. With Touch-Tone dialing, a tone generator at the switch creates the tones for dialing the call.

The processor in the switch accepts the digits and determines the best way to route the call to the receiving subscriber. The receiving telephone set may be attached to the same switch, or connected to another halfway around the world. Regardless, the routing of the call happens in a heartbeat due to a very complex network of switches, signaling, and routing.

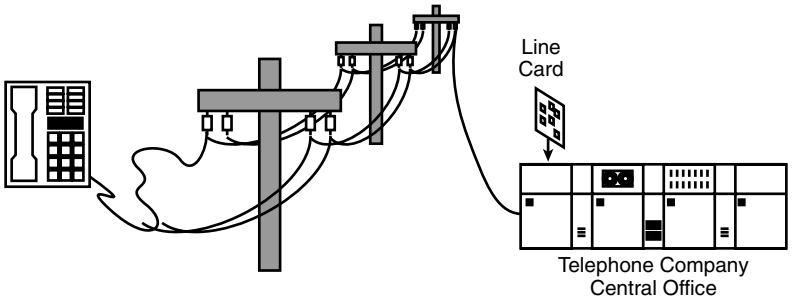

EXHIBIT 51.1 Components of POTS.

However, the process of connecting the telephone to the switching device, or to connect switching devices together to increase calling capabilities, uses lines and trunks.

Connecting Things Together

The problem with most areas of technology is with terminology. The telephony industry is no different. Trunks and lines both refer to the same thing — the circuitry and wiring used to deliver the signal to the subscriber. The fundamental difference between them is where they are used.

Both trunks and lines can be digital or analog. The line is primarily associated with the wiring from the telephone switch to the subscriber (see Exhibit 51.2). This can be either the residential or business subscriber, connected directly to the telephone company's switch, or to a PBX. Essentially, the line typically is associated with carrying the communications of a single subscriber to the switch.

The trunk, on the other hand, is generally the connection from the PBX to the telephone carrier's switch, or from one switch to another. A trunk performs the same function as the line. The only difference is the amount of calls or traffic the two can carry. Because the trunk is used to connect switches together, the trunk can carry much more traffic and calls than the line. The term *circuit* is often used to describe the connection from one device to the other, without attention to the type of connection, analog or digital, or the devices on either end (station or device).

Analog versus Digital

Both the trunk and the line can carry either analog or digital signals. That is to say, they can only carry one type at a time. Conceptually, the connection from origin to destination is called a circuit, and there are two principal circuit types.

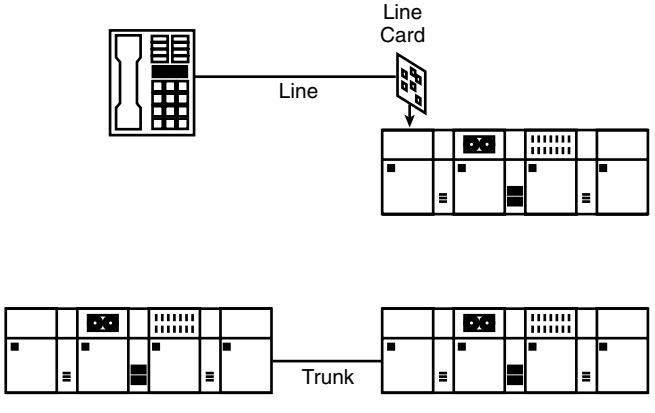

EXHIBIT 51.2 Trunks and lines.

Analog circuits are used to carry voice traffic and digital signals after conversion to sounds. While analog is traditionally associated with voice circuits, many voice calls are made and processed through digital equipment. However, the process of analog/digital conversion is an intense technical discussion and is not described here.

An analog circuit uses the variations in amplitude (volume) and frequency to transmit the information from one caller to the other. The circuit has an available bandwidth of 64K, although 8K of the available bandwidth is used for signaling between the handset and the switch, leaving 56K for the actual voice or data signals.

Think about connecting a computer modem to a phone line. The maximum available speed the modem can function at is 56K. The rationale for the 56K modem should be obvious now. However, most people know a modem connection is rarely made at 56K due to the quality of the circuit, line noise, and the distance from the subscriber to the telephone carrier's switch. Modems are discussed again later in the chapter.

Because analog lines carry the actual voice signals for the conversation, they can be easily intercepted. Anyone with more than one phone in his or her house has experienced the problem with eavesdropping. Anyone who can access the phone circuit can listen to the conversation. A phone tap is not really required — only knowledge of which wires to attach to and a telephone handset.

However, despite the problem associated with eavesdropping, many people do not concern themselves too much with the possibility someone may be listening to their phone call.

The alternative to analog is digital. While the analog line uses sound to transmit information, the digital circuit uses digital signals to represent data. Consequently, the digital circuit technologies are capable of carrying significantly higher speeds as the bandwidth increases on the circuit.

Digital circuits offer a number of advantages. They can carry higher amounts of data traffic and more simultaneous telephone calls than an analog circuit. They offer better protection from eavesdropping and wiretapping due to their design. However, despite the digital signal, any telephone station sharing the same circuit can still eavesdrop on the conversation without difficulty.

The circuits are not the principal cause of security problems. Rather, the concern for most enterprises and individuals arises from the unauthorized and inappropriate use of those circuits.

Lines and trunks can be used in many different ways and configurations to provide the required level of service. Typically, the line connected to a station offers both incoming and outgoing calls. However, this does not have to be the case in all situations.

Direct Inward Dial (DID)

If an outside caller must be connected with an operator before reaching his party in the enterprise, the system is generally called a key switch PBX. However, many PBX systems offer direct inward dial, or DID, where each telephone station is assigned a telephone number that connects the external caller directly to the call recipient.

Direct inward dial makes reaching the intended recipient easier because no operator is involved. However, DID also has disadvantages. Modems connected to DID services can be reached by authorized and unauthorized persons alike. It also makes it easier for individuals to call and solicit information from the workforce, without being screened through a central operator or attendant.

Direct Outward Dial (DOD)

Direct outward dial is exactly the opposite of DID. Some PBX installations require the user to select a free line on his phone or access an operator to place an outside call. With DOD, the caller picks up the phone, dials an access code, such as the digit 9, and then the external phone number. The call is routed to the telephone carrier and connected to the receiving person.

The telephone carrier assembles the components described here to provide service to its subscribers. The telephone carriers then interconnect their systems through gateways to provide the public switched telephone network.

The Public Switched Telephone Network (PSTN)

The pubic switched telephone network is a collection of telephone systems maintained by telephone carriers to provide a global communications infrastructure. It is called the public switched network because it is accessible to the general public and it uses circuit-switching technology to connect the caller to the recipient.

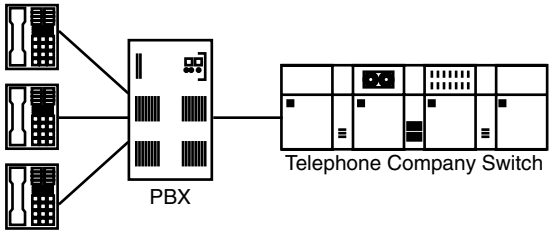

EXHIBIT 51.3 PBX connection.

The goal of the PSTN is to connect the two parties as quickly as possible, using the shortest possible route. However, because the PSTN is dynamic, it can often configure and route the call over a more complex path to achieve the call connection on the first attempt.

While this is extremely complex on a national and global scale, enterprises use a smaller version of the telephone carrier switch called a PBX (or private branch exchange).

The Private Area Branch Exchange (PABX)

The private area branch exchange, or PABX, is also commonly referred to as a PBX. Consequently, you will see the terms used interchangeably. The PBX is effectively a telephone switch for an enterprise; and, like the enterprise, it comes in different sizes. The PBX provides the line card, call processor, and some basic routing. The principal difference is how the PBX connects to the telephone carrier's network. If we compare the PBX to a router in a data network connecting to the Internet, both devices know only one route to send information, or telephone calls, to points outside the network (see Exhibit 51.3).

The PBX has many telephone stations connected to it, like the telephone carrier's switch. The PBX knows how to route calls to the stations connected directly to the same PBX. A call for an external telephone number is routed to the carrier's switch, which then processes the call and routes it to the receiving station.

Both devices have similar security issues, although the telephone carrier has specific concerns: the telephone communications network is recognized as a critical infrastructure element, and there is liability associated with failing to provide service. The enterprise rarely has to deal with these issues; however, the enterprise that fails to provide sufficient controls to prevent the compromise of its PBX may also face specific liabilities.

Network Class of Service (NCOS)

Each station on the phone PBX can be configured with a network class of service, or NCOS. The NCOS defines the type of calls the station can make. Exhibit 51.4 illustrates different NCOS levels.

When examining Exhibit 51.4, we can see that each different class of service offers new abilities for the user at the phone station. Typically, class of service is assigned to the station and not the individual, because few phone systems require user authentication before placing the call.

EXHIBIT 51.4 Network Class-of-Service Levels

Level	Internal	Local Seven-Digit Dialing	Local Ten-Digit Dialing	Domestic Long Distance	International Long Distance
1	X				
2	X	X	X		
3	X	X	X	X	
4	X	X	X	X	X

NOTE: Blocking specific phone numbers or area codes, such as 976, 900, or 809, is not done at the NCOS level but through other call-blocking methods available in the switch.

Through assigning NCOS to various phones, some potential security problems can be avoided. For example, if your enterprise has a phone in the lobby, it should be configured with a class of service low enough to allow calls to internal extensions or local calls only. Long distance should not be permitted from any open-area phone due to the cost associated with those calls.

In some situations, it may be desirable to limit the ability of a phone station to receive calls, while still allowing outgoing calls. This can be defined as another network class of service, without affecting the capabilities of the other stations.

However, not all PBX systems have this feature. If your enterprise systems have it, it should be configured to allow the employees only the ability to make the calls that are required for their specific job responsibilities.

Voicemail

Voicemail is ubiquitous with communications today. However, voicemail is often used as the path to the telephone system and free phone calls for the attacker — and toll fraud for the system owner.

Voicemail is used for recording telephone messages for users who are not available to answer their phones. Users access messages by entering an identifier, which is typically their phone extension number, and a password.

Voicemail problems typically revolve around password management. Because voicemail must work with the phone, the password can only contain digits. This means attacking the password is relatively trivial from the attacker's perspective. Consequently, the traditional password and account management issues exist here as in other systems:

- Passwords the same as the account name
- No password complexity rules
- No password aging or expiry
- No account lockout
- Other voicemail configuration issues

A common configuration problem is through-dialing. With through-dialing, the system accepts a phone number and places the call. The feature can be restricted to allow only internal or local numbers, or to disable it. If through-dialing is allowed and not properly configured, the enterprise now pays the bills for the long-distance or other toll calls made.

Attackers use stale mailboxes — those that have not been accessed in a while — to attempt to gain access to the mailbox. If the mailbox password is obtained, and the voicemail system is configured to allow through-dialing, the attackers are now making free calls. The attacker first changes the greeting on the mailbox to a simple "yes." Now, any collect call made through an automated system expecting the word response "yes" is automatically accepted. The enterprise pays the cost of the call.

The attacker enters the account identifier, typically the phone extension for the mailbox, and the password. Once authenticated by the voicemail system, the attacker then enters the appropriate code and phone number for the external through-call. If there are no restrictions on the digits available, the attacker can dial any phone number anywhere in the world.

The scenario depicted here can be avoided using simple techniques applicable to most systems:

- Change the administrator and attendant passwords.
- Do not use the extension number as the initial password.
- Disable through-dialing.
- Configure voicemail to use a minimum of six digits for the password.
- Enable password history options if available.
- Enable password expiration if available.
- Remove stale mailboxes.

Properly configured, voicemail is a powerful tool for the enterprise, as is the data network and voice conferencing.

Voice Conferencing

Many enterprises use conference calls to regularly conduct business. In the current economic climate, many enterprises use conference calls as the cost-efficient alternative to travel for meetings across disparate locations.

The conference call uses a "bridge," which accepts the calls and determines which conference the caller is to be routed to based upon the phone number and the conference call password.

The security options available to the conference call bridge are technology dependent. Regardless, participants on the conference call should be reminded not to discuss enterprise-sensitive information because anyone who acquires or guesses the conference call information could join the call. Consequently, conference call participant information should be protected to limit participation.

Conference bridges are used for single-time, repetitive, and ad hoc calls using various technologies. Some conference call vendors provide services allowing anyone in the enterprise to have an on-demand conference bridge. These conference bridges use a "host" or chairperson who must be present to start the conference call. The chairperson has a second passcode, used to initiate the call. Any user who learns the host or chairperson code can use the bridge at any time.

Security issues regarding conference bridges include:

- Loss of the chairperson code
- Unauthorized use of the bridge
- Inappropriate access to the bridge
- Loss of sensitive information on the bridge

All of these issues are addressed through proper user awareness — which is fortunate because few enterprises actually operate their own conference bridge, relying instead upon the telephone carrier to maintain the configurations.

If possible, the conference bridge should be configured with the following settings and capabilities:

- The conference call cannot start until the chairperson is present.
- All participants should be disconnected when the chairperson disconnects from the bridge.
- The chairperson should have the option of specifying a second security access code to enter the bridge.
- The chairperson should have commands available to manipulate the bridge, including counting the number of ports in use, muting or un-muting the callers, locking the bridge, and reaching the conference operator.

The chairperson's commands are important for the security of the conference call. Once all participants have joined, the chairperson should verify everyone is there and then lock the bridge. This prevents anyone from joining the conference call.

Security Issues

Throughout the chapter, we have discussed technologies and security issues. However, regardless of the specific configuration of the phone system your enterprise is using, there are some specific security concerns you should be knowledgeable of.

Toll Fraud

Toll fraud is a major concern for enterprises, individuals, and the telephone carriers. Toll fraud occurs when toll-based or chargeable telephone calls are fraudulently made. There are several methods of toll fraud, including inappropriate use by authorized users, theft of services, calling cards, and direct inward dialing to the enterprise's communications system.

According to a 1998 *Consumer News* report, about $4 billion are lost to toll fraud annually. The report is available online at the URL http://www.fcc. gov/Bureaus/Common_Carrier/Factsheets/ttf&you.pdf.

The cost of the fraud is eventually passed on to the businesses and consumers through higher communications costs. In some cases, the telephone carrier holds the subscriber responsible for the charges, which can be devastating. Consequently, enterprises can pay for toll fraud insurance, which pays the telephone carrier

after the enterprise pays the deductible. While toll fraud insurance sounds appealing, it is expensive and the deductibles are generally very high.

It is not impossible to identify toll fraud within your organization. If you have a small enterprise, simply monitoring the phone usage for the various people should be enough to identify calling patterns. For larger organizations, it may be necessary to get calling information from the PBX for analysis. For example, if you can capture the call records from each telephone call, it is possible to assign a cost for each telephone call.

Inappropriate Use of Authorized Access

Every employee in an enterprise typically has a phone on the desk, or access to a company-provided telephone. Most employees have the ability to make long-distance toll calls from their desks. While most employees make long-distance calls on a daily basis as part of their jobs, many will not think twice to make personal long-distance calls at the enterprise's expense.

Monitoring this type of usage and preventing it is difficult for the enterprise. Calling patterns, frequently called *number analysis*, and advising employees of their monthly telecommunications costs are a few ways to combat this problem. Additionally, corporate policies regarding the use of corporate telephone services and penalties for inappropriate use should be established if your enterprise does not have them already. Finally, many organizations use billing or authorization codes when making long-distance phone calls to track the usage and bill the charges to specific departments or clients.

However, if your enterprise has its own PBX with conditional toll deny (CTD) as a feature, you should considering enabling this on phone stations where long-distance or toll calls are not permitted. For example, users should not be able to call specific phone numbers or area codes. Alternatively, a phone station may be denied toll-call privileges altogether.

However, in Europe, implementing CTD is more difficult because it is not uncommon to call many different countries in a single day. Consequently, management of the CTD parameters becomes very difficult. CTD can be configured as a specific option in an NCOS definition, as discussed earlier in the chapter.

Calling Cards

Calling cards are the most common form of toll fraud. Calling-card numbers are stolen and sold on a daily basis around the world. Calling-card theft typically occurs when an individual observes the subscriber entering the number into a public phone. The card number is then recorded by the thief and sold to make other calls.

Calling-card theft is a major problem for telephone carriers, who often have specific fraud units for tracking thieves, and calling software, which monitors the calling patterns and alerts the fraud investigators to unusual calling patterns.

In some cases, hotels will print the calling-card number on the invoices provided to their guests, making the numbers available to a variety of people. Additionally, if the PBX is not configured correctly, the calling-card information is shown on the telephone display, making it easy for anyone nearby to see the digits and use the number.

Other PBX-based problems include last number redial. If the PBX supports last number redial, any employee can recall the last number dialed and obtain the access and calling-card numbers.

Employees should be aware of the problems and costs associated with the illegitimate use of calling cards. Proper protection while using a calling card includes:

- Shielding the number with your hands when entering it
- Memorizing the number so you do not have a card visible when making the call
- Ensuring your company PBX does not store the digits for last number redial
- Ensuring your enterprise PBX does not display the digits on the phone for an extended period of time

Calling cards provide a method for enterprise employees to call any number from any location. However, some enterprises may decide this is not appropriate for their employees. Consequently, they may offer DISA access to the enterprise phone network as an alternative.

DISA

Direct inward system access, or DISA, is a service available on many PBX systems. DISA allows a user to dial an access number, enter an authorization code, and appear to the PBX as an extension. This allows callers to make calls as if they were in the office building, whether the calls are internal to the PBX or external to the enterprise.

DISA offers some distinct advantages. For example, it removes the need to provide calling cards for employees because they can call a number and be part of the enterprise voice network. Additionally, long-distance calls placed through DISA services are billed at the corporate rate because the telephone carrier sees the calls as originating from the enterprise.

DISA's advantages also represent problems. If the DISA access number becomes known, unauthorized users only need to try random numbers to form an authorization code. Given enough time, they will eventually find one and start making what are free calls from their perspective. However, your enterprise pays the bill.

DISA authorization codes, which must be considered passwords, are numeric only because there is no way to enter alphabetic letters on the telephone keypad. Consequently, even an eight-number authorization code is easily defeated.

If your organization does use DISA, there are some things you can do to assist in preventing fraudulent access of the service:

- Frequent analysis of calling patterns
- Monthly "invoices" to the DISA subscribers to keep them aware of the service they are using
- Using a minimum of eight-digit authorization codes
- Forcing changes of the authorization codes every 30 days
- Disabling inactive DISA authorization codes if they are not used for a prescribed period of time or a usage limit is reached
- Enabling authorization code alarms to indicate attempts to defeat or guess DISA authorization codes

The methods discussed are often used by attackers to gain access to the phone system and make unauthorized telephone calls. However, technical aspects aside, some of the more skillful events occur through social engineering techniques.

Social Engineering

The most common ploy from a social engineering perspective is to call an unsuspecting person, indicate the attacker is from the phone company, and request an outside line. The attacker then makes the phone call to the desired location, talks for as long as required, and hangs up. As long as the attacker can find numbers to dial and does not have to go through a central operator, this can go on for months.

Another social engineering attack occurs when a caller claims to be a technical support person. The attacker will solicit confidential information, such as passwords, access numbers, or ID information, all under the guise of providing support or maintenance support to ensure the user's service is not disrupted. In actuality, the attacker is gathering sensitive information for better understanding of the enterprise environment and enabling him to perform an attack.

Other Voice Services

There are other voice services that also create issues for the enterprise, including modems, fax, and wireless services.

Modems

Modems are connected to the enterprise through traditional technologies using the public switched telephone network. Modems provide a method of connectivity through the PSTN to the enterprise data network. When installed on a DID circuit, the modem answers the phone when an incoming call is received. Attackers have regularly looked for these modems using war-dialing techniques.

If your enterprise must provide modems to connect to the enterprise data network, these incoming lines should be outside the enterprise's normal dialing range. This makes it more difficult for the attacker to find.

However, because many end stations are analog, the user could connect the modem to the desktop phone without anyone's knowledge.

This is another advantage of digital circuits. While digital-to-analog converters exist to connect a modem to a digital circuit, this is not infallible technology. Should your enterprise use digital circuits to the desktop, you should implement a program to document and approve all incoming analog circuits and their purpose. This is very important for modems due to their connectivity to the data network.

Fax

The fax machine is still used in many enterprises to send information not easily communicated through other means. The fax transmission sends information such as scanned documents to the remote fax system. The principal concern with fax is the lack of control over the document at the receiving end.

For example, if a document is sent to me using a fax in a shared area, anyone who checks the fax machine can read the message. If the information in the fax is sensitive, private, or otherwise classified, control of the information should not be considered lost.

A second common problem is misdirected faxes. That is, the fax is successfully transmitted, but to the wrong telephone number. Consequently, the intended recipient does not receive the fax.

However, fax can be controlled through various means such as dedicated fax machines in controlled areas. For example,

- Contact the receiver prior to sending the fax.
- Use a dedicated and physically secure fax machine if the information requires it.
- Use a cover page asking for immediate delivery to the recipient.
- Use a cover page asking for notification if the fax is misdirected.

Fax requires the use of analog lines because it uses a modem to establish the connection. Consequently, the inherent risks of the analog line are applicable here. If an attacker can monitor the line, he may be able to intercept the modem tones from the fax machine and read the fax. Addressing this problem is achieved through encrypted fax if document confidentiality is an ultimate concern.

Encrypted fax requires a common or shared key between the two fax machines. Once the connection is established, the document is sent using the shared encryption key and subsequently decoded and printed on the receiving fax machine. If the receiving fax machine does not have the shared key, it cannot decode the fax. Given the higher cost of the encrypted fax machine, it is only a requirement for the most highly classified documents.

Cellular and Wireless Access

Cellular and wireless access to the enterprise is also a problem due to the issues associated with cellular. Wireless access in this case does not refer to wireless access to the data network, but rather wireless access to the voice network.

However, this type of access should concern the security professional because the phone user will employ services such as calling cards and DISA to access the enterprise's voice network. Because cellular and wireless access technologies are often subject to eavesdropping, the DISA access codes or calling card could potentially be retrieved from the wireless caller.

The same is true for conversations — if the conversation between the wireless caller and the enterprise user is of a sensitive nature, it should not be conducted over wireless. Additionally, the chairperson for a conference call should find out if there is anyone on the call who is on a cell phone and determine if that level of access is appropriate for the topic to be discussed.

Voice-over-IP: The Future

The next set of security challenges for the telecommunications industry is Voice-over-IP. The basis for the technology is to convert the voice signals to packets, which are then routed over the IP network. Unlike the traditional circuit-switched voice network, Voice-over-IP is a packet-switched network. Consequently, the same types of problems found in a data network are found in the Voice-over-IP technology.

There are a series of problems in the Voice-over-IP technologies, on which the various vendors are collaborating to establish the appropriate standards to protect the privacy of the Voice-over-IP telephone call. Some of those issues include:

- No authentication of the person making the call
- No encryption of the voice data, allowing anyone who can intercept the packet to reassemble it and hear the voice data
- Quality of service, because the data network has not been traditionally designed to provide the quality-of-service levels associated with the voice network

The complexities in the Voice-over-IP arena for both the technology and related security issues will continue to develop and resolve themselves over the next few years.

Summary

This chapter introduced the basics of telephone systems and security issues. The interconnection of the telephone carriers to establish the public switched telephone network is a complex process. Everyone demands a dial tone when they pick up the handset. Such is the nature of this critical infrastructure.

However, enterprises often consider the telephone their critical infrastructure as well, whether they get their service directly from the telephone carrier or use a PBX to provide internal services, which is connected to the public network.

The exact configurations and security issues are generally very specific to the technology in use. This chapter has presented some of the risks and prevention methods associated with traditional voice security. The telephone is the easiest way to obtain information from a company and the fastest method of moving information around in a nondigital form. Aside from implementing the appropriate configurations for your technologies, the best defense is ensuring your users understand their role in limiting financial and information losses through the telephone network.

Acknowledgments

The author wishes to thank Beth Key, a telecommunications security and fraud investigator from Nortel Networks' voice service department. Ms. Key provided valuable expertise and support during the development of this chapter.

Mignona Cote of Nortel Networks' security vulnerabilities team provided her experiences as an auditor in a major U.S. telecommunications carrier prior to joining Nortel Networks.

The assistance of both these remarkable women contributed to the content of this chapter, and they are examples of the quality and capabilities of the women in our national telecommunications industry.

Secure Voice Communications (VoI)

Valene Skerpac, CISSP

Voice communication is in the midst of an evolution toward network convergence. Over the past several decades, the coalescence of voice and data through the circuit-based, voice-centric public switched telephone network (PSTN) has been limited. Interconnected networks exist today, each maintaining its own set of devices, services, service levels, skill sets, and security standards. These networks anticipate the inevitable and ongoing convergence onto packet- or cell-based, data-centric networks primarily built for the Internet. Recent deregulation changes and cost savings, as well as the potential for new media applications and services, are now driving a progressive move toward voice over some combination of ATM, IP, and MPLS. This new-generation network aims to include novel types of telephony services that utilize packet-switching technology to receive transmission efficiencies while also allowing voice to be packaged in more standard data applications. New security models that include encryption and security services are necessary in telecommunication devices and networks.

This chapter reviews architectures, protocols, features, quality-of-service (QoS), and security issues associated with traditional circuit-based landline and wireless voice communication. The chapter then examines convergence architectures, the effects of evolving standards-based protocols, new quality-of-service methods, and related security issues and solutions.

Circuit-Based PSTN Voice Network

The PSTN has existed in some form for over 100 years. It includes telephones, local and interexchange trunks, transport equipment, and exchanges; and it represents the whole traditional public telephone system. The foundation for the PSTN is dedicated 64 kbps circuits. Two kinds of 64 kbps pulse code modulation techniques are used to encode human analog voice signals into digital streams of 0s and 1s (mu-law, the North American standard; and a-law, the European standard).

The PSTN consists of the local loop that physically connects buildings via landline copper wires to an end-office switch called the central office or Class 5 switch. Communication between central offices connected via trunks is performed through a hierarchy of switches related to call patterns. Many signaling techniques are utilized to perform call control functions. For example, analog connections to the central office use dual-tone multifrequency (DTMF) signaling, an in-band signaling technique transmitted over the voice path. Central office connections through a T1/E1 or T3/E3 use in-band signaling techniques such as MF or robbed bit.

After World War II, the PSTN experienced high demand for greater capacity and increased function. This initiated new standards efforts, which eventually led to the organization in 1956 of the CCITT, the Comité Consultatif International de Télephonie et de Télégraphie, also known as the ITU-T, International Telecommunication Union Telecommunication Standardization Sector. Recommendations known as Signaling System 7 (SS7) were created, and in 1980 a version was completed for implementation. SS7 is a means of sending messages between switches for basic call control and for custom local area signaling services (CLASS). The move to SS7 represented a change to common-channel signaling versus its predecessor, per-trunk signaling.

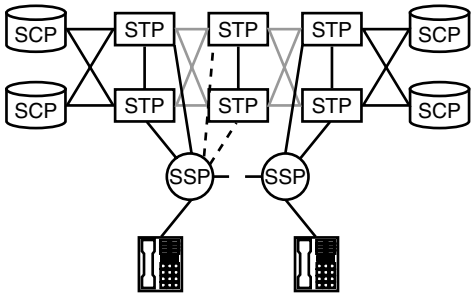

EXHIBIT 52.1 Diagram of SS7 key components and links.

SS7 is fundamental to today's networks. Essential architectural aspects of SS7 include a packet data network that controls and operates on top of the underlying voice networks. Second, a completely different transmission path is utilized for signaling information of voice and data traffic. The signaling system is a packet network optimized to speedily manage many signaling messages over one channel; it supports required functions such as call establishment, billing, and routing. Architecturally, the SS7 network consists of three components, as shown in Exhibit 52.1: service switch points (SSPs), service control points (SCPs), and signal transfer points (STPs). SSP switches originate and terminate calls communicating with customer premise equipment (CPE) to process calls for the user. SCPs are centralized nodes that interface with the other components through the STP to perform functions such as digit translation, call routing, and verification of credit cards. ScPs manage the network configuration and call-completion database to perform the required service logic. STPs translate and route SS7 messages to the appropriate network nodes and databases. In addition to the SS7 signaling data link, there are a number of other SS7 links between the SS7 components whereby certain links help to ensure a reliable SS7 network.

Functional benefits of SS7 networks include reduced post-dialing delay, increased call completion, and connection to the intelligent network (IN). SS7 supports shared databases among switches, providing the groundwork for IN network-based services such as 800 services and advanced intelligent networks (AINs). SS7 enables interconnection and enhanced services, making the whole next generation and conversion possible.

The PSTN assigns a unique number to each telephone line. There are two numbering plans: the North American numbering plan (NANP) and the ITU-T international numbering plan. NANP is an 11-digit or 1+10 dialing plan, whereas the ITU-T is no more than 15 digits, depending on the needs of the country.

Commonly available PSTN features are call waiting, call forwarding, and three-way calling. With SS7 end to end, CLASS features such as ANI, call blocking, calling line ID blocking, automatic callback, and call return (*69) are ready for use. Interexchange carriers (IXCs) sell business features including circuit-switched long distance, calling cards, 800/888/877 numbers, VPNs (where the telephone company manages a private dialing plan), private leased lines, and virtual circuits (Frame Relay or ATM). Security features may include line restrictions, employee authorization codes, virtual access to private networks, and detailed call records to track unusual activity. The PSTN is mandated to perform emergency services. The basic U.S. 911 relays the calling party's telephone number to public safety answering points (PSAPs). Enhanced 911 requirements include the location of the calling party, with some mandates as stringent as location within 50 meters of the handset.

The traditional enterprise private branch exchange (PBX) is crucial to the delivery of high availability, quality voice, and associated features to the end user. It is a sophisticated proprietary computer-based switch that operates as a small, in-house phone company with many features and external access and control. The PBX architecture separates switching and administrative functions, is designed for 99.999 percent reliability, and often integrates with a proprietary voicemail system. Documented PBX threats and baseline security methods are well known and can be referenced in the document *PBX Vulnerability Analysis* by NIST, special publication 800-24. Threats to the PBX include toll fraud theft, eavesdropping on conversations, unauthorized access to routing and address data, data alteration of billing information and system tables to gain additional services, unauthorized access, denial-of-service attacks, and a passive traffic analysis attack. Voice messages are also prone to threats of eavesdropping and accidental or purposeful forwarding. Baseline security policies and controls methods, which to a certain extent depend on the proprietary equipment, need to be implemented. Control methods include manual assurance of database integrity, physical security, operations security, management-initiated controls, PBX system control, and PBX system terminal access control such as password

control. Many telephone and system configuration practices need to be developed and adhered to. These include blocking well-known non-call areas or numbers, restart procedures, software update protection using strong error detection based on cryptography, proper routing through the PBX, disabling open ports, and configuration of each of the many PBX features. User quality-of-service (QoS) expectations of basic voice service are quite high in the area of availability. When people pick up the telephone, they expect a dial tone. Entire businesses are dependant on basic phone service, making availability of service critical. Human voice interaction requires delays of no more that 250 milliseconds.

Carriers experienced fraud prior to the proliferation of SS7 out-of-band signaling utilized for the communication of call establishment and billing information between switches. Thieves attached a box that generated the appropriate signaling tones, permitting a perpetrator to take control of signaling between switches and defeat billing. SS7 enhanced security and prevented unauthorized use.

Within reasonable limitations, PSTN carriers have maintained *closed* circuit-based networks that are not open to public protocols except under legal agreements with specified companies. In the past, central offices depended on physical security, passwords system access, a relatively small set of trained individuals working with controlled network information, network redundancy, and deliberate change control. U.S. telephone carriers are subject to the Communications Assistance for Law Enforcement Act (CALEA) and need to provide access points and certain information when a warrant has been issued for authorized wiretapping.

The network architecture and central office controls described above minimized security exposures, ensuring that high availability and QoS expectations were essentially met. While it is not affordable to secure the entire PSTN, such are the requirements of certain government and commercial users. Encryption of the words spoken into a telephone and decryption of them as they come out of the other telephone is the singular method to implement a secure path between two telephones at arbitrary locations. Such a secure path has never broadly manifested itself cost-effectively for commercial users.

Historically, PSTN voice scramblers have existed since the 1930s but equipment was large, complicated, and costly. By the 1960s, the KY-3 came to market as one of the first practical voice encryption devices. The secure telephone unit, first generation (STU-1) was introduced in 1970, followed in 1975 by the STU-II used by approximately 10,000 users. In 1987, the U.S. National Security Agency (NSA) approved STU-III and made secure telephone service available to defense contractors where multiple vendors such as AT&T, GE, and Motorola offered user-friendly deskset telephones for less than U.S.$2000. During the 1990s, systems came to market such as an ISDN version of STU called STE, offered by L3 Communications, AT&T Clipper phone, Australian Speakeasy, and British Brent telephone. Also available today are commercial security telephones or devices inserted between the handset and telephone that provide encryption at costs ranging from U.S.$100 to $2000, depending on overall capability.

Wireless Voice Communication Networks

Wireless technology in radio form is more than 100 years old. Radio transmission is the induction of an electrical current at a remote location, intended to communicate information whereby the current is produced via the propagation of an electromagnetic wave through space. The wireless spectrum is a space that the world shares, and there are several methods for efficient spectrum reuse. First, the space is partitioned into smaller coverage areas or cells for the purpose of reuse. Second, a multiple access technique is used to allow the sharing of the spectrum among many users. After the space has been specified and multiple users can share a channel, spread spectrum, duplexing, and compression techniques to utilize the bandwidth with even better efficiency are applied.

In digital cellular systems, time division multiplexing (TDMA) and code division multiple (CDMA) access techniques exist. TDMA first splits the frequency spectrum into a number of channels and then applies time division multiplexing to operate multiple users interleaved in time. TDMA standards include Global System for Mobile Communications (GSM), Universal Wireless Communications (UWC), and Japanese Digital Cellular (JDC). CDMA employs universal frequency reuse, whereby everybody utilizes the same frequency at the same time and each conversation is uniquely encoded, providing greater capacity over other techniques. First-generation CDMA standards and second-generation wideband CDMA (WCDMA) both use a unique code for each conversation and a spread spectrum method. WCDMA uses bigger channels, providing for greater call capacity and longer encoding strings than CDMA, increasing security and performance.

Multiple generations of wireless WANs have evolved in a relatively short period of time. The first-generation network used analog transmission and was launched in Japan in 1979. By 1992, second-generation (2G) digital

networks were operational at speeds primarily up to 19.2 kbps. Cellular networks are categorized as analog and digital cellular, whereas PCS, a shorter-range, low-power technology, was digital from its inception. Today, cellular networks have evolved to the 2.5G intermediate-generation network, which provides for enhanced data services on present 2G digital platforms. The third-generation (3G) network includes digital transmission. It also provides for an always-on per-user and terminal connection that supports multimedia broadband applications and data speeds of 144 kbps to 384 kbps, potentially up to 2 Mbps in certain cases. The 3G standards are being developed in Europe and Asia, but worldwide deployment has been slow due to large licensing and build costs. There are many competing cellular standards that are impeding the overall proliferation and interoperability of cellular networks.

Digital cellular architecture, illustrated in Exhibit 52.2, resembles the quickly disappearing analog cellular network yet is expanded to provide for greater capacity, improved security, and roaming capability. A base transceiver station (BTS), which services each cell, is the tower that transmits signals to and from the mobile unit. Given the large number of cells required to address today's capacity needs, a base station controller (BSC) is used to control a set of base station transceivers. The base station controllers provide information to the mobile switching center (MSC), which accesses databases that enable roaming, billing, and interconnection. The mobile switching center interfaces with a gateway mobile switching center that interconnects with the PSTN.

The databases that make roaming and security possible consist of a home location register, visitor location register, authentication center, and equipment identity register. The home location register maintains subscriber information, with more extensive management required for those registered to that mobile switching center area. The visitor location register logs and periodically forwards information about calls made by roaming subscribers for billing and other purposes. The authentication center is associated with the home location register; it protects the subscriber from unauthorized access, delivering security features including encryption, customer identification, etc. The equipment identity register manages a database of equipment, also keeping track of stolen or blacklisted equipment.

Prior to digital cellular security techniques, there was a high amount of toll fraud. Thieves stood on busy street corners, intercepted electronic identification numbers and phone numbers, and then cloned chips. The digitization of identification information allowed for its encryption and enhanced security. Policies and control methods are required to further protect against cellular phone theft. Methods include the use of an encrypted PIN code to telephone access and blocking areas or numbers. Privacy across the air space is improved using digital cellular compression and encoding techniques; CDMA encoding offers the greatest protection of the techniques discussed.

Despite security improvements in the commercial cellular networks, end-to-end security remains a challenge. Pioneering efforts for many of the digital communication, measurement, and data techniques available today

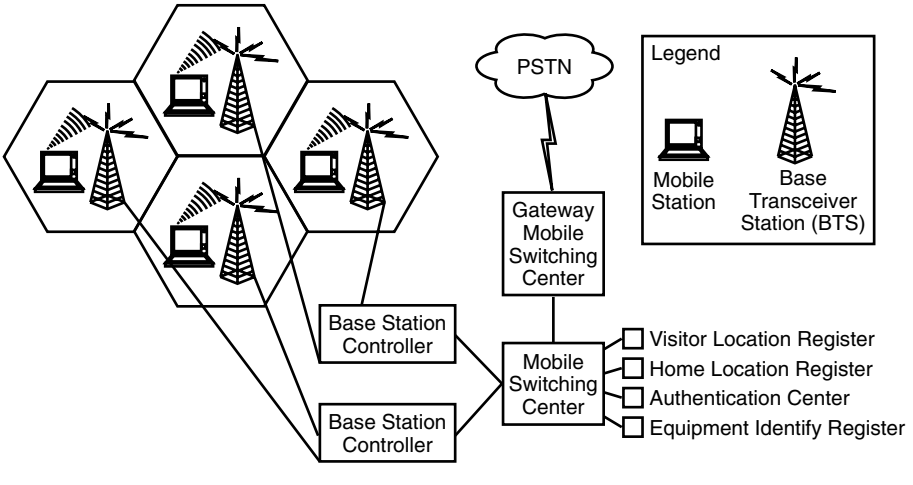

EXHIBIT 52.2 Digital cellular architecture.

were performed in a successful attempt to secure voice communication using FSK–FDM radio transmission during World War II. The SIGSALY system was first deployed in 1943 by Bell Telephone Laboratories, who began the investigation of encoding techniques in 1936 to change voice signals into digital signals and then reconstruct the signals into intelligible voice. The effort was spurred on by U.K. and U.S. allies who needed a solution to replace the vulnerable transatlantic high-frequency radio analog voice communications system called A-3. SIGSALY was a twelve-channel system; ten channels each measured the power of the voice signal in a portion of the whole voice frequency spectrum between 250 and 3000 Hz, and two channels provided information regarding the pitch of the speech and presence of unvoiced (hiss) energy. Encryption keys were generated from thermal noise information (output of mercury-vapor rectifier vacuum tubes) sampled every 20 milliseconds and quantized into six levels of equal probability. The level information was converted into channels of a frequency-shift-keyed audio tone signal, which represented the encryption key, and was then recorded on three hard vinyl phonograph records. The physical transportation and distribution of the records provided key distribution.

In the 1970s, U.S. Government wireless analog solutions for high-grade end-to-end crypto and authentication became available, though still at a high cost compared to commercial offerings. Secure telephone solutions included STU-III compatible, Motorola, and CipherTac2K. STU-III experienced compatibility problems with 2G and 3G networks. This led to the future narrow-band digital terminal (FNBDT) — a digital secure voice protocol operating at the transport layer and above for most data/voice network configurations across multiple media — and mixed excitation linear prediction vocoder (MELP) — an interoperable 2400-bps vocoder specification. Most U.S. Government personnel utilize commercial off-the-shelf solutions for sensitive but unclassified methods that rely on the commercial wireless cellular infrastructure.

Network Convergence

Architecture

Large cost-saving potentials and the promise of future capabilities and services drive the move to voice over a next-generation network. New SS7 switching gateways are required to support legacy services and signaling features and to handle a variety of traffic over a data-centric infrastructure. In addition to performing popular IP services, the next-generation gateway switch needs to support interoperability between PSTN circuits and packet-switching networks such as IP backbones, ATM networks, Frame Relay networks, and emerging Multi-Protocol Label Switching (MPLS) networks. A number of overlapping multimedia standards exist, including H.323, Session Initiation Protocol (SIP), and Media Gateway Control Protocol (MGCP). In addition to the telephony-signaling protocols encompassed within these standards, network elements that facilitate VoIP include VoIP gateways, the Internet telephony directory, media gateways, and softswitches. An evolution and blending of protocols, and gateway and switch functions continues in response to vendors' competitive searches for market dominance.

Take an example of a standard voice call initiated by a user located in a building connected to the central office. The central office links to an SS7 media gateway switch that can utilize the intelligence within the SS7 network to add information required to place the requested call. The call then continues on a packet basis through switches or routers until it reaches a destination media gateway switch, where the voice is unpackaged, undigitalized, and sent to the phone called.

Voice-over-IP (VoIP) changes voice into packets for transmission over a TCP/IP network. VoIP gateways connect the PSTN and the packet-switched Internet and manage the addressing across networks so that PCs and phones can talk to each other. Exhibit 52.3 illustrates major VoIP network components. The VoIP gateway performs packetization and compression of the voice, enhancement of the voice through voice techniques, DTMF signaling capability, voice packet routing, user authentication, and call detail recording for billing purposes. Many solutions exist, such as enterprise VoIP gateway routers, IP PBXs, service-provider VoIP gateways, VoIP access concentrators, and SS7 gateways. The overlapping functionality of the different types of gateways will progress further as mergers and acquisitions continue to occur. When the user dials the number from a VoIP telephone, the VoIP gateway communicates the number to the server; the call-agent software (softswitch) decides what the IP address is for the destination call number and presents back the IP address to the VoIP gateway. The gateway converts the voice signal to IP format, adds the address of the destination node, and sends the signal. The softswitch could be utilized again if enhanced services are required for additional functions.

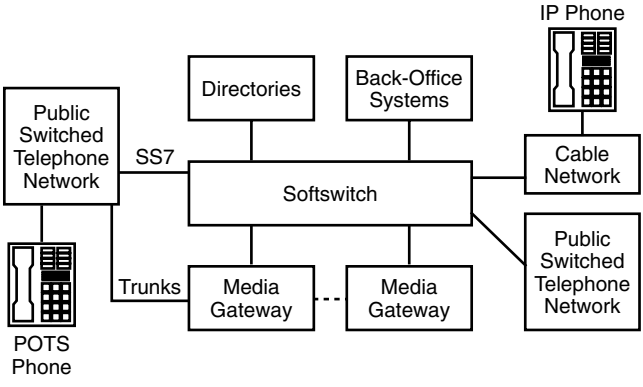

EXHIBIT 52.3 VoIP network architecture.

Media gateways interconnect with the SS7 network, enabling interoperability between the PSTN and packet-switched domains. They handle IP services and support various telephony-signaling protocols and Class 4 and Class 5 services. Media servers include categories of VoIP trunking gateways, VoIP access gateways, and network access service devices.

Vocoders compress and transmit audio over the network; they are another evolving area of standards for Voice-over-the-Internet (VOI). Vocoders used for VoI such as G.711 (48, 56, and 64 kbps high-bit rate) and G.723 (5.3 and 6.3 kbps high-bit rate) are based on existing standards created for digital telephony applications, limiting the telephony signal band of 200–3400 Hz with 8 kHz sampling. This toll-level audio quality is geared for the minimum a human ear needs to recognize speech and is not nearly that of face-to-face communications. With VoIP in a wideband IP end-to-end environment, better vocoders are possible that can achieve more transparent communication and better speaker recognition. New ITU vocoders — G.722.1 operating at 24 kbps and 32 kbps rates and 16 kHz sampling rate — are now used in some IP phone applications. The third-generation partnership project (3GPP)/ETSI (for GSM and WCDMA) merged on the adaptive multi-rate wideband (AMR-WB) at the 50–7000 Hz bandwidth to form the newly approved ITU G722.2 standard, which provides better voice quality at reduced bit rates and allows seamless interface between VoIP systems and wireless base stations. This eliminates the normal degradation of voice quality between vocoders of different systems.

Numbering

The Internet telephony directory, an IETF RFC known as ENUM services, is an important piece in the evolving VoI solution. ENUM is a standard for mapping telephone numbers to an IP address, a scheme wherein DNS maps PSTN phone numbers to appropriate URLs based on the E.164 standard.

To enable a faster time to market, VoIP continues as new features and service models supporting the PSTN and associated legacy standards are introduced. For example, in response to DTMF tone issues, the IETF RFC *RTP Payload for DTMF Digits, Telephony Tones and Telephony Signals* evolved, which specifies how to carry and format tones and events using RTP. In addition to the incorporation of traditional telephone features and new integrated media features, VoIP networks need to provide emergency services and comply with law enforcement surveillance requirements. The requirements as well as various aspects of the technical standards and solutions are evolving.

The move toward IP PBXs is evolving. Companies that cost-effectively integrate voice and data between locations can utilize IP PBXs on their IP networks, gaining additional advantages from simple moves and changes. Challenges exist regarding the nonproprietary telephony-grade server reliability (built for 99.99 percent reliability) and power distribution compared to traditional PBXs. Complete solutions related to voice quality, QoS, lack of features, and cabling distance limitations are yet evolving. A cost-effective, phased approach to an IP converged system (for example, an IP card in a PBX) enables the enterprise to make IP migration choices, support new applications such as messaging, and maintain the traditional PBX investment where appropriate. The move toward computer telephony greatly increases similar types of PBX security threats discussed previously and is explored further in the "VoI Security" section of this chapter.

Quality-of-Service (QoS)

Network performance requirements are dictated by both the ITU SS7/C7 standards and user expectations. The standard requires that the end-to-end call-setup delay cannot exceed 20 to 30 seconds after the ISDN User Part (ISUP) initial address message (IAM) is sent; users expect much faster response times. Human beings do not like delays when they communicate; acceptable end-to-end delays usually need to meet the recommended 150 milliseconds.

QoS guarantees, at very granulated levels of service, are a requirement of next-generation voice networks. QoS is the ability to deliver various levels of service to different kinds of traffic or traffic flows, providing the foundation for tiered pricing based on class-of-service (CoS) and QoS. QoS methods fall into three major categories: first is an architected approach such as ATM; second is a per-flow or session method such as with the reservation protocol of IETF IntServ definitions and MPLS specifications; and third is a packet labeling approach utilizing a QoS priority mark as specified in 802.1p and IETF DiffServ.

ATM is a cell-based (small cell), wide area network (WAN) transport that came from the carrier environment for streaming applications. It is connection oriented, providing a way to set up a predetermined path between source and destination, and it allows for control of network resources in real-time. ATM network resource allocation of CoS and QoS provisioning is well defined; there are four service classes based on traffic characteristics. Further options include the definition of QoS and traffic parameters at the cell level that establish service classes and levels. ATM transmission-path virtual circuits include virtual paths and their virtual channels. The ATM virtual path groups the virtual channels that share the same QoS definitions, easing network management and administration functions.

IP is a flexible, efficient, connectionless, packet-based network transport that extends all the way to the desktop. Packet-switching methods have certain insufficiencies, including delays due to store-and-forward packet-switching mechanisms, jitter, and packet loss. Jitter is the delay in sending bits between two switches. Jitter results in both an end-to-end delay and delay differences between switches that adversely affect certain applications. As congestion occurs at packet switches or routers, packets are lost, hampering real-time applications. Losses of 30 or 40 percent in the voice stream could result in speech with missing syllables that sounds like gibberish.

IntServ and DiffServ are two IP schemes for QoS. IntServ broadens a best-efforts service model, enabling the management of end-to-end packet delays. IntServ reserves resources on a per-flow basis and requires Resource Reservation Protocol (RSVP) as a setup protocol that guarantees bandwidth and a limit to packet delay using router-to-router signaling schemes. Participating protocols include the Real-time Transport Protocol (RTP), which is the transport protocol in which receivers sequence information through packet headers. Real-Time Control Protocol (RTCP) gives feedback of status from senders to receivers. RTP and RTCP are ITU standards under H.225. Real-Time Streaming Protocol (RTSP) runs on top of IP Multicast, UDP, RTP, and RTCP. RSVP supports both IPv4 and IPv6, and is important to scalability and security; it provides a way to ensure that policy-based decisions are followed.

DiffServ is a follow-on QoS approach to IntServ. DiffServ is based on a CoS model; it uses a specified set of building blocks from which many services can be built. DiffServ implements a prioritization scheme that differentiates traffic using certain bits in each packet (IPv4 type-of-service [ToS] byte or IPv6 traffic class byte) that designate how a packet is to be forwarded at each network node. The move to IPv6 is advantageous because the ToS field has limited functionality and there are various interpretations. DiffServ uses traffic classification to prioritize the allocation of resources. The IETF DiffServ draft specifies a management information base, which would allow for DiffServ products to be managed by Simple Network Management Protocol (SNMP).

Multi-Protocol Label Switching (MPLS) is an evolving protocol with standards originally out of the IETF that designates static IP paths. It provides for the traffic engineering capability essential to QoS control and network optimization, and it forms a basis for VPNs. Unlike IP, MPLS can direct traffic through different paths to overcome IP congested route conditions that adversely affect network availability. To steer IPv4 or IPv6 packets over a particular route through the Internet, MPLS adds a label to the packet. To enable routers to direct classes of traffic, MPLS also labels the type of traffic, path, and destination information. A packet on an MPLS network is transmitted through a web of MPLS-enabled routers or ATM switches called label-switching routers (LSRs). At each hop in the MPLS network, the LSR uses the local label to index a forwarding table, which designates a new label to each packet, and sends the packet to an output port. Routes can be defined manually or via RSVP-TE (RSVP with traffic engineering extensions) or MPLS Label Distribution Protocol (LDP). MPLS supports the desired qualities of circuit-switching technology such as bandwidth reservation and delay variation as well as a best-efforts hop-by-hop routing. Using MPLS, service providers can build

VPNs with the benefits of both ATM-like QoS and the flexibility of IP. The potential capabilities of the encapsulating label-based protocol continues to grow; however, there are a number of issues between the IETF and MPLS Forum that need full resolution, such as the transfer of ToS markings from IP headers to MPLS labels and standard LSR interpretation when using MPLS with DiffServ.

The management of voice availability and quality issues is performed through policy-based networking. Information about individual users and groups is associated with network services or classes of service. Network protocols, methods, and directories used to enable the granular time-sensitive requirements of policy-based QoS are Common Open Policy Services (COPS), Directory Enabled Networking (DEN), and Lightweight Directory Access Protocol (LDAP).

VOI Security

Threats to voice communication systems increase given the move to the inherently open Internet. Voice security policies, procedures, and methods discussed previously reflect the legacy closed voice network architecture; they are not adequate for IP telephony networks, which are essentially wide open and require little or no authentication to gain access. New-generation networks require protection from attacks across the legacy voice network, wireless network, WAN, and LAN. Should invalid signaling occur on the legacy network, trunk groups could be taken out of service, calls placed to invalid destinations, resources locked up without proper release, and switches directed to incorrectly reduce the flow of calls. As new IP telephony security standards and vendor functions continue to evolve, service providers and enterprises can make use of voice-oriented firewalls as well as many of the same data security techniques to increase voice security.

Inherent characteristics of Voice-over-IP protocols and multimedia security schemes are in conflict with many current methods used by firewalls or network address translation (NAT). Although no official standards exist, multiple security techniques are available to operate within firewall and NAT constraints. These methods typically use some form of dynamic mediation of ports and addresses whereby each scheme has certain advantages given the configuration and overall requirements of the network. Security standards, issues, and solutions continue to evolve as security extensions to signaling protocols, related standards, and products likewise evolve and proliferate.

SIP, H.323, MGCP, and Megaco/H.248 signaling protocols use TCP as well as UDP for call setup and transport. Transport addresses are embedded in the protocol messages, resulting in a conflict of interest. Secure firewall rules specify static ports for desirable data block H.323 because the signaling protocol uses dynamically allocated port numbers. Related issues trouble NAT devices. An SIP user on an internal network behind a NAT sends an INVITE message to another user outside the network. The outside user extracts the FROM address from the INVITE message and sends a 200(Ok) response back. Because the INVITE message comes from behind the NAT, the FROM address is not correct. The call never connects because the 200 response message does not succeed.

H.323 and SIP security solution examples available today are described. H.323, an established ITU standard designed to handle real-time voice and videoconferencing, has been used successfully for VoIP. The standard is based on the IETF Real-Time Protocol (RTP) and Real-Time Control Protocol (RTCP) in addition to other protocols for call signaling and data and audiovisual communications. This standard is applied to peer-to-peer applications where the intelligence is distributed throughout the network. The network can be partitioned into zones, and each zone is under the control of an intelligent gatekeeper. One voice firewall solution in an H.323 environment makes use of the mediating element that intervenes in the logical process of call setup and tear-down, handles billing capabilities, and provides high-level policy control. In this solution, the mediating element is the H323 gatekeeper; it is call-state aware and trusted to make network-wide policy decisions. The data ports of the voice firewall device connect to the output of the H.323 gateway device. The gatekeeper incorporates firewall management capabilities via API calls; it controls connections to the voice firewall device that opens dynamic "pinholes," which permit the relevant traffic through the voice firewall. Voice firewalls are configured with required pinholes and policy for the domain, and no other traffic can flow through the firewall. For each call setup, additional pinholes are configured dynamically to permit the precise traffic required to carry that call; and no other traffic is allowed. The voice firewall simplicity using stateless packet filtering can perform faster at lower costs compared to a traditional application firewall, with claims of 100 calls per second to drill and seal pinholes and a chassis that supports hundreds of simultaneous calls with less than one millisecond of latency

SIP, an increasingly popular approach, operates at the application layer of the OSI model and is based on IETF RFC 2543. SIP is a peer-to-peer signaling protocol controlling the creation, modification, and termination of sessions with one or more participants. SIP establishes a temporary call to the server, which performs required, enhanced service logic. The SIP stack consists of SIP using Session Description Protocol (SDP), RTCP, and RTP. Recent announcements — a Windows XP® SIP telephony client and designation of SIP as the signaling and call control standard for IP 3G mobile networks — have accelerated service providers' deployments of SIP infrastructures.

Comprehensive firewall and NAT security solutions for SIP service providers include a combination of technologies, including an edge proxy, a firewall control proxy, and a media-enabled firewall. An edge proxy acts as a guard, serving the incoming and outgoing SIP signaling traffic. It performs authentication and authorization of services through transport layer security (TLS) and hides the downstream proxies from the outside network. The edge proxy forwards calls from trusted peers to the next internal hop. The firewall control proxy works in conjunction with the edge proxy and firewall. For each authorized media stream, it dynamically opens and closes pinhole pairs in the firewall. The firewall control proxy also operates closely with the firewall to perform NAT and remotely manages firewall policy and message routing. Dynamic control and failover functions of these firewall control proxies provide the additional required reliability in the service provider network. The media-enabled firewall is a transparent, non-addressable VoIP firewall that does not allow access to the internal network except from the edge proxy. Carrier-class high-performance firewalls can limit entering traffic to the edge proxy and require a secure TLS connection for only media traffic for authorized calls.

Enterprise IP Telephony Security

Threats associated with conversation eavesdropping, call recording and modification, and voicemail forwarding or broadcasting are greater in a VoIP network, where voice files are stored on servers and control and media flows reside on the open network. Threats related to fraud increase given the availability of control information on the network such as billing and call routing. Given the minimal authentication functionality of voice systems, threats related to rogue devices or users increase and can also make it more difficult to track the hacker of a compromised system if an attack is initiated in a phone system.

Protection needs to be provided against denial-of-service (DoS) conditions, malicious software to perform a remote boot, TCP SYN flooding, ping of death, UDP fragment flooding, and ICMP flooding attacks. Control and data flows are prone to eavesdropping and interception given the use of packet sniffers and tools to capture and reassemble generally unencrypted voice streams. Viruses and Trojan horse attacks are possible against PC-based phones that connect to the voice network. Other attacks include a caller identity attack on the IP phone system to gain access as a legitimate user or administrator. Attacks to user registration on the gatekeeper could result in redirected calls. IP spoofing attacks using trusted IP addresses could fool the network that a hacker conversation is that of a trusted computer such as the IP-PBX, resulting in a UDP flood of the voice network.

Although attack mitigation is a primary consideration in VoIP designs, issues of QoS, reliability, performance, scalability, authentication of users and devices, availability, and management are crucial to security. VoIP security requirements are different from data security requirements for several reasons. VoIP applications are under no-downtime, high-availability requirements; operate in a badly behaved manner using dynamically negotiated ports; and are subject to extremely sensitive performance needs. VoIP security solutions are comprehensive; they include signaling protocols, operating systems, administration interface; and they need to fit into existing security environments consisting of firewalls, VPNs, and access servers. Security policies must be in place because they form a basis for an organization's acceptance of benefits and risks associated with VoIP. Certain signaling protocol security recommendations exist and are evolving. For example, the ITU-T H.235 Recommendation under the umbrella of H.323 provides for authentication, privacy, and integrity within the current H-Series protocol framework. Vendor products, however, do not necessarily fully implement such protection. In the absence of widely adopted standards, today's efforts rely on securing the surrounding network and its components.

Enterprise VoIP security design makes use of segmentation and the switched infrastructure for QoS, scalability, manageability, and security. Today, layer 3 segmentation of IP voice from the traditional IP data network aids in the mitigation of attacks. A combination of virtual LANs (VLANs), access control, and stateful firewall provides for voice and data segmentation at the network access layer. Data devices on a separate segment from the voice segment cannot instigate call monitoring, and the use of a switched infrastructure baffles devices on the same segment sufficiently to prevent call monitoring and maintain confidentiality. Not all IP phones with

data ports, however, support other than basic layer 2 connectivity that acts as a hub, combining the data and voice segments. Enhanced layer 2 support is required in the IP phone for VLAN technology (like 802.1q), which is one aspect needed to perform network segmentation today. The use of PC-based IP phones provides an avenue for attacks such as a UDP flood DoS attack on the voice segment making a stateful firewall that brokers the data–voice interaction required. PC-based IP phones are more susceptible to attacks than closed custom operating system IP phones because they are open and sit within the data network that is prone to network attacks such as worms or viruses. Controlling access between the data and voice segments uses a strategically located stateful firewall. The voice firewall provides host-based DoS protection against connection starvation and fragmentation attacks, dynamic per-port granular access through the firewall, spoof mitigation, and general filtering. Typical authorized connections such as voicemail connections in the data segment, call establishment, voice browsing via the voice segment proxy server, IP phone configuration setting, and voice proxy server data resource access generally use well-known TCP ports or a combination of well-known TCP ports and UDP. The VoIP firewall handles known TCP traditionally and opens port-level granular access for UDP between segments. If higher-risk PC-based IP phones are utilized, it is possible to implement a private address space for IP telephony devices as provided by RFC 1918. Separate address spaces reduce potential traffic communication outside the network and keep hackers from being able to scan a properly configured voice segment for vulnerabilities.

The main mechanism for device authentication of IP phones is via the MAC address. Assuming automatic configuration has been disabled, an IP phone that tries to download a network configuration from an IP-PBX needs to exhibit a MAC address known to the IP-PBX to proceed with the configuration process. This precludes the insertion of a rogue phone into the network and subsequent call placement unless a MAC address is spoofed. User log-on is supported on some IP phones for device setup as well as identification of the user to the IP-PBX, although this could be inconvenient in certain environments. To prevent rogue device attacks, employ traditional best practice regarding locking down switched ports, segments, and services holds. In an IP telephony environment, several additional methods could be deployed to further guard against such attacks. Assignment of static IP addresses to known MAC addresses versus Dynamic Host Configuration Protocol (DHCP) could be used so that, if an unknown device is plugged into the network, it does not receive an address. Also, assuming segmentation, separate voice and data DHCP servers means that a DoS attack on the DHCP data segment server has little chance of affecting the voice segment. The *temporary use only when needed* guideline should be implemented for the commonly available automatic phone registration feature that boot-straps an unknown phone with a temporary configuration. A MAC address monitoring tool on the voice network that tracks changes in MAC to IP address pairings could be helpful, given that voice MAC addresses are fairly static. Assuming network segmentation, filtering could be used to limit devices from unknown segments as well as keeping unknown devices within the segment from connecting to the IP-PBX.

Voice servers are prone to similar attacks as data servers and therefore could require tools such as an intrusion detection system (IDS) to alarm, log, and perhaps react to attack signatures found in the voice network. There are no voice control protocol attack signatures today, but an IDS could be used for UDP DoS attack and HTTP exploits that apply to a voice network. Protection of servers also includes best practices, such as disabling unnecessary services, applying OS patches, turning off unused voice features, and limiting the number of applications running on the server. Traditional best practices should be followed for the variety of voice server management techniques, such as HTTP, SSL, and SNMP.

Wireless Convergence

Wireless carriers look to next-generation networks to cost-effectively accommodate increased traffic loads and to form a basis for a pure packet network as they gradually move toward 3G networks. The MSCs in a circuit-switched wireless network as described earlier in this chapter interconnect in a meshed architecture that lacks easy scaling or cost-effective expansion; a common packet infrastructure to interconnect MSCs could overcome limitations and aid in the move to 3G networks. In this architecture, the common packet framework uses packet tandems consisting of centralized MGCs or softswitches that control distributed MGs deployed and located with MSCs. TDM trunks from each MSC are terminated on an MG that performs IP or ATM conversion under the management of the softswitch. Because point-to-point connections no longer exist between MSCs, a less complicated network emerges that requires less bandwidth. Now MSCs can be added to the network with one softswitch connection instead of multiple MSC connections. Using media gateways negates the need to upgrade software at each MSC to deploy next-generation services, and it offloads precious switching center

resources. Centrally located softswitches with gateway intelligence can perform lookups and route calls directly to the serving MSC versus the extensive routing required among MSCs or gateway MSCs to perform lookups at the home location register. With the progression of this and other IP-centric models, crucial registration, authentication, and equipment network databases need to be protected.

Evolving new-generation services require real-time metering and integration of session management with the transfer data. Service providers look to support secure virtual private networks (VPNs) between subscribers and providers of content, services, and applications. While the emphasis of 2.5G and 3G mobile networks is on the delivery of data and new multimedia applications, current voice services must be sustained and new integrated voice capabilities exploited. Regardless of specific implementations, it is clear that voice networks and systems will continue to change along with new-generation networks.

Glossary of Terms

AIN (Advanced Intelligent Network) — The second generation of intelligent networks, which was pioneered by Bellcore and later spun off as Telcordia. A common service-independent network architecture geared to quickly produce customizable telecommunication services.

ATM (Asynchronous Transfer Mode) — A cell-based international packet-switching standard where each packet has a uniform cell size of 53 bytes. It is a high-bandwidth, fast packet-switching and multiplexing method that enables end-to-end communication of multimedia traffic. ATM is an architected quality-of-service solution that facilitates multi-service and multi-rate connections using a high-capacity, low-latency switching method.

CCITT (Comité Consultatif International de Télephonie et de Télégraphie) — Advisory committee to the ITU, now known as the ITU-T, that influences engineers, manufacturers, and administrators.

CoS (Class-of-Service) — Categories of subscribers or traffic corresponding to priority levels that form the basis for network resource allocation.

CPE (Customer Premise Equipment) — Equipment owned and managed by the customer and located on the customer premise.

DTMF (Dual-Tone Multi-Frequency Signaling) — A signaling technique for push-button telephone sets in which a matrix combination of two frequencies, each from a set of four, is used to send numerical address information. The two sets of four frequencies are (1) 697, 770, 852, and 941 Hz; and (2) 1209, 1336, 1477, and 1633 Hz.

IP (Internet Protocol) — A protocol that specifies data format and performs routing functions and path selection through a TCP/IP network. These functions provide techniques for handling unreliable data and specifying the way network nodes process data, how to perform error processing, and when to throw out unreliable data.

IN (Intelligent Network) — An advanced services architecture for telecommunications networks.

ITU-T (International Telecommunication Union) — A telecommunications advisory committee to the ITU that influences engineers, manufacturers, and administrators.
MPLS (Multi-Protocol Label Switching) — An IETF effort designed to simplify and improve IP packet exchange and provide network operators with a flexible way to engineer traffic during link failures and congestion. MPLS integrates information about network links (layer 2) such as bandwidth, latency, and utilization with the IP (layer 3) into one system.
NIST (National Institute of Standards and Technology) — A U.S. national group that was referred to as the National Bureau of Standards prior to 1988.
PBX (Private Branch Exchange) — A telephone switch residing at the customer location that sets up and manages voice-grade circuits between telephone users and the switched telephone network. Customer premise switching is usually performed by the PBX as well as a number of additional enhanced features, such as least-cost routing and call-detail recording.
PSTN (Public Switched Telephone Network) — The entire legacy public telephone network, which includes telephones, local and interexchange trunks, communication equipment, and exchanges.
QoS (Quality-of-Service) — A network service methodology where network applications specify their requirements to the network prior to transmission, either implicitly by the application or explicitly by the network manager.
RSVP (Reservation Resource Protocol) — An Internet protocol that enables QoS; an application can reserve resources along a path from source to destination. RSVP-enabled routers then schedule and prioritize packets in support of specified levels of QoS.
RTP (Real-Time Transport Protocol) — A protocol that transmits real-time data on the Internet. Sending and receiving applications use RTP mechanisms to support streaming data such as audio and video.
RTSP (Real-Time Streaming Protocol) — A protocol that runs on top of IP multicasting, UDP, RTP, and RTCP.
SCP (Service Control Point) — A centralized node that holds service logic for call management.
SSP (Service-Switching Point) — An origination or termination call switch.
STP (Service Transfer Point) — A switch that translates SS7 messages and routes them to the appropriate network nodes and databases.
SS7 (Signaling System 7) — An ITU-defined common signaling protocol that offloads PSTN data traffic congestion onto a wireless or wireline digital broadband network. SS7 signaling can occur between any SS7 node, and not only between switches that are immediately connected to one another.

PREVENTING DNS ATTACKS

Mark Bell

INSIDE

How DNS Works, Opportunities — Abusing the DNS Trust, Poisoning the Cache, Averting DNS Attacks, Encryption

INTRODUCTION

Of all the Internet services, the Domain Name Service (DNS) is the most used, and perhaps the most vulnerable. Without DNS, users would have to know the "dotted quad" address of every resource that they use on the Internet; humans have a poor memory for numbers, but can recall the names of Web sites without much difficulty. In many cases, a company's Web address can be derived by adding "www" and "com" to each side of the company name; for example, www.microsoft.com. All of this depends on DNS. Imagine having to enter 199.29.24.3 instead of www.crcpress.com into a browser, and having to somehow remember the address of all of the other Web sites in that way. If DNS is essential now, when Internet addresses are only 32 bits long (IPv4), imagine the problem when IPv6 is widely adopted and many addresses increase to 128 bits.

DNS was designed by Paul Mockapetris of USC in 1984, and was described in RFCs 882 and 883. At that time, little thought was given to security; the service was designed to be efficient and reliable so that it could be deployed and used with the minimum of effort. It fulfilled all expectations and has been in continuous use since its inception, with remarkably few problems. If the lack of concern for security seems surprising, it should be remembered that at that time, the Internet community was much smaller, and use of the Internet was restricted to universities, government departments, the military, etc. — and widespread use of the Internet was not envisaged. TCP/IP was supposed to be the "temporary" network, a stopgap suite of protocols that would be replaced in a few years by the OSI suite — what was the point of spending much time on something that would be obsolete in a few years? The fiction that OSI

PAYOFF IDEA

Although still a rare occurrence, DNS attacks are increasing. Data encryption makes DNS attacks pointless, and also protects many other services on the Internet.

Auerbach Publications

would replace TCP/IP continued until the late 1980s, and was responsible for many decisions that seem poor in retrospect.

How DNS Works

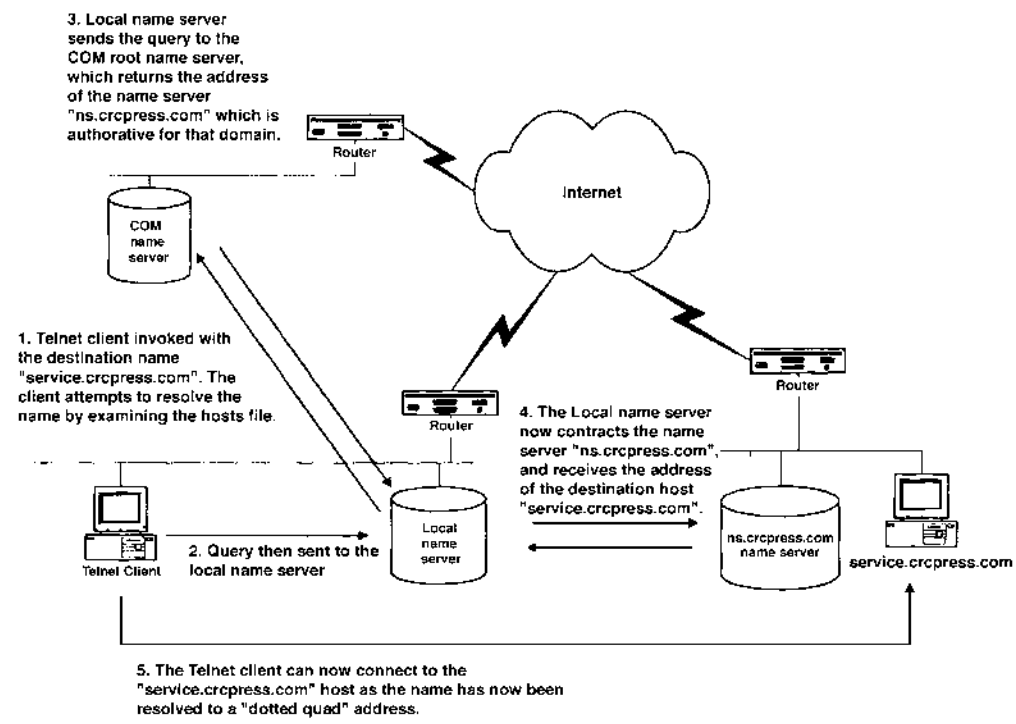
In order to understand the vulnerability of DNS, one needs to know how it functions — at least in enough detail to follow the flow of information. Nearly all TCP/IP applications and services are based on the client/server model; in Unix, telnet is the client and telnetd is the server. With telnet, a user enters "telnet service.crcpress.com," invoking the telnet client and passing the name of the host as a parameter. The client passes the parameter — in this case, service.crcpress.com — to a resolver routine compiled into the client code, and the resolver then attempts to resolve the name into a dotted quad address. The resolver first looks in a file on the host machine — "/etc/hosts" on Unix — to see if there is an entry matching the destination host name. If there is no entry, the resolver then sends a query to the local name server, whose address must be known to the client host. (See Exhibit 1.)

The name server will look in his cache to see if there is an entry for the host. There are several ways that the name may have been placed in the cache:

1. If the destination host is on the local network, the name and address will have been entered into a table by the DNS administrator. This table is kept on the hard disk, and is reloaded every time the name server boots up. These are the addresses for which this server is considered to be "authoritative." The name server is the "primary" server for these names.
2. The name server also has a list of servers entered into this same table, which are authoritative for other sites. When the name server boots, it will download the name/address table from each of these servers and add the contents to its own table. The name server is said to be "secondary" to these other servers.
3. The name server has resolved the same name for another client recently, and the entry is still valid.

If there is no entry in the cache, the name server will pass the query to one of the root servers or a parent server to see if the name exists in the cache on one of these machines. How does the name server know which root server to query? The last part of the name will be the domain in which the name resides, so the address "service.crcpress.com" is in the .com domain. The domains are organized by function — a commercial, for-profit company is in the .com domain, government departments are in the .gov domain, and military installations are in the .mil domain, etc.

EXHIBIT 1 — Resolving a Domain Name



The com server has a table containing the address of all the name servers (at least "top level" servers) in the .com domain; every time a new company joins the .com domain, the address of its main name server is added to the table. The com server will return the address of a name server that can be queried for the address of the destination host, in this case ns.crcpress.com. The client's name server will then query ns.crcpress.com for the address associated with service.crcpress.com, and will be sent the dotted quad address, together with a time for which the name/address pair is guaranteed to be valid (TTL — Time to Live). This address will be added to the cache in the local name server, and kept there until the TTL has expired. In this way, the name server that resolves a query can control how long the query is to be considered valid by other name servers.

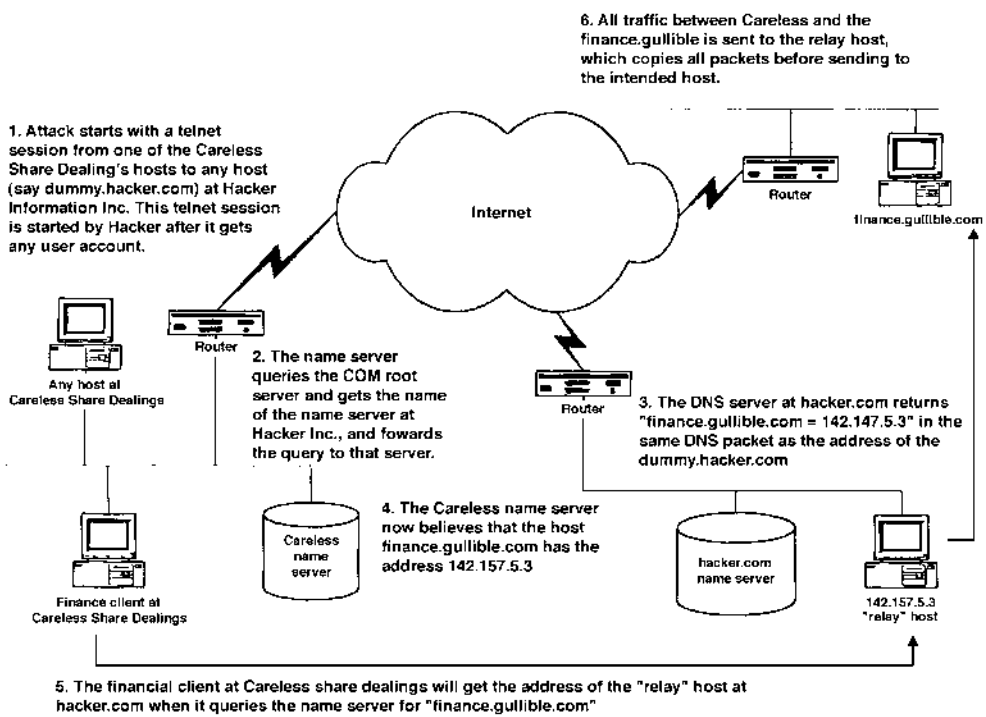
The client host can now open the telnet session with the destination host, but has had to trust the Domain Name Service completely — there is no real way of checking that the resolution is correct, and that the telnet session is being opened with the correct host. This is the problem with the DNS service — it relies on trust, which means that it is open to abuse.

Opportunities — Abusing the DNS Trust

The most obvious damage that can be inflicted on an Internet site is to corrupt the name server's table, or enter the names of invalid addresses with hosts, so that the users would not be able to initiate Internet services without knowing their dotted quad address; this would be relatively harmless, because the users would realize a problem existed, and would be able to flush the name server's cache. This is just mindless vandalism, quickly discovered and speedily resolved. There are other possibilities, however, one of which will be explored in this article.

Imagine a company (Careless Share Dealings, Inc.) carries out financial transactions with another company (Gullible Stocks PLC) via the Internet on a regular basis, and that another person or company (Hacker Information) could benefit if it could read these transactions in a timely manner — perhaps these transactions could be shared dealings between two brokers, with the transactions being automatically recorded every 30 minutes (see Exhibit 2). If the company's name server could be persuaded that the address of the financial server at Gullible had changed, and the new address was relay.hacker.com, then all of the information would be sent to the new address. Now, all that the host at Hacker has to do is to copy the details of every packet to a file on the hard disk, and relay the packet on to its proper destination, Gullible Stocks. Assuming that the share dealing software used TCP, two sessions would be set up: one between Careless and Hacker and another between Hacker and Gullible. Note that the traffic from Gullible back to Careless would follow the same path; DNS is used by the original client (Careless) because Careless does not know the

EXHIBIT 2 — Poisoning the DNS Cache



address of the server (Gullible). When the server receives a request to start a session, he gets the address of the client in the TCP/IP packet, so he has no need to use DNS. He is trusting that the client is who he says he is — in this case, a bad assumption. Even if the service between Careless and Gullible had passwords that changed every 30 seconds, this would not prevent the attack from taking place because Hacker does not need to know the password — he is passing on valid information from Careless.

Poisoning the Cache

The most obvious way to fool the Careless name server into believing that the address of the Gullible Finance server had changed would be to break into the name server at Gullible and place the new address in the table. This would risk discovery, however, because all of the other hosts at Gullible would also get the incorrect address; if Gullible had a firewall, there would be logs showing that traffic between two hosts on the Gullible site is being diverted to another host on the Internet and relayed back, and the game would be over.

Another way that the attack can succeed for the longer term would be to penetrate the name server at Careless. Because the Careless name server does not have the name/address pair of the Gullible finance server in a permanent table, the Careless name server would have to serve as the primary server for the Gullible domain; this could be done without affecting the hosts at Gullible — they would still be sending their queries to the Gullible name server. However, the changes to the Careless name server would soon be noticed by the DNS administrator, and again the game would be over.

The best strategy is to use a name server somewhere else on the Internet and exploit the biggest weakness of name servers — the complete trust they must have in any other name servers in order to be efficient. When a name server sends a query, it not only accepts the answer to the original query, but will also accept answers to queries it has not made, and will cache those answers without attempting authentication. This allows a name server to send a list of recent updates any time that it answers a query, and helps to reduce the name resolution traffic on the Internet. Now, all that the attacker needs to do is to make a modification to the server at Hacker Information and then trigger a query to Hacker from Careless. This can be done in several ways; some examples follow:

1. Forge mail on the Careless mail server and address the mail to a user at Hacker Information. This would cause the mail server to query the name server at Careless for the Hacker mail server and, of course, the name server would eventually query the name server at Hacker after contacting the root name server.

2. Break into any machine on the Careless site, and telnet to any host on the Hacker site. This would trigger a DNS query, with the same results.
3. Alter a URL on a Web server at the Careless site or any Web server the users at Careless will visit. This will also trigger a name query.

This is almost a perfect "man-in-the-middle" attack, with very little chance of tracking down the attacker. Even if one could trace the machine running the relay software, it is probable that it belongs to an innocent third party who is unaware that his machine has been compromised. The hacker will be sending the captured information to an unused account on another innocent's machine, and will log in at leisure to collect it. The attacker could also improve the strategy by using someone else's DNS server to launch the initial poisoning attack

Averting DNS Attacks

One of the popular misconceptions about DNS is that a "double reverse lookup" can be used to authenticate name resolution and prevent this attack. This works as follows:

1. The name is resolved in the usual manner; i.e., DNS.
2. When the client receives the answer, an inverse query is made, where the address is sent to a DNS server and a name is returned.
3. The client then compares the name returned with the name used in the original query, and aborts the transaction if the names do not coincide.

This sounds good, but in practice, this is unworkable for several reasons. What happens if the attacker has not only poisoned the cache with the name/address pair, but has also poisoned the inverse cache? The names would then coincide. If two servers were used — one to resolve the original query and one for the inverse check — there would be no guarantee that both servers had not been poisoned. The biggest problem with the double reverse lookup is that it can only be performed on the primary and secondary servers — the client would have to send the inverse query directly to the name server at Gullible. Name servers do not refer inverse queries they cannot resolve to other name servers; so, if the inverse query is sent to the Careless name server, it would be returned as unresolved.

The best way to prevent DNS attacks is to put the names and addresses of critical hosts in the host's file. The client resolver will look at this file before sending a query to DNS, and this will avert all DNS attacks using any of the host names in the host's file. The problem here is that this

is labor intensive; the whole purpose of the DNS system is to prevent this kind of maintenance burden. In any case, this is only possible for relatively few hosts, although one could cut the amount of duplication by maintaining a central copy of the host's file, and distributing it to other hosts as needed.

Encryption

Many of the security problems on the Internet have a common cause — data is being transported in clear text or in other forms that can easily be read. The real answer to most of these problems is to encrypt all data in transit. What would be the point of the DNS attack, and copying the data from the resulting relay software on the Hacker host, if the data could not be read? The technology to encrypt data has been available for years. SNA has always been able to encrypt data so that it cannot be read in transit, and it is obvious (with hindsight) that this should have been part of the original IP specification. A secure channel can be imposed between Internet sites by the use of encryption routers that will scramble all of the data transmitted between specified sites. Custom applications should be written to encrypt all data in transit; the availability of encryption libraries from RSA and other vendors has simplified development of secure applications.

The real point here is that the choice has to be made between replacing DNS with a more secure service, or rendering DNS attacks pointless by data encryption. The first option only cures the problems with DNS — assuming that a truly secure version of DNS is possible. The second option will render DNS attacks pointless and also protect many other services on the Internet at the same time.

DNS attacks are still a rare occurrence on the Internet. Other attacks, such as the sniffer attack, can be launched more easily and require less knowledge. There are simpler and more direct ways of achieving the same ends — intercepting and copying data in transit — but as precautions are taken against these, simpler methods become more common, and life becomes more difficult for the hacker, one can expect to see an increase in the incidents of DNS attacks.

PROTECTING A NETWORK FROM SPOOFING AND DENIAL OF SERVICE ATTACKS

Gilbert Held

INSIDE

Spoofing; Spoofing Methods; Blocking Spoofed Addresses; Anti-spoofing Statements; Ping Attacks; Directed Broadcasts

INTRODUCTION

Along with the evolution of technology, we have witnessed an unfortunate increase in random violence in society. While it is doubtful if the two are related, it is a matter of fact that some violence is directed at computers operated by federal, state, and local governments, universities, and commercial organizations. That violence typically occurs in the form of attempts to break into computers via a remote communications link or to deny other persons the use of computational facilities by transmitting a sequence of bogus requests to the network to which a computer is connected. Because either situation can adversely affect the operational capability of an organization's computational facilities, any steps one can initiate to enhance the security of a network and networked computers may alleviate such attacks.

This article examines several common types of hacker attacks against networks and networked computers. In doing so, it first examines how the attack occurs. Once an appreciation for the method associated with an attack is obtained, attention can focus on techniques that can be used to prevent such attacks. Because the vast majority of routers used for Internet and intranet communications are manufactured by Cisco Systems, examples illustrating the use of the Cisco Systems' Internetwork Opera-

PAYOFF IDEA

Protecting one's network from outside attack has become more critical than ever. This article examines several common types of hacker attacks against networks and illustrates methods to prevent those attacks.

tion System (IOS) will be used when applicable to denote different methods to enhance network security. By examining the information presented in this article, one will note practical methods that can be implemented to add additional protection to an organization's network. Thus, this article serves both as a tutorial concerning spoofing and denial of service attacks, as well as a practical guide to prevent such activities.

SPOOFING

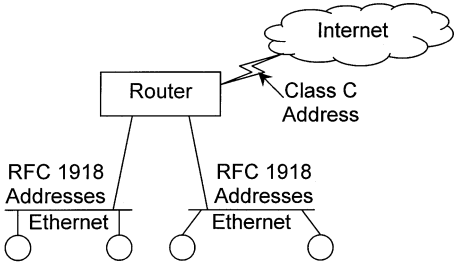
According to Mr. Webster, the term "spoof" means to "deceive or hide." In communications, the term "spoofing" is typically associated with a person attempting to perform an illegal operation. That person, commonly referred to as a hacker, spoofs or hides the source address contained in the packets he or she transmits. The rationale for hiding the hacker's source address is to make it difficult, if not impossible, for the true source of the attack to be identified. Because spoofing is employed by most hackers that spend the time to develop different types of network attacks, one should first examine how spoofing occurs. This is followed by a discussion of methods one can employ to prevent certain types of spoofed packets from flowing into a network.

SPOOFING METHODS

There are several methods hackers can use to spoof their source addresses. The easiest method is to configure their protocol stack with a bogus address. In a TCP/IP environment, this can be easily accomplished by a person coding a bogus IP address in the network address configuration screen displayed by the operating system supported by their computer. Because only the destination address is normally checked by networking devices (such as routers and gateways), it is relatively easy to hide one's identity by configuring a bogus source IP address in one's protocol stack.

When configuring a bogus IP address, hackers, for some unknown reason, commonly use either an address associated with the attacked network or with an RFC 1918 address. Concerning the latter, RFC 1918 defines three blocks of IP addresses for use on private IP networks. Because the use of RFC 1918 addresses on networks directly connected to the Internet would result in duplicated IP addresses, they are barred from direct use on the Internet. Instead, they are commonly used by organizations that have more computers than assigned IP addresses. For example, assume an organization originally requested one Class C IP address from their Internet Service Provider (ISP). A Class C IP address is capable of supporting up to 254 hosts, because host addresses 0 and 255 cannot be used. Now suppose the organization grew and required more than 254 workstations to be connected to the Internet. While the organization could request another Class C network address from its ISP, such addresses are becoming difficult to obtain and the organization might have

EXHIBIT 1 — Using RFC 1918 Addresses and Network Address Translation to Support Internet Connectivity for Many Workstations



to wait weeks or months to obtain the requested address. As an alternative, the organization could use RFC 1918 addresses and use its router to perform network address translation as illustrated in Exhibit 1.

In examining Exhibit 1, note that two Ethernet segments are shown behind the router. Each segment could represent an individual Class C network using RFC 1918 addresses. The router would translate those RFC 1918 addresses to either a group of pooled Class C addresses or one Class C address, with the method of translation based on the manner in which the router's translation facility was configured.

If a pooled Class C address is used, the number of simultaneous sessions is limited to 254. If one Class C address is used, the router uses TCP and UDP port numbers to translate from RFC 1918 addresses to a common Class C address, with port numbers used to keep track of each address translation. Because there are thousands of unused port numbers, this method provides a greater translation capability as it limits or avoids potential contention between users behind the router requesting access to the Internet and available IP addresses.

Perhaps because RFC 1918 addresses are popularly used by many organizations, yet hidden by network address translation, they are commonly used as a source address when a hacker configures his or her protocol stack. Exhibit 2 lists the three address blocks reserved for private IP networks under RFC 1918.

EXHIBIT 2 — RFC 1918 Address Blocks

10.0.0.0	10.255.255.255
172.16.0.0	172.31.255.255
192.168.0.0	192.168.255.255

The use of an RFC 1918 address or the selection of an address from the target network results in a static source address. While this is by far the most common method of IP address spoofing, on occasion a sophisticated hacker will write a program that randomly generates source addresses. As will be noted shortly, only when those randomly generated source addresses represent an address on the target network or an RFC 1918 address are they relatively easy to block.

BLOCKING SPOOFED ADDRESSES

Because a router represents the point of entry into a network, it also represents one's first line of defense. Most routers support packet filtering, allowing the network administrator to configure the router to either permit or deny the flow of packets, based on the contents of one or more fields in a packet.

Cisco routers use access lists as a mechanism to perform packet filtering. A Cisco router supports two basic types of access lists: standard and extended. A Cisco standard IP access list performs filtering based on the source address in each packet. The format of a standard IP access list statement is shown below:

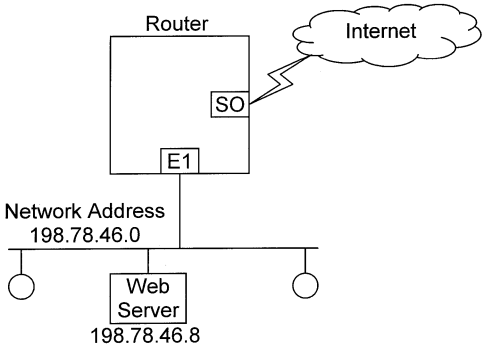
access-list list# [permit/deny][ip address][mask][log]

The list# is a number between 1 and 99 and identifies the access list as a standard access list. Each access list statement contains either the keyword "permit" or "deny," which results in the packet with the indicated IP address either being permitted to flow through a router or sent to the great bit bucket in the sky. The mask represents a wildcard mask that functions in a reverse manner to a subnet mask. That is, a binary 0 is used to represent a "don't-care" condition. Note this is the opposite of the use of binary 0s and 1s in a subnet mask. In fact, the wildcard mask used by a Cisco router is the inverse of a subnet mask, and each position in the wildcard mask can be obtained by subtracting the value of the subnet mask for that position from 255.

The keyword "log" is optional and when included results in each match against a packet being displayed on the router's console. Logging can facilitate the development of access lists as well as serve as a mechanism to display activity that the access list was constructed to permit or deny. Thus, on occasion, it can be used to see if one's router is under attack or if suspicious activity is occurring.

In a Cisco router environment, access lists are applied to an interface in the inbound or outbound direction. To do so, one would use an interface command and an ip access-group command. Because spoofed IP addresses represent packets with bogus source addresses, one can use either standard or extended access lists to block such packets from enter-

EXHIBIT 3 — Connecting an Ethernet Segment to the Ethernet



ing a network. Since extended access lists will be discussed and described later in this article, we first illustrate the use of a standard access list to block packets with spoofed IP addresses. In doing so, assume an organization uses a Cisco router as illustrated in Exhibit 3 to connect a single Ethernet segment with a Web server and conventional workstations to the Internet. In examining Exhibit 3, note that it is assumed that the network address is 198.78.46.0 and the server has the IP address of 198.78.46.8.

ANTI-SPOOFING STATEMENTS

Because statements in a Cisco access list are operated upon in their sequence, top down, one should place anti-spoofing statements at the beginning of the access list. Since one wants to protect the network from persons attempting to remotely access the network via the Internet, one would apply the anti-spoofing statements in the access list to be created to the serial interface of the router. The access list will be applied in the inbound direction since one wants to examine packets flowing from the Internet toward the organization's Ethernet segment for bogus IP addresses.

The example shown in Exhibit 4 illustrates the configuration and application of a Cisco standard IP access list to effect anti-spoofing operations. In this example, four deny statements at the beginning of the access list preclude packets with a source address of any possible host on the organization's network, as well as any RFC 1918 address from flowing through the router.

The first deny statement checks each packet for a source address associated with the 198.78.46.0 network. Note that the wildcard mask of 0.0.0.255 results in the router matching the first three positions of each dotted decimal address but not caring about the fourth position. Thus, any

EXHIBIT 4 — An Access List that Performs Anti-Spoofing Operations

```
interface serial 0
ip access-group1 in
!
ip access-list1 deny 198.78.46.0 0.0.0.255
ip access-list1 deny 10.0.0.0 0.255.255.255
ip access-list1 deny 172.16.0.0.0 0.31.255.255
ip access-list1 deny 192.168.0.0. 0.0.255.255   ip access-list1 permit 0.0.0.0 255.255.255.255
```

packet with a source address associated with the internal network will be tossed into the great bit bucket in the sky. The next three deny statements in effect bar packets that use any RFC 1918 address as their source address. Because an access list denies all packets unless explicitly permitted, the access list just created would support anti-spoofing but disallow all other packets. Thus, a permit statement was added at the end of the access list. That statement uses a wildcard mask of 255.255.255.255, which in effect is a complete don't-care and represents the keyword "any" that one can use synonymously in a Cisco access list to represent an address and mask value of 0.0.0.0 255.255.255.255. Since statements are evaluated in their order in the list, if a packet does not have a source address on the 198.78.46.0 network or an RFC 1918 address, it is permitted to flow through the router. Also note that the command "interface serial 0" defines serial port 0 as the interface the access list will be applied to, while the command "ip access-group 1 in" defines that access-list1 will be applied to the serial 0 port in the inbound direction.

Now that there is an appreciation for how one can prevent packets with spoofed IP addresses from flowing into a network, attention can be turned to the manner by which one can prevent several types of denial of service attacks.

PING ATTACKS

One of the more common methods of creating a denial of service attack occurs when a person in a computer laboratory goes from workstation to workstation and configures each computer to ping a target using the -t option supported by most versions of Windows. The -t option results in the computer continuously pinging the target IP address. While one or a few workstations continuously pinging a Web server will only slightly impact the performance of the server, setting 50 or 100 or more workstations to continuously ping a server can result in the server spending most of its time responding to pings instead of user queries.

One method that can be used to prevent a ping attack is to block pings from entering the network. If the organization uses a Cisco router, one can block pings through the use of an extended IP access list. The format of a Cisco extended IP access list is shown below.

access-list list# [permit/deny] protocol [source address]
[source-wildcard][source port][destination address]
[destination-wildcard][destination port][options]

Unlike a standard IP access list that is limited to filtering based on the source address in a packet, an extended access list permits filtering based on several fields. Those fields include the type of protocol transported in the packet, its source address and destination address, and upper layer protocol information. Concerning the latter, one can use extended IP access lists to filter packets based on the value in their source and destination port fields. In addition to the preceding, an extended access list supports a range of options (such as "log"), as well as other keywords to enable specific types of access-list functions.

Returning to the problem at hand, how can one bar pings into an organization's network? The answer to this question is to use an extended IP access list. To do so, one would configure an access list statement that uses the ICMP protocol, since pings are transported by ICMP echo-request packets. The following Cisco extended IP access list statement could be used to block pings:

access-list 101 deny icmp any any echo-request

In the above extended IP access list statement, one will block echo-requests (pings) from any source address flowing to any destination address. Because one would apply the access list to the serial interface in the inbound direction, it would block pings from any address on the Internet destined to any address on the organization's Ethernet network. Knowing how to block pings, one can focus attention on another type of hacker denial of service attack — as directed broadcasts.

DIRECTED BROADCASTS

Refocusing on Exhibit 3, one notes that the network address of 198.78.46.0 represents a Class C network. A Class C network uses 3 bytes of its 4-byte address for the network address and 1 byte for the host address. Although an 8-bit byte can support 256 distinct numbers (0 to 255), an address of 0 is used to represent "this network," while an address of 255 is used to represent a "broadcast" address. Thus, a maximum of 254 hosts can be connected to a Class C network.

A directed broadcast occurs when a user on one network addresses a packet to the broadcast address of another network. In this example, that would be accomplished by sending a packet to the destination address of 198.78.46.255. The arrival of this packet results in the router converting the layer 3 packet into a layer 2 Ethernet frame addressed to everyone on the network as a layer 2 broadcast. This means that each host on

the Ethernet network will respond to the frame and results in a heavy load of traffic flowing on the LAN.

One of the first types of directed broadcast attacks is referred to as a Smurf attack. Under this denial of service attack method, a hacker created a program that transmitted thousands of echo-request packets to the broadcast address of a target network. To provide an even more insidious attack, the hacker spoofed his or her IP address to that of a host on another network that he or she also desired to attack. The result of this directed broadcast attack was to deny service to *two* networks through a *single* attack.

Each host on the target network that is attacked with a directed broadcast responds to each echo-request with an echo-response. Thus, each ping flowing onto the target network can result in up to 254 responses. When multiplied by a continuous sequence of echo-requests flowing to the target network, this will literally flood the target network, denying bandwidth to other applications. Because the source IP address is spoofed, responses are directed to the spoofed address. If the hacker used an IP address of a host on another network that the hacker wishes to harm, the effect of the attack is a secondary attack. The secondary attack results in tens of thousands to millions of echo-responses flowing to the spoofed IP address, clogging the Internet access connection to the secondary network.

Although the original Smurf attack used ICMP echo-requests that could be blocked by an access list constructed to block inbound pings, hackers soon turned to the directed broadcast of other types of packets in an attempt to deny service by using a large amount of network bandwidth. Recognizing the problem of directed broadcasts, Cisco Systems and other router manufacturers soon added the capability to block directed broadcasts on each router interface. On a Cisco router, one would use the following IOS command to turn off the ability for packets containing a directed broadcast address to flow through the router:

```
no ip directed-broadcast
```

SUMMARY

This article focused on methods that can be used to prevent packets containing commonly used spoofed IP addresses from flowing into an organization's network. In addition, it also examined how several popular denial of service attacks operate and methods one can employ to block such attacks.

When considering measures that one can employ to secure a network, it is important to note that there is no such thing as a totally secure network. Unfortunately for society, many hackers are very smart and view the disruption of the operational status of a network as a challenge, pe-

riodically developing new methods to disrupt network activity. To keep up with the latest threats in network security, one should subscribe to security bulletins issued by the Computer Emergency Response Team (CERT) as well as periodically review release notes issued by the manufacturer of your organization's routers and firewalls. Doing so will alert one to new threats, as well as potential methods one can use to alleviate or minimize the effect of such threats.

Packet Sniffers: Use and Misuse

Steve A. Rodgers, CISSP

A packet sniffer is a tool used to monitor and capture data traveling over a network. The packet sniffer is similar to a telephone wiretap; but instead of listening to phone conversations, it listens to network packets and conversations between hosts on the network. The word *sniffer* is generically used to describe packet capture tools, similar to the way *crescent wrench* is used to describe an adjustable wrench. The original sniffer was a product created by Network General (now a division of Network Associates called Sniffer Technologies).

Packet sniffers were originally designed to assist network administrators in troubleshooting their networks. Packet sniffers have many other legitimate uses, but they also have an equal number of sinister uses. This chapter discusses some legitimate uses for sniffers, as well as several ways an unauthorized user or hacker might use a sniffer to compromise the security of a network.

How Do Packet Sniffers Work?

The idea of sniffing or packet capturing may seem very high-tech. In reality it is a very simple technology. First, a quick primer on Ethernet. Ethernet operates on a principle called *Carrier Sense Multiple Access with Collision Detection* (CSMA/CD). In essence, the network interface card (NIC) attempts to communicate on the wire (or Ethernet). Because Ethernet is a shared technology, the NIC must wait for an "opening" on the wire before communicating. If no other host is communicating, then the NIC simply sends the packet. If, however, another host is already communicating, the network card will wait for a random, short period of time and then try to retransmit.

Normally, the host is only interested in packets destined for its address; but because Ethernet is a shared technology, all the packet sniffer needs to do is turn the NIC on in promiscuous mode and "listen" to the packets on the wire. The network adapter can capture packets from the data-link layer all the way through the application layer of the OSI model. Once these packets have been captured, they can be summarized in reports or viewed individually. In addition, filters can be set up either before or after a capture session. A filter allows the capturing or displaying of only those protocols defined in the filter.

Ethereal

Several software packages exist for capturing and analyzing packets and network traffic. One of the most popular is Ethereal. This network protocol analyzer can be downloaded from http://www.ethereal.com/ and installed in a matter of minutes. Various operating systems are supported, including Sun Solaris, HP-UX, BSD (several distributions), Linux (several distributions), and Microsoft Windows (95/98/ME, NT4/2000/XP). At the time of this writing, Ethereal was open-source software licensed under the GNU General Public License.

After download and installation, the security practitioner can simply click on "Capture" and then "Start," choose the appropriate network adapter, and then click on "OK." The capture session begins, and a summary window displays statistics about the packets as they are being captured (see Exhibit 53.1).

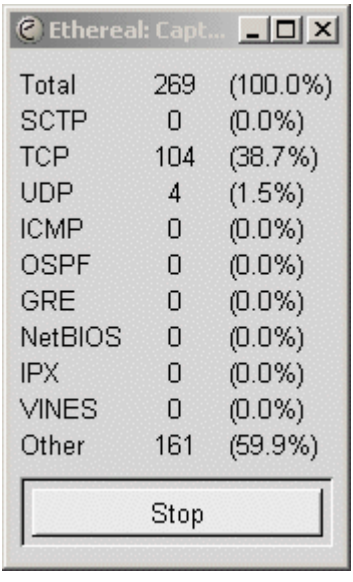

EXHIBIT 53.1 Summary window with statistics about the packets as they are being captured.

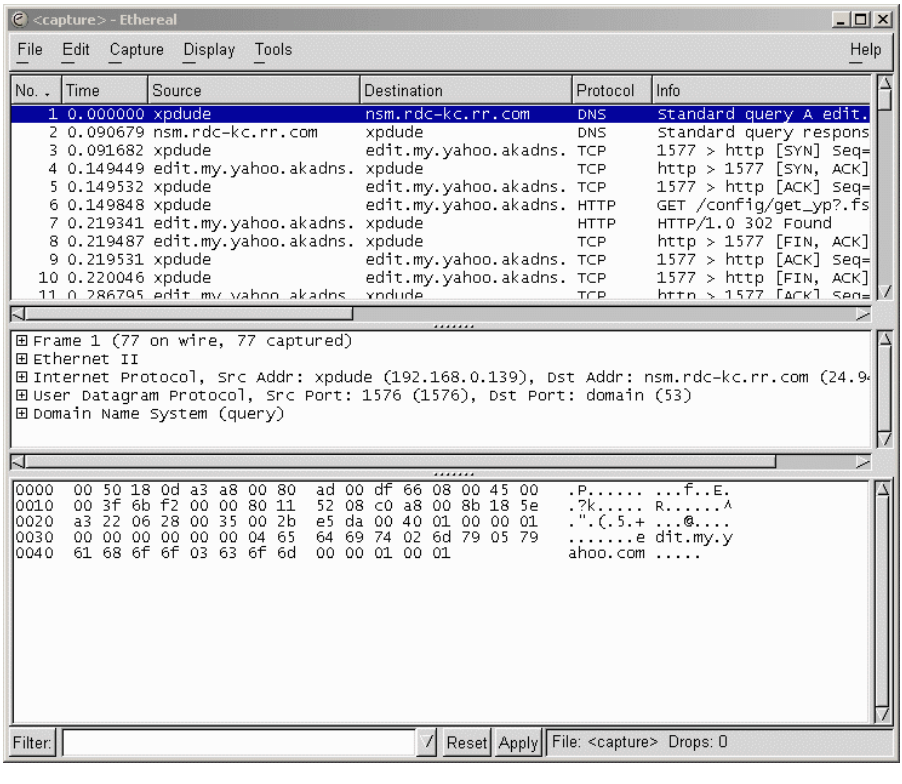

EXHIBIT 53.2 The Ethereal capture session.

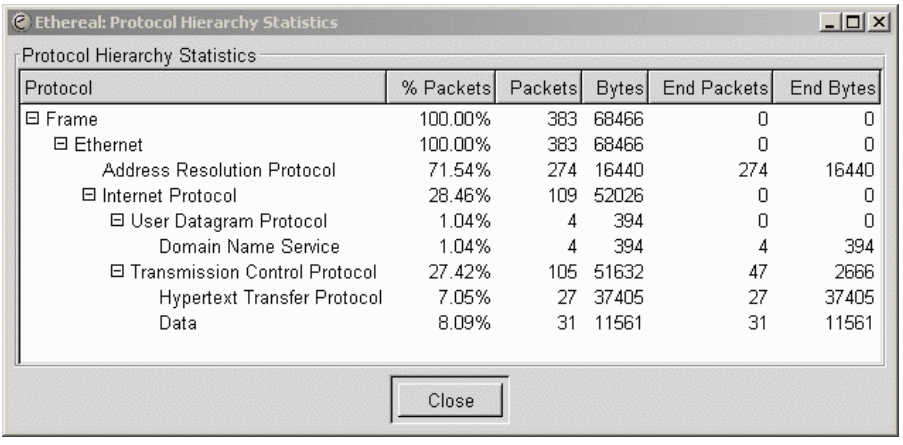
Simply click on "Stop" to end the capture session. Exhibit 53.2 shows an example of what the Ethereal capture session looks like. The top window of the session displays the individual packets in the capture session. The information displayed includes the packet number, the time the packet arrived since the capture was



Protocol	% Packets	Packets	Bytes	End Packets	End Bytes
⊟ Frame	100.00%	383	68466	0	0
⊟ Ethernet	100.00%	383	68466	0	0
Address Resolution Protocol	71.54%	274	16440	274	16440
⊟ Internet Protocol	28.46%	109	52026	0	0
⊟ User Datagram Protocol	1.04%	4	394	0	0
Domain Name Service	1.04%	4	394	4	394
⊟ Transmission Control Protocol	27.42%	105	51632	47	2666
Hypertext Transfer Protocol	7.05%	27	37405	27	37405
Data	8.09%	31	11561	31	11561

EXHIBIT 53.3 The protocol hierarchy statistics.

started, the source address of the packet, the destination address of the packet, the protocol, and other information about the packet.

The second window parses and displays the individual packet in an easily readable format, in this case packet number one. Further detail regarding the protocol and the source and destination addresses is displayed in summary format.

The third window shows a data dump of the packet displaying both the hex and ASCII values of the entire packet.

Further packet analysis can be done by clicking on the "Tools" menu. Clicking on "Protocol Hierarchy Statistics" will generate a summary report of the protocols captured during the session. Exhibit 53.3 shows an example of what the protocol hierarchy statistics would look like.

The security practitioner can also get overall statistics on the session, including total packets captured, elapsed time, average packets per second, and the number of dropped packets.

Ethereal is a very powerful tool that is freely available over the Internet. While it may take an expert to fully understand the capture sessions, it does not take an expert to download and install the tool. Certainly the aspiring hacker would have no trouble with the installation and configuration. The security practitioner should understand the availability, features, and ease of use of packet sniffers like Ethereal. Having an awareness of these tools will allow the security practitioner to better understand how the packet sniffer could be used to exploit weaknesses and how to mitigate risk associated with them.

Legitimate Uses

Because the sniffer was invented to help network administrators, many legitimate uses exist for it. Troubleshooting was the first use for the sniffer, but performance analysis quickly followed. Now, many uses for sniffers exist, including those for intrusion detection.

Troubleshooting

The most obvious use for a sniffer is to troubleshoot a network or application problem. From a network troubleshooting perspective, capture tools can tell the network administrator how many computers are communicating on a network segment, what protocols are used, who is sending or receiving the most traffic, and many other details about the network and its hosts. For example, some network-centric applications are very complex and have many components. Here is a list of some of some components that play a role in a typical client/server application:

- Client hardware
- Client software (OS and application)
- Server hardware

- Server software (OS and application)
- Routers
- Switches
- Hubs
- Ethernet network, T1s, T3s, etc.

This complexity often makes the application extremely difficult to troubleshoot from a network perspective. A packet sniffer can be placed anywhere along the path of the client/server application and can unravel the mystery of why an application is not functioning correctly. Is it the network? Is it the application? Perhaps it has to do with lookup issues in a database. The sniffer, in the hands of a skilled network analyst, can help determine the answers to these questions.

A packet sniffer is a powerful troubleshooting tool for several reasons. It can filter traffic based on many variables. For example, let us say the network administrator is trying to troubleshoot a slow client/server application. He knows the server name is *slopoke.xyzcompany.com* and the host's name is *impatient.xyzcompany.com*. The administrator can set up a filter to only watch traffic between the server and client.

The placement of the packet sniffer is critical to the success of the troubleshooting. Because the sniffer only sees packets on the *local* network segment, the sniffer must be placed in the correct location. In addition, when analyzing the capture, the analyst must keep the location of the packet sniffer in mind in order to interpret the capture correctly.

If the analyst suspects the server is responding slowly, the sniffer could be placed on the same network segment as the server to gather as much information about the server traffic as possible. Conversely, if the client is suspected of being the cause, the sniffer should be placed on the same network segment as the client. It may be necessary to place the tool somewhere between the two endpoints.

In addition to placement, the network administrator may need to set up a filter to only watch certain protocols. For instance, if a Web application using HTTP on port 80 is having problems, it may be beneficial to create a filter to only capture HTTP packets on port 80. This filter will significantly reduce the amount of data the troubleshooting will need to sift through to find the problem. Keep in mind, however, that setting this filter can configure the sniffer to miss important packets that could be the root cause of the problem.

Performance and Network Analysis

Another legitimate use of a packet sniffer is for network performance analysis. Many packet sniffer tools can also provide a basic level of network performance and analysis. They can display the general health of the network, network utilization, error rates, summary of protocols, etc. Specialized performance management tools use specialized packet sniffers called RMON probes to capture and forward information to a reporting console. These systems collect and store network performance and analysis information in a database so the information can be displayed on an operator console, or displayed in graphs or summary reports.

Network-Based Intrusion Detection

Network-based intrusion detection systems (IDSs) use a sniffer-like packet capture tool as the primary means of capturing data for analysis. A network IDS captures packets and compares the packet signatures to its database of attacks for known attack signatures. If it sees a match, it logs the appropriate information to the IDS logs. The security practitioner can then go back and review these logs to determine what happened. If in fact the attack was successful, this information can later be used to determine how to mitigate the attack or vulnerability to prevent it from happening in the future.

Verifying Security Configurations

Just as the network administrator can use the sniffer to troubleshoot a network problem, so too can the security practitioner use the sniffer to verify security configurations. A security practitioner can use a packet sniffer to review a VPN application to see if data is being transferred between gateways or hosts in encrypted format.

The packet sniffer can also be used to verify a firewall configuration. For example, if a security practitioner has recently installed a new firewall, it would be prudent to test the firewall to make sure its configuration is stopping the protocols it has been configured to stop. The security practitioner can place a packet sniffer on

the network behind the firewall and then use a separate host to scan ports of the firewall, or open up connections to hosts that sit behind the firewall. If the firewall is configured correctly, it will only allow ports and connections to be established based on its rule set. Any discrepancies could be reviewed to determine if the firewall is misconfigured or if there is simply an underlying problem with the firewall architecture.

Misuse

Sniffing has long been one of the most popular forms of passive attacks by hackers. The ability to "listen" to network conversations is very powerful and intriguing. A hacker can use the packet sniffer for a variety of attacks and information-gathering activities. They can be installed to capture usernames and passwords, gather information on other hosts attached to the same network, read e-mail, or capture other proprietary information or data.

Hackers are notorious for installing *root kits* on their victim hosts. These root kits contain various programs designed to circumvent security on a host and allow a hacker to access a host without the administrator's knowledge. Most modern root kits, or backdoor programs, include tools such as stealth backdoors, keystroke loggers, and often specialized packet sniffers that can capture sensitive information. The SubSeven backdoor for Windows even includes a remotely accessible GUI (graphical user interface) packet sniffer. The GUI makes the packet sniffer easily accessible and simple to use. The packet sniffer can be configured to collect network traffic, save this information into a log, and relay these logs.

Network Discovery

Information gathering is one of the first steps hackers must take when attacking a host. In this phase of the attack, they are trying to learn as much about a host or network as they can. If the attackers have already compromised a host and installed a packet sniffer, they can quickly learn more about the compromised host as well as other hosts with whom that host communicates. Hosts are often configured to trust one another. This trust can quickly be discovered using a packet sniffer. In addition, the attacker can quickly learn about other hosts on the same network by monitoring the network traffic and activity.

Network topology information can also be gathered. By reviewing the IP addresses and subnets in the captures, the attacker can quickly get a feel for the layout of the network. What hosts exist on the network and are critical? What other subnets exist on the network? Are there extranet connections to other companies or vendors? All of these questions can be answered by analyzing the network traffic captured by the packet sniffer.

Credential Sniffing

Credential sniffing is the act of using a packet capture tool to specifically look for usernames and passwords. Several programs exist only for this specific purpose. One such UNIX program called *Esniff.c* only captures the first 300 bytes of all Telnet, FTP, and rlogin sessions. This particular program can capture username and password information very quickly and efficiently.

In the Windows environment, L0phtcrack is a program that contains a sniffer that can capture hashed passwords used by Windows systems using LAN manager authentication. Once the hash has been captured, the L0phtcrack program runs a dictionary attack against the password. Depending on the length and complexity of the password, it can be cracked in a matter of minutes, hours, or days.

Another popular and powerful password sniffing program is *dsniff*. This tool's primary purpose is credential sniffing and can be used on a wide range of protocols including, but not limited to, HTTP, HTTPS, POP3, and SSH.

Use of a specific program like Esniff.c, L0phtcrack, or dsniff is not even necessary, depending on the application or protocol. A simple packet sniffer tool in the hands of a skilled hacker can be very effective. This is due to the very insecure nature of the various protocols. Exhibit 53.4lists some of the protocols that are susceptible to packet sniffing.

E-Mail Sniffing

How many network administrators or security practitioners have sent or received a password via e-mail? Most, if not all, have at some point in time. Very few e-mail systems are configured to use encryption and are therefore

EXHIBIT 53.4 Protocols Vulnerable to Packet Sniffing

Protocol	Vulnerability
Telnet and rlogin	Credentials and data are sent in cleartext
HTTP	Basic authentication sends credentials in a simple encoded form, not encrypted; easily readable if SSL or other encryption is not used
FTP	Credentials and data are sent in cleartext
POP3 and IMAP	Credentials and data are sent in cleartext
SNMP	Community strings for SNMPv1 (the most widely used) are sent in cleartext, including both *public* and *private* community strings

vulnerable to packet sniffers. Not only is the content of the e-mail vulnerable but the usernames and passwords are often vulnerable as well. POP3 (Post Office Protocol version 3) is a very popular way to access Internet e-mail. POP3 in its basic form uses usernames and passwords that are not encrypted. In addition, the data can be easily read.

Security is always a balance of what is secure and what is convenient. Accessing e-mail via a POP3 client is very convenient. It is also very insecure. One of the risks security practitioners must be aware of is that, by allowing POP3 e-mail into their enterprise network, they may also be giving hackers both a username and password to access their internal network. Many systems within an enterprise are configured with the same usernames; and from the user's standpoint, they often synchronize their passwords across multiple systems for simplicity's sake or possibly use a single sign-on system. For example, say John Smith has a username of "JSMITH" and has a password of "FvYQ-6d3." His username would not be difficult to guess, but his password is fairly complex and contains a random string of characters and numbers. The enterprise network that John is accessing has decided to configure its e-mail server to accept POP3 connections because several users, including John, wanted to use a POP3 client to remotely access their e-mail. The enterprise also has a VPN device configured with the same username and password as the e-mail system. If attackers compromise John's password via a packet sniffer watching the POP3 authentication sequence, they may quickly learn they now have access directly into the enterprise network using the same username and password on the Internet-accessible host called "VPN."

This example demonstrates the vulnerability associated with allowing certain insecure protocols and system configurations. Although the password may not have been accessible through brute force, the attackers were able to capture the password in the clear along with its associated username. In addition, they were able to capitalize on the vulnerability by applying the same username and password to a completely separate system.

Advanced Sniffing Tools

Switched Ethernet Networks

"No need to worry. I have a switched Ethernet network." Wrong! It used to be common for network administrators to refer to a switched network as secure. While it is true they are more secure, several vulnerabilities and techniques have surfaced over the past several years that make them less secure.

Reconfigure SPAN/Mirror Port

The most obvious way to capture packets in a switched network is to reconfigure the switch to send all packets to the port into which the packet sniffer is plugged. This can be done with one simple command line in a Cisco router. Once configured, the switch will send all packets for a port, group of ports, or even an entire VLAN directly to the specified port.

This emphasizes the need for increased switch security in today's environments. A single switch without a password, or with a simple password, can allow an intruder access to a plethora of data and information. Incidentally, this is an excellent reason why a single Ethernet switch should not be used inside and outside a firewall. Ideally, the outside, inside, and DMZ should have their own separate physical switches. Also, use a

stronger form of authentication on the network devices other than passwords only. If passwords must be used, make sure they are very complex; and do not use the same password for the outside, DMZ, and inside switches.

Switch Jamming

Switch jamming involves overflowing the address table of a switch with a flood of false MAC addresses. For some switches this will cause the switch to change from "bridging" mode into "repeating" mode, where all frames are broadcast to all ports. When the switch is in repeating mode, it acts like a hub and allows an attacker to capture packets as if they were on the same local area network.

ARP Redirect

An ARP redirect is where a host is configured to send a false ARP request to another host or router. This false request essentially tricks the target host or router into sending traffic destined for the victim host to the attack host. Packets are then forwarded from the attacker's computer back to the victim host, so the victim cannot tell the communication is being intercepted. Several programs exist that allow this to occur, such as *ettercap*, *angst*, and *dsniff*.

ICMP Redirect

An ICMP redirect is similar to the ARP redirect, but in this case the victim's host is told to send packets directly to an attacker's host, regardless of how the switch thinks the information should be sent. This too would allow an attacker to capture packets to and from a remote host.

Fake MAC Address

Switches forward information based on the MAC (Media Access Control) address of the various hosts to which it is connected. The MAC address is a hardware address that is supposed to uniquely identify each node of a network. This MAC address can be faked or forged, which can result in the switch forwarding packets (originally destined for the victim's host) to the attacker's host. It is possible to intercept this traffic and then forward the traffic back to the victim computer, so the victim host does not know the traffic is being intercepted.

Other Switch Vulnerabilities

Several other vulnerabilities related to switched networks exist; but the important thing to remember is that, just because a network is built entirely of switches, it does not mean that the network is not vulnerable to packet sniffing. Even without exploiting a switch network vulnerability, an attacker could install a packet sniffer on a compromised host.

Wireless Networks

Wireless networks add a new dimension to packet sniffing. In the wired world, an attacker must either remotely compromise a system or gain physical access to the network in order to capture packets. The advent of the wireless network has allowed attackers to gain access to an enterprise without ever setting foot inside the premises. For example, with a simple setup including a laptop, a wireless network card, and software packages downloaded over the Internet, an attacker has the ability to detect, connect to, and monitor traffic on a victim's network.

The increase in the popularity of wireless networks has also been followed by an increase in *war-driving*. War-driving is the act of driving around in a car searching for wireless access points and networks with wireless sniffer-like tools. The hacker can even configure a GPS device to log the exact location of the wireless network. Information on these wireless networks and their locations can be added to a database for future reference. Several sites on the Internet even compile information that people have gathered from around the world on wireless networks and their locations.

Reducing the Risk

There are many ways to reduce the risk associated with packet sniffers. Some of them are easy to implement, while others take complete reengineering of systems and processes.

Use Encryption

The best way to mitigate risk associated with packet sniffers is to use encryption. Encryption can be deployed at the network level, in the applications, and even at the host level. Exhibit 53.5 lists the "insecure" protocols discussed in the previous section, and suggests a "secure" solution that can be deployed.

Security practitioners should be aware of the protocols in use on their networks. They should also be aware of the protocols used to connect to and transfer information outside their network (either over the Internet or via extranet connections). A quick way to determine if protocols vulnerable to sniffing are being used is to check the rule set on the Internet or extranet firewalls. If insecure protocols are found, the security practitioner should investigate each instance and determine exactly what information is being transferred and how sensitive the information is. If the information is sensitive and a more secure alternative exists, the practitioner should recommend and implement a secure alternative. Often, this requires the security practitioner to educate the users on the issues associated with using insecure means to connect to and send information to external parties.

IPSec VPNs

A properly configured IPSec VPN can significantly reduce the risk associated with insecure protocols as well. The VPN can be configured from host to host, host to gateway, or gateway to gateway, depending on the environment and its requirements. The VPN "tunnels" the traffic in a secure fashion that prevents an attacker from sniffing the traffic as it traverses the network. Keep in mind, however, that even if a VPN is installed, an attack could still compromise the endpoints of the VPN and have access to the sensitive information directly on the host. This highlights the increased need for strong host security on the VPN endpoint, whether it is a Windows client connecting from a home network or a VPN router terminating multiple VPN connections.

Use Strong Authentication

Because passwords are vulnerable to brute-force attack or outright sniffing over the network, an obvious risk mitigation would be to stop using passwords and use a stronger authentication mechanism. This could involve using Kerberos, token cards, smart cards, or even biometrics. The security practitioner must take into consideration the business requirements and the costs associated with each solution before determining which authentication method suits a particular system, application, or enterprise as a whole.

By configuring a system to use a strong authentication method, the vulnerability of discovered passwords is no longer an issue.

Patches and Updates

To capture packets on the network, a hacker must first compromise a host (assuming the hacker does not have physical access). If all the latest patches have been applied to the hosts, the risk of someone compromising a host and installing a capture tool will be significantly reduced.

EXHIBIT 53.5 Suggestions for Mitigating Risk Associated with Insecure Protocols

Insecure Protocol	Secure Solution
Telnet and rlogin	Replace Telnet or rlogin with Secure Shell (SSH)
HTTP	Run the HTTP or HTTPS session over a Secure Socket Layer (SSL) or Transport Layer Security (TLS) connection
FTP	Replace with secure copy (SCP) or create an IPSec VPN between the hosts
POP3 and IMAP	Replace with SMIME or use PGP encryption
SNMP	Increase the security by using SNMPv2 or SNMPv3, or create a management IPSec VPN between the host and the network management server

Secure the Wiring Closets

Because physical access is one way to access a network, make sure your wiring closets are locked. It is a very simple process to ensure the doors are secured to the wiring closets. A good attack and penetration test will often begin with a check of the physical security and of the security of the wiring closets. If access to a closet is gained and a packet sniffer is set up, a great deal of information can be obtained in short order.

There is an obvious reason why an attack and penetration might begin this way. If the perimeter network and the remote access into a company are strong, the physical security may likely be the weak link in the chain. A hacker who is intent on gaining access to the network goes through the same thought process. Also, keep in mind that with the majority of attacks originating from inside the network, you can mitigate the risk of an internal employee using a packet sniffer in a wiring closet by simply locking the doors.

Detecting Packet Sniffers

Another way to reduce the risk associated with packet sniffers is to monitor the monitors, so to speak. This involves running a tool that can detect a host's network interface cards running in promiscuous mode. Several tools exist, from simple command-line utilities — which tell whether or not a NIC on the local host is running in promiscuous mode — to more elaborate programs such as Antisniff, which actively scans the network segment looking for other hosts with NICs running in promiscuous mode.

Summary

The sniffer can be a powerful tool in the hands of the network administrator or security practitioner. Unfortunately, it can be equally powerful in the hands of the hacker. Not only are these tools powerful, but they are also relatively easy to download off the Internet, install, and use. Security practitioners must be aware of the dangers of packet sniffers and must design and deploy security solutions that mitigate the risks associated with them. Keep in mind that using a packet sniffer to gather credential information on one system can often be used to access other unrelated systems with the same username and password.

54

ISPs and Denial-of-Service Attacks

K. Narayanaswamy, Ph.D.

A denial-of-service (DoS) attack is any malicious attempt to deprive legitimate customers of their ability to access services, such as a Web server. DoS attacks fall into two broad categories:

1. *Server vulnerability DoS attacks:* attacks that exploit known bugs in operating systems and servers. These attacks typically will use the bugs to crash programs that users routinely rely upon, thereby depriving those users of their normal access to the services provided by those programs. Examples of vulnerable systems include all operating systems, such as Windows NT or Linux, and various Internet-based services, such as DNS, Microsoft's IIS Servers, Web servers, etc. All of these programs, which have important and useful purposes, also have bugs that hackers exploit to bring them down or hack into them. This kind of DoS attack usually comes from a single location and searches for a known vulnerability in one of the programs it is targeting. Once it finds such a program, the DoS attack will attempt to crash the program to deny service to other users. Such an attack does not require high bandwidth.
2. *Packet flooding DoS attacks:* attacks that exploit weaknesses in the Internet infrastructure and its protocols. Floods of seemingly normal packets are used to overwhelm the processing resources of programs, thereby denying users the ability to use those services. Unlike the previous category of DoS attacks, which exploit bugs, flood attacks require high bandwidth in order to succeed. Rather than use the attacker's own infrastructure to mount the attack (which might be easier to detect), the attacker is increasingly likely to carry out attacks through intermediary computers (called *zombies*) that the attacker has earlier broken into. Zombies are coordinated by the hacker at a later time to launch a *distributed* DoS (DDoS) attack on a victim. Such attacks are extremely difficult to trace and defend with the present-day Internet. Most zombies come from home computers, universities, and other vulnerable infrastructures. Often, the owners of the computers are not even aware that their machines are being co-opted in such attacks. The hacker community has invented numerous scripts to make it convenient for those interested in mounting such attacks to set up and orchestrate the zombies. Many references are available on this topic.[1–4]

We will invariably use the term "DoS attacks" to mean all denial-of-service attacks, and DDoS to mean flood attacks as described above.

As with most things in life, there is good news and bad news in regard to DDoS attacks. The bad news is that there is no "silver bullet" in terms of technology that will make the problem disappear. The good news, however, is that with a combination of common-sense processes and practices with, in due course, appropriate technology, the impact of DDoS attacks can be greatly reduced.

The Importance of DDoS Attacks

Many wonder why network security and DDoS problems in particular have seemingly increased suddenly in seriousness and importance. The main reason, ironically, is the unanticipated growth and success of ISPs. The rapid growth of affordable, high-bandwidth connection technologies (such as DSL, cable modem, etc.) offered by various ISPs has brought in every imaginable type of customer to the fast Internet access arena: corporations, community colleges, small businesses, and the full gamut of home users.

Unfortunately, people who upgrade their bandwidth do not necessarily upgrade their knowledge of network security at the same time; all they see is what they can accomplish with speed. Few foresee the potential security dangers until it is too late. As a result, the Internet has rapidly become a high-speed network with depressingly low per-site security expertise. Such a network is almost an ideal platform to exploit in various ways, including the mounting of DoS attacks. Architecturally, ISPs are ideally situated to play a crucial role in containing the problem, although they have traditionally not been proactive on security matters.

A recent study by the University of San Diego estimates that there are over 4000 DDoS attacks every week.[5] Financial damages from the infamous February 2000 attacks on Yahoo, CNN, and eBay were estimated to be around $1 billion.[6] Microsoft, Internet security watchdog CERT, the Department of Defense, and even the White House have been targeted by attackers. Of course, these are high-profile installations, with some options when it comes to responses. Stephen Gibson documents how helpless the average enterprise might be to ward off DDoS attacks (at www.scr.com). There is no doubt that DoS attacks are becoming more numerous and deadly.

Why Is DDoS an ISP Problem?

When major corporations suffer the kind of financial losses just described and given the fanatically deterministic American psyche that requires a scapegoat (if not a reasonable explanation) for every calamity and the litigious culture that has resulted from it, rightly or wrongly, someone is eventually going to pay dearly. The day is not far off when, in the wake of a devastating DDoS attack, an enterprise will pursue litigation against the owner of the infrastructure that could (arguably) have prevented an attack with due diligence. A recent article explores this issue further from the legal perspective of an ISP.[7]

Our position is not so much that you need to handle DDoS problems proactively today; however, we do believe you would be negligent not to examine the issue immediately from a cost/benefit perspective. Even if you have already undertaken such an assessment, you may need to revisit the topic in light of new developments and the state of the computing world after September 11, 2001.

The Internet has a much-ballyhooed, beloved, open, chaotic, *laissez faire* philosophical foundation. This principle permeates the underlying Internet architecture, which is optimized for speed and ease of growth and which, in turn, has facilitated the spectacular explosion and evolution of this infrastructure. For example, thus far, the market has prioritized issues of privacy, speed, and cost over other considerations such as security. However, changes may be afoot and ISPs should pay attention.

Most security problems at various enterprise networks are beyond the reasonable scope of ISPs to fix. However, the DDoS problem is indeed technically different. Individual sites *cannot* effectively defend themselves against DDoS attacks without some help from their infrastructure providers. When under DDoS attack, the enterprise cannot block out the attack traffic or attempt to clear upstream congestion to allow some of its desirable traffic to get through. Thus, the very nature of the DDoS problem virtually compels the involvement of ISPs. The best possible outcome for ISPs is to jump in and shape the emerging DDoS solutions voluntarily with dignity and concern, rather than being perceived as having been dragged, kicking and screaming, into a dialogue they do not want.

Uncle Sam is weighing in heavily on DDoS as well. In December 2001, the U.S. Government held a DDoS technology conference in Arlington, Virginia, sponsored by the Defense Advanced Research Projects Agency (DARPA) and the Joint Task Force–Central Network Operations. Fourteen carefully screened companies were selected to present their specific DDoS solutions to the government. Newly designated cyber-security czar Richard Clarke, who keynoted the conference, stressed the critical importance of DDoS and how the administration views this problem as a threat to the nation's infrastructure, and that protecting the Internet infrastructure is indeed part of the larger problem of homeland security. The current Republican administration, one might safely assume, is disposed toward deregulation and letting the market sort out the DDoS problem. In the reality of post-September 11 thinking, however, it is entirely conceivable that ISPs will eventually be forced to contend with government regulations mandating what they should provide by way of DDoS protection.

What Can ISPs Do About DDoS Attacks?

When it comes to DDoS attacks, security becomes a two-way street. Not only must the ISP focus on providing as much protection as possible against incoming DDoS attacks against its customers, but it must also do as much as possible to prevent outgoing DDoS attacks from being launched from its own infrastructure against others. All these measures are feasible and cost very little in today's ISP environment. Minimal measures such as these can significantly reduce the impact of DDoS attacks on the infrastructure, perhaps staving off more draconian measures mandated by the government.

An ISP today must have the ability to contend with the DDoS problem at different levels:

- Understand and implement best practices to defend against DDoS attacks.
- Understand and implement necessary procedures to help customers during DDoS attacks.
- Assess DDoS technologies to see if they can help.

We address each of these major areas below.

Defending against DDoS Attacks

In discussing what an ISP can do, it is important to distinguish the ISP's own infrastructure (its routers, hosts, servers, etc.), which it fully controls, from the infrastructure of the customers who lease its Internet connectivity, which the ISP cannot, and should not, control. Most of the measures we recommend for ISPs are also appropriate for their customers to carry out. The extent to which ISPs can encourage or enable their customers to follow these practices will be directly correlated to the number of DDoS attacks.

Step 1: Ensure the Integrity of the Infrastructure

An ISP plays a critical role in the Internet infrastructure. It is, therefore, very important for ISPs to ensure that their own routers and hosts are resistant to hacker compromise. This means following all the necessary best practices to protect these machines from break-ins and intrusions of any kind. Passwords for user and root accounts must be protected with extra care, and old accounts must be rendered null and void as soon as possible.

In addition, ISPs should ensure that their critical servers (DNS, Web, etc.) are always current on software patches, particularly if they are security related. These programs will typically have bugs that the vendor eliminates through new patches.

When providing services such as Telnet, FTP, etc., ISPs should consider the secure versions of these protocols such as SSH, SCP, etc. The latter versions use encryption to set up secure connections, making it more difficult for hackers using packet sniffing tools to acquire usernames and passwords, for example.

ISPs can do little to ensure that their users are as conscientious about these matters as they ought to be. However, providing users with the knowledge and tools necessary to follow good security practices themselves will be very helpful.

Step 2: Resist Zombies in the Infrastructure

Zombies are created by hackers who break into computers. Although by no means a panacea, tools such as intrusion detection systems (IDSs) provide some amount of help in detecting when parts of an infrastructure have become compromised. These tools vary widely in functionality, capability, and cost. They have a lot of utility in securing computing assets beyond DDoS protection. (A good source on this topic is Reference 8.) Certainly, larger customers of the ISP with significant computing assets should also consider such tools.

Where possible, the ISP should provide users (e.g., home users or small businesses) with the necessary software (e.g., downloadable firewalls) to help them. Many ISPs are already providing free firewalls, such as ZoneAlarm, with their access software. Such firewalls can be set up to maximize restrictions on the customers' computers (e.g., blocking services that typical home computers are never likely to provide). Simple measures like these can greatly improve the ability of these computers to resist hackers.

Most zombies can be now be discovered and removed from a computer by the traditional virus scanning software from McAffee, Symantec, and other vendors. It is important to scan not just programs but also any documents with executable content (such as macros). In other words, everything on a disk requires scanning. The only major problem with all virus scanning regimes is that they currently use databases that have signatures of known viruses, and these databases require frequent updates as new viruses are created.

As with firewalls, at least in cases where users clearly can use the help, the ISP could try bundling its access software, if any, with appropriate virus scanning software and make it something the user has to contend with before getting on the Internet.

Step 3: Implement Appropriate Router Filters

Many DDoS attacks (e.g., Trinoo, Tribal Flood, etc.) rely on source address spoofing, an underlying vulnerability of the Internet protocols whereby the sender of a packet can conjure up a source address other than his actual address. In fact, the protocols allow packets to have completely fabricated, nonexistent source addresses. Several attacks actually rely on this weakness in the Internet. This makes attacks much more difficult to trace because one cannot figure out the source just by examining the packet contents because the attacker controls that.

There is no legitimate reason why an ISP should forward outgoing packets that do not have source addresses from its known legitimate range of addresses. It is relatively easy, given present-day routers, to filter outgoing packets at the border of an ISP that do not have valid source addresses. This is called ingress filtering, described in more detail in RFC 2267.

Routers can also implement egress filtering at the point where traffic enters the ISP to ensure that source addresses are valid to the extent possible (e.g., source addresses cannot be from the ISP, packets from specific interfaces must match expected IP addresses, etc.). Note that such filters do not eliminate all DDoS attacks; however, they do force attackers to use methods that are more sophisticated and do not rely on ISPs forwarding packets with obviously forged source addresses.

Many ISPs also have blocks of IP addresses set aside that will never be the source or destination of Internet traffic (see RFC 1918). These are addresses for traffic that will never reach the Internet. The ISP should neither accept traffic with this destination, nor should it allow outbound traffic from those IP addresses set aside in this manner.

Step 4: Disable Facilities You May Not Need

Every port that you open (albeit to provide a legitimate service) is a potential gate for hackers to exploit. Therefore, ISPs, like all enterprises, should ensure they block any and all services for which there is no need. Customer sites should certainly be provided with the same recommendations.

You should evaluate the following features to see if they are enabled and what positive value you get from their being enabled in your network:

- *Directed broadcast.* Some DDoS attacks rely on the ability to broadcast packets to many different addresses to amplify the impact of their handiwork. Directed broadcast is a feature that should not be needed for inbound traffic on border routers at the ISP.
- *Source routing.* This is a feature that enables the sender of a packet to specify an ISP address through which the packet must be routed. Unless there is a compelling reason not to, this feature should be disabled because compromised computers within the ISP infrastructure can exploit this feature to become more difficult to locate during attacks.

Step 5: Impose Rate Limits on ICMP and UDP Traffic

Many DDoS attacks exploit the vulnerability of the Internet where the entire bandwidth can be filled with undesirable packets of different descriptions. ICMP (Internet Control Message Protocol, or ping) packets and User Datagram Protocol (UDP) are examples of this class of packets. You cannot completely eliminate these kinds of packets, but neither should you allow the entire bandwidth to be filled with such packets.

The solution is to use your routers to specify rate limits for such packets. Most routers come with simple mechanisms called class-based queuing (CBQ), which you can use to specify the bandwidth allocation for different classes of packets. You can use these facilities to limit the rates allocated for ICMP, UDP, and other kinds of packets that do not have legitimate reasons to hog all available bandwidth.

Assisting Customers during a DDoS Attack

It is never wise to test a fire hydrant during a deadly blaze. In a similar manner, every ISP will do well to think through its plans should one of its customers become the target of DDoS attacks. In particular, this will entail full understanding and training of the ISP's support personnel in as many (preferably all) of the following areas as possible:

- *Know which upstream providers forward traffic to the ISP.* ISP personnel need to be familiar with the various providers with whom the ISP has Internet connections and the specific service level agreements (SLAs) with each, if any. During a DDoS attack, bad traffic will typically flow from one or more of these upstream providers, and the options of an ISP to help its customers will depend on the specifics of its agreements with its upstream providers.
- *Be able to identify and isolate traffic to a specific provider.* Once the customer calls during a DDoS directed at his infrastructure, the ISP should be able to determine the source of the bad traffic. All personnel should be trained in the necessary diagnostics to do so. Customers will typically call with the ISP addresses they see on the attack traffic. While this might not be the actual source of the attack, because of source spoofing, it should help the ISP in locating which provider is forwarding the bad traffic.
- *Be able to filter or limit the rate of traffic from a given provider.* Often, the ISP will be able to contact the upstream provider to either filter or limit the rate of attack traffic. If the SLA does not allow for this, the ISP can consider applying such a filter at its own router to block the attack traffic.
- *Have reliable points of contact with each provider.* The DDoS response by an ISP is only as good as its personnel and their knowledge of what to do and whom to contact from their upstream providers. Once again, such contacts cannot be cultivated after an attack has occurred. It is better to have these pieces of information in advance. Holding DDoS attack exercises to ensure that people can carry out their duties during such attacks is the best way to make sure that everyone knows what to do to help the customer.

Assessing DDoS Technologies

Technological solutions to the DDoS problem are intrinsically complex. DDoS attacks are a symptom of the vulnerabilities of the Internet, and a single site is impossible to protect without cooperation from upstream infrastructure. New products are indeed emerging in this field; however, if you are looking to eliminate the problem by buying an affordable rack-mountable panacea that keeps you in a safe cocoon, you are fresh out of luck.

Rather than give you a laundry list of all the vendors, I am going to categorize these products somewhat by the problems they solve, their features, and their functionality so that you can compare apples to apples. Still, the comparison can be a difficult one because various products do different things and more vendors are continually entering this emerging, niche market.

Protection against Outgoing DDoS Attacks

Unlike virus protection tools, which are very general in focus, these tools are geared just to find DoS worms and scripts. There are basically two kinds of products that you can find here.

Host-Based DDoS Protection

Such protection typically prevents hosts from being taken over as zombies in a DDoS attack. These tools work in one of two major ways: (1) signature analysis, which, like traditional virus scanners, stores a database of known scripts and patterns and scans for known attack programs; and (2) behavior analysis, which monitors key system parameters for the behavior underlying the attacks (rather than the specific attack programs) and aborts the programs and processes that induce the underlying bad behavior.

Established vendors of virus scanning products, such as McAffee, Symantec, and others, have extended their purview to include DoS attacks. Other vendors provide behavior-analytic DDoS protection that essentially detects and prevents DDoS behavior emanating from a host. The major problem with host-based DDoS protection, from an ISP's perspective, is that one cannot force the customers to use such tools or to scan their disks for zombies, etc.

Damage-Control Devices

A few recent products (such as Captus' *Captio* and Cs3, Inc.'s *Reverse Firewall*[9,10]) focus on containing the harm that DDoS attacks can do in the outgoing direction. They restrict the damage from DDoS to the smallest possible network. These devices can be quite useful in conjunction with host-based scanning tools. Note that the damage-control devices do not actually prevent an infrastructure from becoming compromised; however, they do provide notification that there is bad traffic from your network and provide its precise origin. Moreover, they give you time to act by throttling the attack at the perimeter of your network and sending you a notification.

ISPs could consider using these devices as insurance to insulate themselves from the damage bad customers can do to them as infrastructure providers.

Protection against Incoming Attacks

As we have mentioned before, defending against incoming attacks at a particular site requires cooperation from the upstream infrastructure. This makes DDoS protection products quite complex. Moreover, various vendors have tended to realize the necessary cooperation in very different ways. A full treatment of all of these products is well beyond the scope of this chapter. However, here are several issues you need to consider as an ISP when evaluating these products:

- *Are the devices inline or offline?* An inline device will add, however minimally, to the latency. Some of the devices are built using hardware in an effort to reduce latency. Offline devices, while they do not have that problem, do not have the full benefit of looking at all the traffic in real-time. This could affect their ability to defend effectively.
- *Do the devices require infrastructure changes and where do they reside?* Some of the devices either replace or deploy alongside existing routers and firewalls. Other technologies require replacement of the existing infrastructure. Some of the devices need to be close to the core routers of the network, while most require placement along upstream paths from the site being protected.
- *How do the devices detect DDoS attacks and what is the likelihood of false positives?* The degree of sophistication of the mechanism of detection and its effectiveness in indicating real attacks is all-important in any security technology. After all, a dog that barks the entire day does protect you from some burglars — but you just might stop listening to its warnings! Most of the techniques use comparisons of actual traffic to stored profiles of attacks, or "normal" traffic, etc. A variety of signature-based heuristics are applied to detect attacks. The jury is still out on how effective such techniques will be in the long run.
- *How do the devices know where the attack is coming from?* A major problem in dealing effectively with DDoS attacks is to know, with any degree of certainty, the source of the attacks. Because of source address spoofing on the Internet, packets do not necessarily have to originate where they say they do. All the technologies have to figure out is from where in the upstream infrastructure the attack traffic is flowing. It is the routers along the attack path that must cooperate to defend against the attack. Some of the approaches require that their devices communicate in real-time to form an aggregate picture of where the attack is originating.
- *What is the range of responses the devices will take and are you comfortable with them?* Any DDoS defense must minimally stop the attack from reaching the intended victim, thereby preventing the victim's computing resources from deteriorating or crashing. However, the real challenge of any DDoS defense is to find ways for legitimate customers to get through while penalizing only the attackers. This turns out to be *the* major technical challenge in this area. The most common response includes trying to install appropriate filters and rate limits to push the attack traffic to the outer edge of the realm of control of these devices. At the present time, all the devices that provide DDoS defense fall into this category. How effective they will be remains to be seen.

The products mentioned here are quite pricey even though the technologies are still being tested under fire. DDoS will have to be a very important threat in order for smaller ISPs to feel justified in investing their dollars in these devices. Finally, many of the approaches are proprietary in nature, so side-by-side technical comparisons are difficult to conduct. Some industry publications do seem to have tested some of these devices in various ways. A sampling of vendors and their offerings, applying the above yardsticks, is provided here:

- *Arbor Networks* (www.arbornetworks.com): offline devices, near core routers, anomaly-based detection; source is tracked by communication between devices, and defense is typically the positioning of a filter at a router where the bad traffic enters the network
- *Asta Networks* (www.astanetworks.com): offline devices that work alongside routers within a network and upstream, signature-based detection; source is tracked by upstream devices, and defense is to use filters at upstream routers

- *Captus Networks*
  (www.captusnetworks.com): inline device used to throttle incoming or outgoing attacks; uses windowing to detect non-TCP traffic and does not provide ways for customers to get in; works as a damage-control device for outgoing attacks
- *Cs3, Inc.*
  (www.cs3-inc.com): inline devices, modified routers, and firewalls; routers mark packets with path information to provide fair service, and firewalls throttle attacks; source of the attack provided by the path information, and upstream neighbors are used to limit attack traffic when requested; *Reverse Firewall* is a damage-control device for outgoing attacks
- *Mazu Networks*
  (www.mazunetworks.com): inline devices at key points in network; deviations from stored historical traffic profile indicate attack; the source of the attack is pinpointed by communication between devices, and defense is provided by using filters to block out the bad traffic
- *Okena*
  (www.okena.com): host-based system that has extended intrusion detection facilities to provide protection against zombies; it is a way to keep one's infrastructure clean but is not intended to protect against incoming attacks

Important Resources

Finally, the world of DoS, as is indeed the world of Internet security, is dynamic. If your customers are important to you, you should have people that are on top of the latest threats and countermeasures. Excellent resources in the DoS security arena include:

- *Computer Emergency Response Team (CERT)* (www.cert.org): a vast repository of wisdom about all security-related problems with a growing section on DoS attacks; you should monitor this site regularly to find out what you need to know about this area. This site has a very independent and academic flavor. Funded by the Department of Defense, this organization is likely to play an even bigger role in putting out alerts and other information on DDoS.
- *System Administration, Networking and Security (SANS) Institute* (www.sans.org): a cooperative forum in which you can instantly access the expertise of over 90,000 professionals worldwide. It is an organization of industry professionals, unlike CERT. There is certainly a practical orientation to this organization. It offers courses, conferences, seminars, and White Papers on various topics that are well worth the investment. It also provides alerts and analyses on security incidents through incidents.org, a related facility.

Domain 3
Security Management Practices

Security management entails the identification of an organization's information assets and the development, documentation, and implementation of policies, standards, procedures, and guidelines. It also includes management tools such as data classification and risk assessment (risk analysis) that are used to identify threats, classify assets, and to rate their vulnerabilities so that effective security controls can be implemented.

In this domain, we address the importance of establishing the foundation for the security program with policies that reflect the organization's philosophy about information asset protection. Among the practices discussed are how to deal with risk and how a practitioner manages risk to develop the trust and assurance required from information systems.

The organization's users are a critical component in achieving and maintaining information assurance. The best information security policy will sit dormant on a shelf unless the security manager has an effective, enterprisewide, ongoing security awareness campaign. Training experts agree that a well-developed communication plan can spell the difference between the success or failure of a security program.

Measuring ROI on Security

Carl F. Endorf, CISSP, SSCP, GSEC

Finding a return on investment (ROI) has never been easy; and for technology, it has been even more difficult. To make matters more complicated, the return on security investment (ROSI) has been nebulous at best. It is easy to say that a Web defacement or hack attack will cause a "loss of customer confidence," but what does that really mean? What is the financial impact on an organization if it experiences a loss of customer confidence? What needs to be determined is the causation of the financial impact and the event itself.[1] I believe that there are clear methods to do this.

The purpose of this chapter is to discuss the basic methods of finding the ROSI for an organization and the implications that this will have on the business of security. We also examine a seven-step analysis to help determine the ROI for security.

Understanding ROI

It is easy to get security money *after* you are attacked, but the problem is trying to get the money before that happens. How do you quantify what security gets you? If you spend an additional $3,000,000 this year on security, how do you justify it? What is the return on that investment? As a security professional, you see different vulnerabilities and attacks on a daily basis and it may be very clear to you that your enterprise needs to be more secure. But from a business perspective, it is not always that clear. Executives realize that threats are a reality, but they want some way to quantify these threats and know what the cost is for implementing a security measure or the financial consequences if they do not.

Many security managers rely on a soft return on investment (SROI) that is not based on actual data but on FUD (fear, uncertainty, and doubt) to sell the need for new security measures or the expansion of existing ones. The idea is that if you can scare enough people they will give you the money. The problem with this is that it can lead to implementing technology that is not always needed or that solves a problem where there is minimal risk of that threat.

Today more than ever, with a recession in the economy, it is difficult to justify with any solid evidence what security expenses are needed. For example, if you need to add three security people and update your firewalls, this will result in more uptime and less downtime on the network, which means the company will make more money; but where is the quantifiable value associated with staffing and firewalls?[2] The SROI will not help justify these costs.

This leads to the better answer of basing security expenditures on real numbers and obtaining a hard return on investment (HROI). The HROI will give a quantitative answer that will help justify the use of security and can help determine the operational cost of security.

Getting an HROI can be accomplished in much the same way a risk assessment is done. The following seven steps are involved in the process:[3]

1. Asset identification and valuation

2. Threat and vulnerability exposure factor (EF)
3. Determine the single loss expectancy (SLE)
4. Annualized rate of occurrence (ARO)
5. Compute the annual loss expectancy (ALE)
6. Survey controls
7. Calculate the ROSI

Asset Identification and Valuation

First, you need to list your organization's tangible and intangible assets. We define "tangible" as an asset that has physical form and "intangible" items as any item that does not have physical form, such as goodwill and intellectual property. Tangible items can usually be tracked easily in small organizations, but this becomes progressively more difficult as the size increases. Typically, larger organizations will have an asset management/tracking area that can provide a list. You will then need to assign a dollar value to each tangible asset, with depreciation taken into account. One way this can be done is as follows:[4]

$$\frac{\text{Cost} - \text{Salvage Value}}{\text{Useful Life}} = \text{Yearly Depreciation}$$

Next, make a list of intangible items. This can be subjective and is based on perceived value, but the following questions will help: "Knowing what you do about the asset, what would you pay to have that asset if you did not already own it?" and "What revenue will this asset bring to the organization in the future?"

Another possibility is to rank all your assets, both tangible and intangible, according to your perceived value of them. Given that you have values for the tangible assets, placement of the intangibles relative to the tangibles should help you in valuing the intangible assets.

Threat and Vulnerability Exposure Factor

Now that the assets have been identified, it is necessary to examine the possible threats to each of these assets. This is not a definite as there are many variables involved, but the subject matter experts for many of these assets can help identify exposures. This is an estimate; it cannot include everything possible because we do not know all the possible exposures.

The next step is to examine the threat and vulnerability exposure factor (EF). The EF is the percentage of loss a realized threat event would have on a specific asset, that is, the consequence. The EF can be a large number, as is the case of a major event such as a fire or a small number like the loss of a hard drive. It can be expressed from 0 to 100 percent of loss if exposed to a specific event. For example, if a virus brought down your Web farm, this may cause a 75 percent loss in the Web farm's functionality.

Determine the Single Loss Expectancy

The single loss expectancy (SLE) measures the specific impact, monetary or otherwise, of a single event. The following formula derives the SLE:[5]

$$\text{Asset value} \times \text{Exposure factor} = \text{SLE}$$

Annualized Rate of Occurrence

The annualized rate of occurrence (ARO) is the frequency with which a threat is expected to occur. The number is based on the severity of controls and the likelihood that someone will get past these controls.[6] ARO values fall within the range from 0.0 (never) to a large number.

The ARO is not a definite number and can be subjective. It is best based on probability from observed data, much like insurance. You will need to look at your organization's metrics on hardware, software, and past threats. For example, Company X looks at the past five years' incident handling data and finds that there was

an average of three attempts per external employee for the 100 external employees attempting unauthorized access. This would calculate to an ARO of 300, or 3 attempts × 100 external employees = 300.

Annual Loss Expectancy

The annual loss expectancy (ALE) can now be determined from the data collected. The following formula sets for the calculation needed:

$$\text{Single loss expectancy (SLE)} \times \text{Annual rate of occurrence (ARO)} = \text{ALE}$$

The ALE is the number you can use to justify your security expenditures. For example, you want to protect your payroll server within the company. The server itself will not cause a direct loss to the company if compromised, but will result in loss of reputation if exposed. The value of the system itself is $10,000, and the information and loss of reputation is placed at $250,000. The SLE has been placed at 75 percent and the ARO at 0.3. Using the formula above, we obtain an SLE of $58,500 ($260,000 × 0.75) × 0.3 = $58,500. Once the ALE is known, it can be used by information security management to determine a cost-effective risk mitigation strategy.[3]

Survey Controls

It is now essential to survey the controls that you have in your existing security architecture and examine the SLE of those assets. If the loss expectancy is exceptionally high, you would want to consider new controls to mitigate those threats. For example, using the situation in the previous section, we have an SLE of $58,000; but if we are spending $100,000 a year to protect it, we are spending more than we need and new controls should be selected. It is best if each exposure has a control identified for it on a per-exposure basis.

Calculate Your ROSI

Now we are at the point of being able to calculate the ROSI. The basic calculation for ROI is the Return/Assets. Therefore, we can subtract the cost of what we expect to lose in a year for a specific asset from the annual cost of the control:

$$\text{Annual loss expectancy (ALE)} - \text{Current cost of control (CCC)} = \text{ROSI}$$

For example, if in the past we had a cost of $500,000 a year due to security breaches and we add an intrusion detection system (IDS) that costs the company $250,000 a year (this includes support, maintenance, and management) and is 80 percent effective, then we have a positive ROI of $150,000.

ROSI Example

Now apply the seven steps to the following situation. You are asked to protect a small database that contains critical business data. The data has been valued at $5,000,000 and has never been compromised. Based on recent events in similar companies with this type server and data, the probability of an attack has been estimated to happen about once every 20 years. You are asked to look at the current access controls in place that are costing the company $95,000 a year to maintain and see what the ROSI is on these controls.

As you can see from Exhibit 57.1, the total ROSI for the current access control gives the organization a positive ROSI of $130,000 per year.

Arguments against ROSI

One argument is that valuating the ROSI lacks precision and is based on approximations. This is true to an extent; but as more data is collected within your organization and the industry, the picture will become clearer, much like insurance actuarial tables can predict the probabilities of certain events. Another argument is that these hard numbers can give a company a false sense of security because the company feels these numbers are

EXHIBIT 57.1 ROSI for Proprietary Confidential Data

Steps			Formula
Asset identification and valuation	**Asset**: proprietary confidential data	Valuation: $5,000,000	
Threat and vulnerability exposure factor (EF)	**Threat:** disclosure of data	**EF:** 90%	
Determine the single loss expectancy (SLE)	$5,000,000 × .90 =	**SLE:** $4,500,000	Asset Value × Exposure Factor = SLE
Annualized rate of occurrence (ARO)	Based on observed data, the probability is 1 in 20 years	ARO = 0.05	
Compute the annual loss expectancy (ALE)	$4,500,000 × .05 =	**ALE** = $225,000	Single Loss Expectancy (SLE) × Annual Rate of Occurrence (ARO) = ALE
Survey controls	Current controls are costing $95,000		
Calculate ROSI	$225,000 – $95,000	ROSI = $130,000	Annual loss expectancy (ALE) – Current cost of control (CCC) = ROSI

exact but needs to keep in mind that they need reevaluation. Another argument is that that the ROSI is immutable; but if it is made a part of the annual review process, this should not be the case.[3]

Conclusion

This chapter discussed a seven-step methodology to help determine the ROSI for an organization. The methods used were basic and could each be explained in much more depth, but they do illustrate that hard numbers can be obtained. These hard numbers help security managers to go away from using FUD and relying on better data. The data presented here is based on the principles of probability theory and statistics.

Although much of the data that the ROSI is based on is still in its infancy, it will likely take shape in the near future. The key is getting credible data to base the numbers on. We see this taking shape in the insurance industry as hacking insurance is being offered; these are steps in the right direction. It is likely that the insurance industry will be a driving force in the science of ROSI.[2]

Security Patch Management

Jeffrey Davis, CISSP

Patch management is an important part of securing your computing environment. New security vulnerabilities are found in software and systems every day, and these vulnerabilities can introduce risk into an organization's information technology infrastructure. Patches and updates to systems are needed to mitigate these vulnerabilities. Gartner Group reports that 90 percent of machines are exploited using known vulnerabilities that had patches available. A good patch management process can minimize these risks by ensuring the patches are applied. It can also shorten the timeframe that an organization is exposed to newly discovered vulnerabilities by making sure patches are applied in a timely manner. These patch management processes consist of several different components and need to take into account an organization's structure, policies, risk tolerance, and available resources.

Why Patch Management?

Patch management provides a method to significantly reduce risks to your computing environment. There have been a number of large impacting worm outbreaks that used known vulnerabilities as their mechanism for spreading. Some examples of these include:

- *Sadmind* used a known UNIX vulnerability to spread from UNIX machine to UNIX machine, as well as a Microsoft IIS vulnerability to deface Web sites.
- *Code Red I and II* used known vulnerabilities in Microsoft IIS servers.
- *Nimda* used known vulnerabilities in Microsoft IIS servers.

All of these vulnerabilities had patches available from vendors. In some cases these patches had been available for more than two years before the worm outbreak. Exhibit 58.1 shows the length of time that elapsed between the discovery of the vulnerability and the release of its patch, and the outbreak of a worm that exploited it.

Each one of these worms spread quickly and had a devastating effect on Internet traffic as well as organizations' internal networks. The speed and breadth of the spread indicated that many machines were not updated and were vulnerable to the exploit used to infect those machines. The loss of service and productivity caused by these worms could have been minimized by good patch management practices.

These worms also demonstrated the risk of vulnerable machines connected to networks and the ability of those machines to deny service to other machines. In some cases, single machines that were infected were able to flood local area networks with enough packets to saturate the available bandwidth. This shows that vulnerable machines are not only vulnerable to compromise themselves, but they are also at risk to deny service to other machines that share network resources. This greatly increases the risk of having a machine on a network that is not patched against known vulnerabilities.

Another threat is hackers looking for machines to compromise. One of the methods employed is to use automated tools to scan for vulnerable machines. Once these machines are identified, they are compromised and then used to scan for more machines to exploit. Machines that are fully patched will be more difficult to

EXHIBIT 58.1 Length of Time between Discovery and Worm Outbreak

Worm	Date of Outbreak	Vector of Infection	Date Patch for Vulnerability Was Made Available	No. of Days Systems Were Vulnerable
Sadmind/IIS	5/8/2000	Sadmind daemon on Solaris, used to deface Microsoft IIS Web sites	Sadmind patch available 12/29/1999, IIS patch available 10/17/2000	Sadmind: 496 days IIS: 203 days
Code Red I	7/19/2001	Microsoft IIS	Patch available 6/18/2001	31 days
Nimda	9/18/2001	Microsoft IIS and e-mail clients	IIS patch available 5/15/2001 E-mail client patch available 4/3/2001	IIS: 126 days E-mail client: 156 days

compromise and will be passed over in favor of machines that have vulnerabilities. Keeping systems patched against known vulnerabilities will greatly reduce the risk of being compromised in this fashion.

One specific example where patch management directly mitigates a threat is in the updating of anti-virus software. Viruses are one of the biggest threats to computer systems and spread through many different vectors. Anti-virus software is used to mitigate this threat and prevent systems from being infected. When new viruses come out, the anti-virus software needs to be updated to detect and clean them. These updates can come out at various time intervals, varying from as often as hourly to as infrequent as weekly. In older versions of anti-virus software, these updates had to be retrieved and applied manually. Most new versions will retrieve and update the software via the Internet with no user interaction and at prescribed intervals. Automation of this process and its integration into the software have greatly improved the level of protection against virus threats and reduced the threat of virus infections because of outdated anti-virus software. Other software applications have also begun to automate the patching process but a large majority of software still exists that needs to be patched manually or through the use of third-party automated tools. A good patch management process can ensure that this software is kept up-to-date and leverage the automated processes, where possible.

All in all, patch management is a proactive way of reducing risk in an organization's information systems environment. The amount of time spent in applying patches to systems is time well spent and can help prevent loss due to system compromise through vulnerabilities that those patches are meant to mitigate.

Types of Patches

Patches for software come in different types. These can be point patches/hotfixes, bundled patches, and version releases. Point patches/hotfixes are released to address specific issues and most security patches are released in this category. These patches usually undergo a minimal amount of testing because the issues need to be addressed quickly. These fixes can be riskier to apply to systems because they are not tested thoroughly and may cause errors to applications. Vendors may not guarantee that these fixes will not break other functions. Point fixes are then usually rolled up into bundled patches that undergo more rigorous testing and are fully supported by the vendor. They come out at regular time intervals and are usually larger in size because they contain multiple fixes. Organizations usually prefer to apply these bundled patches because they are more fully tested than point patches. Version releases are similar to bundled patches but may also contain new features or functions. It is also significant to note that some patches may require that a system have other patches applied (prerequisites) or be at a specific version in order to function correctly. This may require a system to be updated to a more current version just to apply a point fix that addresses a new vulnerability. A patch management process needs to take all of these types of patches into consideration and be able to deal with each one appropriately.

It is also important to make sure that patches are obtained from a trusted source and verified as authentic. There have been cases where software has been modified to include backdoors that allow unauthorized access. To mitigate this risk, some vendors will digitally sign their patches. These signatures should be checked before applying the patch to ensure that the patch is authentic and has not been changed.

Software Phases

Software will progress through different phases during its use, and vendors will support software differently, depending on the phase the software is in. The first phase that is important to a patch management process is the initial *introduction phase.* During this stage, there may be many software problems found that will need to be resolved. Patches may need to be applied quickly not only to solve security issues, but also functionality issues. Vendors are usually very supportive in this phase, with timely updates. The next phase is *production use.* This is the stage in which most software is utilized. Vulnerabilities found in this stage will usually go through an assessment to determine their impact. Some vendors will be more proactive and timely in providing patches for vulnerabilities while others may want to provide patches as part of normal version release cycles. Patch management processes need to be able to track and distribute the various point patches as well as the bundled patches and version updates that need to be applied. The last phase that software goes through that is important to patch management is the *unsupported* or *legacy stage.* In this stage, the vendor may no longer support the software and patches may not be available. This software can be risky to run as part of an organization because any new vulnerability found cannot be mitigated. While a patch management process may not be helpful in this situation, because there are no patches to be applied, it is important to know of the existence of this software so that its risks to an organization can be evaluated and understood. Vendors usually make users aware, well ahead of time, of when software is no longer supported. Planning ahead for this situation is important.

Threat Awareness and Assessment

One challenge in patch management is to know when a new vulnerability has been discovered. This is important in keeping the window of opportunity to be exploited by a vulnerability to a minimum. There are a variety of methods to keep up-to-date with new vulnerabilities. One is the monitoring of alerts by the Computer Emergency Response Team (CERT) at Carnegie Mellon. This is a U.S. Government-sponsored team that monitors and coordinates computer security incidents and vulnerabilities. The CERT Web site and mailing list provide a good source of alerts for newly discovered vulnerabilities. Another good source of information is the Bugtraq mailing list currently hosted at Security Focus. This is a moderated mailing list that discusses vulnerabilities to systems. Exhibit 58.2 lists the Web sites for these sources as well as some others, and can be very useful.

Major software vendors will also have mailing lists used to alert their users to software vulnerabilities and how to obtain patches for them. Monitoring these lists is an important part of staying aware of new vulnerabilities and the actions needed to mitigate them.

Once patches are made available, a decision on the process of applying them must be made. As mentioned, some point patches may not be fully tested before being released. Most system administrators will want to try the patches on a test machine before applying them to production systems. They will also want to fully understand the process to remove a patch if it causes errors to the application. Installing patches on a test machine will enable system administrators to practice the patch application and removal process. Production systems may also have designated maintenance windows to minimize downtime. These windows can occur as often as once a day to as infrequently as once every three months or longer. They usually occur during periods of low activity so that the impact to system users is low. There may also be designated "quiet times" during which only emergency changes can be made. These quiet times can be centered on business-critical activities

EXHIBIT 58.2 List of Vulnerability Information Sources

such as financial book close or product release cycles. These restrictions can greatly increase the time during which a system is vulnerable because a patch cannot be deployed. In some cases, the threat of a vulnerability being used to compromise a system will be so great that it will require that the patch be applied sooner than the regular maintenance window and will need to bypass these restrictions. To facilitate this, a rating system can be used to categorize vulnerability as to the probability of being exploited and the level of threat that it presents to the organization. The different ratings can be used to determine if a patch can wait for the normal maintenance process or if it should be applied in a timelier manner. In any case, patch installation should always go through the organization's formal change control management procedure.

There are a number of different factors that should be taken into account when rating an organization's vulnerabilities, including:

- *The vector or method of exploitability.* If the vulnerability is easily exploited by an available method of exploitability, then its risk will be far greater than one in which the vector is not readily available. An example of this would be a vulnerability that is exploitable over a network versus one that requires a login to the system. The vector for the network exploit is available to more potential threats than the one that requires local access and would increase the risk of the vulnerability being exploited. Network exploits can be further broken down into those that can be mitigated by firewall filtering and those that are allowed to pass through to internal networks, thereby greatly increasing the set of systems that are at risk. Examples of this pass-through would be exploits of Internet Web servers using HTTP traffic or an exploit of a DNS server using a specially crafted DNS request. These applications must be exposed to Internet traffic in order to provide their functionality. The risk for these applications to vulnerabilities exploitable via the network can be very high.
- *Length of time to apply a patch via normal change control processes.* Most production systems follow a change control process that involves testing and documenting changes before implementing them. This can take anywhere from a couple of hours to many days, depending on the complexity of the change. If a new vulnerability presents a sufficiently high threat to a system, this process may need to be shortened or expedited on an emergency basis. This may be especially true if an active exploit is moving through the network.
- *Availability of an exploit.* If an exploit for a particular vulnerability is available at a public information source, it can greatly increase the threat of a vulnerability being exploited. The public availability of an exploit brings it to the attention of more people, which increases the risk of its being used to compromise systems. These public information sources may include vulnerability development mailing lists and also Web sites that contain archives of exploits for different operating systems and platforms. It is important to note that it should not be assumed that if an exploit is not made public, it does not exist.
- *Criticality of the systems that are vulnerable.* Vulnerabilities to systems that are more important or to ones that provide infrastructure services may present more of a threat than vulnerabilities to less important systems. Critical systems can include infrastructure systems such as DNS servers and authentication servers, network devices such as routers and switches, as well as critical application servers. These systems may be important to an organization in maintaining its business and the risk to them needs to be kept to a minimum. There may also be cases where vulnerabilities are made public but the systems that are vulnerable are not critical to the business. This may mean that the vulnerability might not need to be mitigated as quickly.
- *Complexity of the patch.* Some patches are very simple to apply and others may require many changes to a system in order to be implemented correctly. The more complex the change to a system, the more likely that it will introduce unanticipated errors. This can be especially true of bundled patches or version upgrades. Trying the patches first in a test environment can help in mitigating this risk. However, there is not always time to perform this testing — especially during an outbreak of a worm or virus.

Using these factors, vulnerabilities and the subsequent patch can be rated in four different categories:

- *Normal.* This means that there is a low threat of the vulnerability being exploited and that the patch for it can be applied using the normal change control process and within the normal maintenance window. There can also be other mitigating factors that limit the attack vector, such as firewalls or other configuration changes that can be made to mitigate the vulnerability.
- *Urgent.* This means that there is a moderate threat of the vulnerability being exploited. This can include vulnerabilities that have been disclosed, but no exploit has been made available publicly and there are

EXHIBIT 58.3 Summary of Rating Categories and Actions

Rating	Risk Level	Level of Testing	Wait for Maintenance Window?
Normal	Low	Fully test	Yes
Urgent	Medium	Fully test	No
Critical	High	Minimal testing	No
Emergency	High/exploit in progress	None or very little	No

no reports of it being currently exploited. The patch for this vulnerability may go through the normal testing processes but may not wait for the normal change control maintenance window.

- *Critical.* This means that there is a high threat of the vulnerability being exploited. The attack vector of the exploit may be easily accessible and an exploit for the vulnerability is known and in the public domain. It may also be a threat to an infrastructure system. The patch for this vulnerability must be applied as soon as possible in order to mitigate this threat. It may still undergo some limited testing but will not wait for a normal change control window.
- *Emergency.* This means that the vulnerability is being actively exploited and needs to be patched immediately. Some examples of the use of this rating include cases of worms and viruses that are spreading through a network. The patch for this vulnerability is applied immediately, bypassing any testing or change management windows. This is done because the threat of the exploit is immediate and the risk of the change to the system is outweighed by the risk of the exploit.

These rating categories are summarized in Exhibit 58.3.

Some vendors have implemented their own rating systems to assist in communicating the level of threat that a vulnerability has for their product. It is important to understand the definitions of their different rating levels. Some of them adjust their ratings, depending on whether the system is connected to the Internet or not, and this may or may not apply to your organization. These definitions need to be evaluated and the rating system adjusted for your computing environment so that you can properly rate the vulnerabilities and the actions needed to mitigate them.

Process Overview

One of the first things that needs to be done to establish a patch management process is to institute a policy, as part of the organization's security policy, that software and systems need to be kept current and secure. This policy should be agreed to and communicated to all of the information technology system owners and administrators. Doing this up-front will make everyone aware that they are expected to apply patches in a timely manner. This policy will then drive the requirements for a patch management process. One other situation that needs to be addressed is the use of machines on the internal network that are not owned by the organization and not subject to its policies. This situation may introduce machines on the internal network that have not been patched and are in an unknown state. Many organizations will not allow these machines on the network because of that risk. However, outsourcing of an organization's functions and the use of contractors may make this policy difficult to implement.

The next step that needs to be taken in instituting a patch management process is to inventory the machines and software in your organization. Information that needs to be collected includes operating system type and version, installed applications along with their versions, contact information for the system administrator, and any other information needed to assess the risk from new vulnerabilities and patch the system. It is also important to inventory network devices such as printers and routers as these may also have vulnerabilities that will need to be patched. This inventory needs to be kept up-to-date and can be used to understand what threats are applicable to your environment by comparing new product vulnerabilities to the products that are present in your environment. In small organizations, this may be as simple as a spreadsheet that lists the various operating systems and application versions. In larger organizations, keeping these lists up-to-date becomes more of a challenge. There are software tools that will assist in this. These tools can be run periodically on systems to update a master database of software and version information. When a new vulnerability is made public, this information can be used to determine which systems in the environment are vulnerable and which systems need to have patches applied.

The actual patching mechanism can be a manual process initiated by a systems administrator, or it could be an automated system utilized by a central organization. An automated process can either be a "push" or a "pull" model. A "pull" model waits for a system to check for a patch from a distribution point. Systems will be configured to check at regular intervals. The advantage of a "pull" model is that new systems can be added with little effort, as the distribution point may not need to know anything about the clients it serves. A "push" model will initiate the patch from a central location. The advantage of a "push" system is that it has the ability to distribute a patch faster because it does not have to wait for a system to check for a patch. One disadvantage is that it requires more administration to add new machines as well as remove obsolete machines from the environment. Automated patching processes tend to be more effective when used for large numbers of end-user machines. End users do not tend to be aware of when they need to patch and may also not have the technical skills to apply the patches properly. Automation can ensure that the patches get applied in a timely manner because they can be controlled by a central organization. Automation also works best in environments that are standardized so that the machines are configured the same way. In more diverse environments, automated processes tend to become more complex because they require patching packages that take into account each separate variation of the environment.

Server administrators usually prefer manual patch processes because they prefer more control over the changes that are made to their servers. Applying patches presents a risk of breaking the applications that run on servers, and server applications tend to be more complicated than ones that run on end-user machines. Production servers will usually require back-out procedures in case the patch causes errors in applications. Automated patch processes may not be easily backed out because the automation may hide the actual changes being made to the server.

One other issue that needs to be addressed is the deployment of new machines into the infrastructure. As part of the deployment process, these machines will need to be patched to the appropriate level before being utilized. It is also important that they be integrated into the patch management inventory process to ensure that they receive future patches. Failure to do this will slowly erode the effectiveness of the patch management process.

Patch Management and Incident Response

Patching systems is a key part of responding to virus and worm incidents. Updating anti-virus software or applying fixes to systems may be the only way to halt the spread of a network worm or e-mail virus. Having an automated patch system can greatly decrease the amount of time it takes to patch large numbers of systems and mitigate these threats. However, provisions still need to be made for patching systems without the automated systems. The automated process can be disabled by the worm or virus, or the nature of the incident may require that the system be taken off the network and patched before being put back on the network. This was evident during the Code Red worm, in which systems were rebooted to clean the worm out of memory but, if left connected to the network, were almost immediately re-infected. This meant that network-based services, like file shares or Web sites that contained the patch, could not be used. So instead of using an automated patching system, a manual method using removable media had to be employed. This greatly increased the time needed to recover from this worm. If automated patching processes are used, care should be taken to protect them because, if these systems become incapacitated during an incident, then they cannot be used to help resolve it.

Compliance

Enforcing proper patch management is an important part of the process. This is especially true if non-automated methods are utilized. Periodic checks for compliance should be utilized to measure the effectiveness of the process. These checks can include:

- *Periodic system audits.* Manually checking your information systems can uncover systems that are not in compliance. This checking can be more complete than network scanning but is more personnel resource intensive.
- *Network vulnerability scanning.* This method is useful in checking large numbers of systems without much effort. This can be done on a regular basis and the information used to determine which systems

have been patched and which have not. One drawback is that this method will not be able to check for vulnerabilities that are not detectable over the network.

- *Login scripts.* Some network operating systems support login scripts that run when they authenticate to network resources. These scripts can be used to check the system compliance with patch management policy and have the benefit of being run every time a system authenticates. This check can also optionally deny access until the system is patched to the proper level. This has the benefit of forcing systems into compliance, or else they will not be able to access network resources. This can be especially useful when there is an outbreak of a new worm or virus. Systems with the particular vulnerability being exploited can be denied access until they are patched.

Compliance processes are very important when dealing with remote access users — especially those that utilize virtual private network (VPN) access via the Internet. Because these machines are on the Internet, they may be exposed to more threats than machines that are on an internal network behind a firewall. While connected to the Internet, machines may become infected by a worm or a virus and when they then connect to the internal network, they may carry this infection to internal systems. Having a process that checks the patch levels of these systems before allowing them access to internal network resources can greatly reduce the threat from such machines.

Exceptions

Systems may not always be capable of being patched to a secure level. One reason may be because the software vendor may no longer support the software. Most vendors will support software only for a certain length of time and then they will drop it from their supported software list. Having unsupported software in an organization can be very risky, as any new vulnerability will not be mitigated. Most organizations will transition to the newer versions of the software before this happens. In some cases, they will not be able to do this. The new version may require new hardware or it may not include necessary features. When this happens, the organization needs to understand the risk and balance it against the needs of the business as well as consider the cost of moving to a supported system. Other controls or precautions can be put in place to help mitigate the risk. These include additional network controls through the use of firewalls or host-based intrusion detection, which can detect configuration changes. Anti-virus software may also provide some measure of protection. It is also important to continually evaluate newly discovered vulnerabilities. If a high-risk vulnerability is found, it may be necessary to reevaluate the need for the system and to either adjust the controls or decommission the system. Systems that are exempt from patching can represent a significant risk to an organization and need to be managed appropriately.

Conclusion

Patch management is one of the key pieces of securing your information technology infrastructure. Patching against known vulnerabilities can reduce the known threats against your information systems. It provides a proactive way to reduce risk and can make a difference in ensuring the integrity and availability of your information systems. It is a straightforward way to make your systems more secure and reduce the threat to your information technology infrastructure.

Purposes of Information Security Management

Harold F. Tipton

Managing computer and network security programs has become an increasingly difficult and challenging job. Dramatic advances in computing and communications technology during the past five years have redirected the focus of data processing from the computing center to the terminals in individual offices and homes. The result is that managers must now monitor security on a more widely dispersed level. These changes are continuing to accelerate, making the security manager's job increasingly difficult.

The information security manager must establish and maintain a security program that ensures three requirements: the confidentiality, integrity, and availability of the company's information resources. Some security experts argue that two other requirements may be added to these three: utility and authenticity (i.e., accuracy). In this discussion, however, the usefulness and authenticity of information are addressed within the context of the three basic requirements of security management.

CONFIDENTIALITY

Confidentiality is the protection of information in the system so that unauthorized persons cannot access it. Many believe this type of protection is of most importance to military and government organizations that need to keep plans and capabilities secret from potential enemies. However, it can also be significant to businesses that need to protect proprietary trade secrets from competitors or prevent unauthorized persons from accessing the company's sensitive information (e.g., legal, personnel, or medical information). Privacy issues, which have received an increasing amount of attention in the past few years, place the importance of confidentiality on protecting personal information maintained in automated systems by both government agencies and private-sector organizations.

Confidentiality must be well defined, and procedures for maintaining confidentiality must be carefully implemented, especially for standalone computers. A crucial aspect of confidentiality is user identification and authentication. Positive identification of each system user is essential to ensuring the effectiveness of policies that specify who is allowed access to which data items.

Threats to Confidentiality

Confidentiality can be compromised in several ways. The following are some of the most commonly encountered threats to information confidentiality:

- Hackers.
- Masqueraders.
- Unauthorized user activity.
- Unprotected downloaded files.
- Local area networks (LANs).
- Trojan horses.

Hackers. A hacker is someone who bypasses the system's access controls by taking advantage of security weaknesses that the systems developers have left in the system. In addition, many hackers are adept at discovering the passwords of authorized users who fail to choose passwords that are difficult to guess or not included in the dictionary. The activities of hackers represent serious threats to the confidentiality of information in computer systems. Many hackers have created copies of inadequately protected files and placed them in areas of the system where they can be accessed by unauthorized persons.

Masqueraders. A masquerader is an authorized user of the system who has obtained the password of another user and thus gains access to files available to the other user. Masqueraders are often able to read and copy confidential files. Masquerading is a common occurrence in companies that allow users to share passwords.

Unauthorized User Activity. This type of activity occurs when authorized system users gain access to files that they are not authorized to access. Weak access controls often enable unauthorized access, which can compromise confidential files.

Unprotected Downloaded Files. Downloading can compromise confidential information if, in the process, files are moved from the secure environment of a host computer to an unprotected microcomputer for local processing. While on the microcomputer, unattended confidential information could be accessed by authorized users.

Local Area Networks. LANs present a special confidentiality threat because data flowing through a LAN can be viewed at any node of the network, whether or not the data is addressed to that node. This is particularly significant because the unencrypted user IDs and secret passwords of users logging on to the host are subject to compromise as this data travels from the user's node through the LAN to the host. Any confidential information not intended for viewing at every node should be protected by encryption.

Trojan Horses. Trojan horses can be programmed to copy confidential files to unprotected areas of the system when they are unknowingly executed by users who have authorized access to those files. Once executed, the Trojan horse becomes resident on the user's system and can routinely copy confidential files to unprotected resources.

Confidentiality Models

Confidentiality models are used to describe what actions must be taken to ensure the confidentiality of information. These models can specify how security tools are used to achieve the desired level of confidentiality.

The most commonly used model for describing the enforcement of confidentiality is the Bell-LaPadula model. It defines the relationships between objects (i.e., the files, records, programs, and equipment that contain or receive information) and subjects (i.e., the persons, processes, or devices that cause information to flow between the objects). The relationships are described in terms of the subject's assigned level of access or privilege and the object's level of sensitivity. In military terms, these would be described as the security clearance of the subject and security classification of the object.

Subjects access objects to read, write, or read and write information. The Bell-LaPadula model enforces the lattice principle, which specifies that subjects are allowed write access to objects at the same or higher level as the subject, read access to objects at the same or lower level, and read/write access to only those objects at the same level as the subject. This prevents the ability to write higher-classified information into a lower-classified file or to disclose higher-classified information to a lower-classified individual. Because an object's level indicates the security level of data it contains, all the data within a single object must be at the same level. This type of model is called flow model, because it ensures that information at a given security level flows only to an equal or higher level.

Another type of model that is commonly used is the access control model, which organizes a system into objects (i.e., resources being acted on), subjects (i.e., the persons or programs doing the action), and operations (i.e., the process of the interaction). A set of rules specifies which

operations can be performed on an object by which subjects. This type of model has the additional benefit of ensuring the integrity of information as well as the confidentiality; the flow model supports only confidentiality.

Implementing Confidentiality Models

The trusted system criteria provide the best guidelines for implementing confidentiality models. These criteria were developed by the National Computer Security Center and are published in the *Department of Defense Trusted Computer System Evaluation Criteria* (commonly referred to as the Orange Book), which discusses information confidentiality in considerable detail. In addition, the National Computer Security Center has developed a Trusted Network Interpretation that applies the Orange Book criteria to networks; the network interpretation is described in the *Trusted Network Interpretation of the Trusted Computer System Evaluation Criteria* (commonly referred to as the Red Book).

INTEGRITY

Integrity is the protection of system data from intentional or accidental unauthorized changes. The challenge of the security program is to ensure that data is maintained in the state that users expect. Although the security program cannot improve the accuracy of data that is put into the system by users, it can help ensure that any changes are intended and correctly applied.

An additional element of integrity is the need to protect the process or program used to manipulate the data from unauthorized modification. A critical requirement of both commercial and government data processing is to ensure the integrity of data to prevent fraud and errors. It is imperative, therefore, that no user be able to modify data in a way that might corrupt or lose assets or financial records or render decision-making information unreliable. Examples of government systems in which integrity is crucial include air traffic control systems, military fire control systems (which control the firing of automated weapons), and Social Security and welfare systems. Examples of commercial systems that require a high level of integrity include medical prescription systems, credit reporting systems, production control systems, and payroll systems.

As with the confidentiality policy, identification and authentication of users are key elements of the information integrity policy. Integrity depends on access controls; therefore, it is necessary to positively and uniquely identify all persons who attempt access.

Protecting Against Threats to Integrity

Like confidentiality, integrity can be compromised by hackers, masqueraders, unauthorized user activity, unprotected downloaded files, LANs, and unauthorized programs (e.g., Trojan horses and viruses), because

each of these threats can lead to unauthorized changes to data or programs. For example, authorized users can corrupt data and programs accidentally or intentionally if their activities on the system are not properly controlled.

Three basic principles are used to establish integrity controls:

1. granting access on a need-to-know basis,
2. separation of duties,
3. rotation of duties.

Need-to-Know Access. Users should be granted access only to those files and programs that they need in order to perform their assigned job functions. User access to production data or source code should be further restricted through use of well-formed transactions, which ensure that users can change data only in controlled ways that maintain the integrity of data. A common element of well-formed transactions is the recording of data modifications in a log that can be reviewed later to ensure that only authorized and correct changes were made. To be effective, well-formed transactions must ensure that data can be manipulated only by a specific set of programs. These programs must be inspected for proper construction, installation, and controls to prevent unauthorized modification.

Because users must be able to work efficiently, access privileges should be judiciously granted to allow sufficient operational flexibility; need-to-know access should enable maximum control with minimum restrictions on users. The security program must employ a careful balance between ideal security and practical productivity.

Separation of Duties. To ensure that no single employee has control of a transaction from beginning to end, two or more people should be responsible for performing it — for example, anyone allowed to create or certify a well-formed transaction should not be allowed to execute it. Thus, a transaction cannot be manipulated for personal gain unless all persons responsible for it participate.

Rotation of Duties. Job assignments should be changed periodically so that it is more difficult for users to collaborate to exercise complete control of a transaction and subvert it for fraudulent purposes. This principle is effective when used in conjunction with a separation of duties. Problems in effectively rotating duties usually appear in organizations with limited staff resources and inadequate training programs.

Integrity Models

Integrity models are used to describe what needs to be done to enforce the information integrity policy. There are three goals of integrity, which the models address in various ways:

1. Preventing unauthorized users from making modifications to data or programs.
2. Preventing authorized users from making improper or unauthorized modifications.
3. Maintaining internal and external consistency of data and programs.

The first step in creating an integrity model for a system is to identify and label those data items for which integrity must be ensured. Two procedures are then applied to these data items. The first procedure verifies that the data items are in a valid state (i.e., they are what the users or owners believe them to be because they have not been changed). The second procedure is the transformation procedure or well-formed transaction, which changes the data items from one valid state to another. If only a transformation procedure is able to change data items, the integrity of the data is maintained. Integrity enforcement systems usually require that all transformation procedures be logged, to provide an audit trail of data item changes.

Another aspect of preserving integrity relates to the system itself rather than only the data items in the system. The system must perform consistently and reliably — that is, it must always do what the users or owners expect it to do.

National Computer Security Center Report 79–91, "Integrity in Automated Information Systems" (September 1991), discusses several integrity models. Included are five models that suggest different approaches to achieving integrity:

1. Biba,
2. Goguen-Meseguer,
3. Sutherland,
4. Clark-Wilson,
5. Brewer-Nash.

The Biba Model. The first model to address integrity in computer systems was based on a hierarchical lattice of integrity levels defined by Biba in 1977. The Biba integrity model is similar to the Bell-LaPadula model for confidentiality in that it uses subjects and objects; in addition, it controls object modification in the same way that Bell-LaPadula controls disclosure.

Biba's integrity policy consists of three parts. The first part specifies that a subject cannot execute objects that have a lower level of integrity than the subject. The second part specifies that a subject cannot modify objects that have a higher level of integrity. The third part specifies that a subject may not request service from subjects that have a higher integrity level.

The Goguen-Meseguer Model. The Goguen-Meseguer model, published in 1982, is based on the mathematical principle governing automatons (i.e., a control mechanism designed to automatically follow a predetermined sequence of operations or respond to encoded instructions) and includes domain separation. In this context, a domain is the list of objects that a user can access; users can be grouped according to their defined domains. Separating users into different domains ensures that users cannot interfere with each other's activities. All the information about which activities users are allowed to perform is included in a capabilities table.

In addition, the system contains information not related to permissions (e.g., user programs, data, and messages). The combination of all this information is called the state of the system. The automaton theory used as a basis for this model predefines all of the states and transitions between states, which prevents unauthorized users from making modifications to data or programs.

The Sutherland Model. The Sutherland model, published in 1986, approaches integrity by focusing on the problem of inference (i.e., the use of covert channels to influence the results of a process). This model is based on a state machine and consists of a set of states, a set of possible initial states, and a transformation function that maps states from the initial state to the current state.

Although the Sutherland model does not directly invoke a protection mechanism, it contains access restrictions related to subjects and information flow restrictions between objects. Therefore, it prevents unauthorized users from modifying data or programs.

The Clark-Wilson Model. The Clark-Wilson model, published in 1987 and updated in 1989, involves two primary elements for achieving data integrity — the well-formed transaction and separation of duties. Well-formed transactions, as previously mentioned, prevent users from manipulating data, thus ensuring the internal consistency of data. Separation of duties prevents authorized users from making improper modifications, thus preserving the external consistency of data by ensuring that data in the system reflects the real-world data it represents.

The Clark-Wilson model differs from the other models that are subject and object oriented by introducing a third access element — programs — resulting in what is called an access triple, which prevents unauthorized users from modifying data or programs. In addition, this model uses integrity verification and transformation procedures to maintain internal and external consistency of data. The verification procedures confirm that the data conforms to the integrity specifications at the time the verification is performed. The transformation procedures are designed to take the system

from one valid state to the next. The Clark-Wilson model is believed to address all three goals of integrity.

The Brewer-Nash Model. The Brewer-Nash model, published in 1989, uses basic mathematical theory to implement dynamically changing access authorizations. This model can provide integrity in an integrated data base. In addition, it can provide confidentiality of information if the integrated data base is shared by competing companies; subjects can access only those objects that do not conflict with standards of fair competition.

Implementation involves grouping data sets into discrete classes, each class representing a different conflict of interest (e.g., classified information about a company is not made available to a competitor). Assuming that a subject initially accesses a data set in each of the classes, the subject would be prevented from accessing any other data set in each class. This isolation of data sets within a class provides the capability to keep one company's data separate from a competitor's in an integrated data base, thus preventing authorized users from making improper modifications to data outside their purview.

Implementing Integrity Models

The integrity models may be implemented in various ways to provide the integrity protection specified in the security policy. National Computer Security Center Report 79–91 discusses several implementations, including those by Lipner, Boebert and Kain, Lee and Shockley, Karger, Jueneman, and Gong. These six implementations are discussed in the following sections.

The Lipner Implementation. The Lipner implementation, published in 1982, describes two ways of implementing integrity. One uses the Bell-LaPadula confidentiality model, and the other uses both the Bell-LaPadula model and the Biba integrity model. Both methods assign security levels and functional categories to subjects and objects. For subjects, this translates into a person's clearance level and job function (e.g., user, operator, applications programmer, or systems programmer). For objects, the sensitivity of the data or program and its functions (e.g., test data, production data, application program, or system program) are defined.

Lipner's first method, using only Bell-LaPadula model, assigns subjects to one of two sensitivity levels — system manager and anyone else — and to one of four job categories. Objects (i.e., file types) are assigned specific levels and categories. Most of the subjects and objects are assigned the same level; therefore, categories become the most significant integrity (i.e., access control) mechanism. The applications programmers, systems programmers, and users are confined to their own domains according to their

assigned categories, thus preventing unauthorized users from modifying data.

Lipner's second method combines Biba's integrity model with the Bell-LaPadula basic security implementation. This combination of models helps prevent contamination of high-integrity data by low-integrity data or programs. The assignment of levels and categories to subjects and objects remains the same as for Lipner's first method. Integrity levels are used to avoid the unauthorized modification of system programs; integrity categories are used to separate domains that are based on functional areas (e.g., production or research and development). This method prevents unauthorized users from modifying data and prevents authorized users from making improper data modifications.

Lipner's methods were the first to separate objects into data and programs. The importance of this concept becomes clear when viewed in terms of implementing the Clark-Wilson integrity model; because programs allow users to manipulate data, it is necessary to control which programs a user may access and which objects a program can manipulate.

The Boebert and Kain Implementations. Boebert and Kain independently proposed (in 1985 and 1988, respectively) implementations of the Goguen-Meseguer integrity model. This implementation uses a subsystem that cannot be bypassed; the actions performed on this subsystem cannot be undone and must be correct. This type of subsystem is featured in the system's logical coprocessor kernel, which checks every access attempt to ensure that the access is consistent with the security policy being invoked.

Three security attributes are related to subjects and objects in this implementation. First, subjects and objects are assigned sensitivity levels. Second, subjects are identified according to the user in whose behalf the subject is acting, and objects are identified according to the list of users who can access the object and the access rights users can execute. Third, the domain (i.e., subsystem) that the program is a part of is defined for subjects, and the object type is defined according to the information contained within the object.

When the system must determine the kind of access a subject is allowed, all three of these security attributes are used. Sensitivity levels of subjects and objects are compared to enforce the mandatory access control policy. To enforce discretionary access control, the access control lists are checked. Finally, access rights are determined by comparing the subject domain with the object type.

By isolating the action rather than the user, the Boebert and Kain implementation ensures that unauthorized users cannot modify data. The use of

domains requires that actions be performed in only one location and in only one way; a user who cannot access the domain cannot perform the action.

The Lee and Shockley Implementations. In 1988, Lee and Shockley independently developed implementations of the Clark-Wilson integrity model using Biba's integrity categories and trusted subjects. Both of these implementations were based on sensitivity levels constructed from independent elements. Each level represents a sensitivity to disclosure and a sensitivity to modification.

Data is manipulated by certified transactions, which are trusted subjects. The trusted subject can transform data from a specific input type to a specific output type. The Biba lattice philosophy is implemented so that a subject may not read above its level in disclosure or below its level in integrity. Every subject and object has both disclosure and integrity levels for use in this implementation. The Lee and Shockley implementations prevent unauthorized users from modifying data.

The Karger Implementation. In 1988, Karger proposed another implementation of the Clark-Wilson integrity model, augmenting it with his secure capabilities architecture (developed in 1984) and a generic lattice security model. In this implementation, audit trails play a much more prominent part in the enforcement of security than in other implementations. The capabilities architecture combined with access control lists that represent the security lattice provide for improved flexibility in implementing integrity.

In addition, the Karger implementation requires that the access control lists contain the specifics of the Clark-Wilson triples (i.e., the names of the subjects and objects the user is requesting access to and the names of the programs that provide the access), thereby enabling implementation of static separation of duties. Static separation of duties prevents unauthorized users from modifying data and prevents authorized users from making improper modifications.

The part of Karger's implementation that uses capabilities with access control lists limits actions to particular domains. The complex access control lists not only contain the triples but specify the order in which the transactions must be executed. These lists are used with audit-based capabilities to enforce dynamic separation of duties.

The Karger implementation provides three levels of integrity protection. First, triples in the access control lists allow for basic integrity (i.e., static separation of duties). Second, the capabilities architecture can be used with access control lists to provide faster access and domain separation. Third, access control lists and the capabilities architecture support both dynamic separation of duties and well-formed transactions.

The Jueneman Implementation. In 1989, Jueneman proposed a defensive detection implementation for use on dynamic networks of interconnected trusted computers communicating through unsecured media. This implementation was based on mandatory and discretionary access controls, encryption, checksums, and digital signatures. It prevents unauthorized users from modifying data.

The control mechanisms in this implementation support the philosophy that the originator of an object is responsible for its confidentiality and that the recipient is responsible for its integrity in a network environment. The mandatory access controls prevent unauthorized modification within the trusted computers and detect modifications external to the trusted computers. The discretionary access controls prevent the modification, destruction, or renaming of an object by a user who qualifies under mandatory control but lacks the owner's permission to access the object. The encryption mechanism is used to avoid unauthorized disclosure of the object. The encryption mechanism is used to avoid unauthorized disclosure of the object. Checksums verify that the communication received is the communication that was sent, and digital signatures are evidence of the source of the communication.

The Gong Implementation. The Gong implementation, developed in 1989, is an identity-based and capability-oriented security system for distributed systems in a network environment. Capabilities identify each object and specify the access rights (i.e., read, write and update) to be allowed each subject that is authorized access. Access authorizations are provided in an access list.

The Gong implementation consists of subjects (i.e., users), objects, object servers, and a centralized access control server. The access control server contains the access control lists, and the object server contains the capability controls for each object.

This implementation is very flexible because it is independent of the protection policy (i.e., the Bell-LaPadula disclosure lattice, the Biba integrity lattice, the Clark-Wilson access triples, or the Lee-Shockley nonhierarchical categories). The Gong implementation can be used to prevent unauthorized users from modifying data and to prevent authorized users from making unauthorized modifications.

AVAILABILITY

Availability is the assurance that a computer system is accessible by authorized users whenever needed. Two facets of availability are typically discussed:

1. Denial of service.
2. Loss of data processing capabilities as a result of natural disasters (e.g., fires, floods, storms, or earthquakes) or human actions (e.g., bombs or strikes).

Denial of service usually refers to actions that tie up computing services in a way that renders the system unusable by authorized users. For example, the Internet worm overloaded about 10% of the computer systems on the network, causing them to be nonresponsive to the needs of users.

The loss of data processing capabilities as a result of natural disasters or human actions is perhaps more common. Such losses are countered by contingency planning, which helps minimize the time that a data processing capability remains unavailable. Contingency planning — which may involve business resumption planning, alternative-site processing, or simply disaster recovery planning — provides an alternative means of processing, thereby ensuring availability.

Physical, technical, and administrative issues are important aspects of security initiatives that address availability. The physical issues include access controls that prevent unauthorized persons from coming into contact with computing resources, various fire and water control mechanisms, hot and cold sites for use in alternative-site processing, and off-site backup storage facilities. The technical issues include fault-tolerance mechanisms (e.g., hardware redundancy, disk mirroring, and application checkpoint restart), electronic vaulting (i.e., automatic backup to a secure, off-site location), and access control software to prevent unauthorized users from disrupting services. The administrative issues include access control policies, operating procedures, contingency planning, and user training. Although not obviously an important initiative, adequate training of operators, programmers, and security personnel can help avoid many computing stages that result in the loss of availability. In addition, availability can be restricted if a security office accidentally locks up an access control data base during routine maintenance, thus preventing authorized users access for an extended period of time.

Considerable effort is being devoted to addressing various aspects of availability. For example, significant research has focused on achieving more fault-tolerant computing. Another sign that availability is a primary concern is that increasing investments are being made in disaster recovery planning combined with alternative-site processing facilities. Investments in antiviral products are escalating as well; denial of service associated with computer viruses, Trojan horses, and logic bombs is one of today's major security problems.

Known threats to availability can be expected to continue. New threats may emerge as technology evolves, making it quicker and easier for users to share information resources with other users, often at remote locations.

SUMMARY

The three basic purposes of security management — integrity, confidentiality, and availability — are present in all systems. Whether a system emphasizes one or the other of these purposes depends on the functions performed by the applications. For example, air traffic control systems do not require a high level of information confidentiality; however, a high degree of integrity is crucial to avoid disastrous misguiding of aircraft, and availability is important to avoid disruption of air traffic services.

Automobile companies, on the other hand, often go to extreme lengths to protect the confidentiality of new designs, whereas integrity and availability are of lesser concern. Military weapons systems also must have a high level of confidentiality to avoid enemy compromise. In addition, they must provide high levels of integrity (to ensure reliability) and availability (to ensure that the system operates as expected when needed).

Historically, confidentiality has received the most attention, probably because of its importance in military and government applications. As a result, capabilities to provide confidentiality in computer systems are considerably more advanced than those providing integrity or availability. Significant research efforts have recently been focused on the integrity issue. Still, little attention has been paid to availability, with the exception of building fault tolerance into vendor products and including hot and cold sites for backup processing in disaster recovery planning.

The combination of integrity, availability, and confidentiality in appropriate proportions to support the organization's goals can provide users with a trustworthy system — that is, users can trust it will consistently perform according to their expectations. Trustworthiness has a broader definition than security in that it combines security with safety and reliability as well as the protection of privacy (which is already considered to be a part of security). In addition, many of the mechanisms that provide security also make systems more trustworthy in general. These multipurpose safeguards should be exploited to the extent practicable.

The Building Blocks of Information Security

Ken M. Shaurette

INFORMATION SECURITY IS NOT JUST ABOUT TECHNOLOGICAL CONTROLS. SECURITY CANNOT BE ACHIEVED SOLELY THROUGH THE APPLICATION OF SOFTWARE OR HARDWARE. Any attempt to implement technology controls without considering the cultural and social attitudes of the corporation is a formula for disaster. The best approach to effective security is a layered approach that encompasses both technological and nontechnological safeguards. Ideally, these safeguards should be used to achieve an acceptable level of protection while enhancing business productivity. While the concept may sound simple, the challenge is to strike a balance between being too restrictive (overly cautious) or too open (not cautious enough).

Security technology alone cannot eliminate all exposures. Security managers must integrate themselves with existing corporate support systems. Together with their peers, they will develop the security policies, standards, procedures, and guidelines that form the foundation for security activities. This approach will ensure that security becomes a function of the corporation — not an obstacle to business.

A successful layered approach must look at all aspects of security. A layered approach concentrating on technology alone becomes like a house of cards. Without a foundation based on solid policies, the security infrastructure is just cards standing side by side, with each technology becoming a separate card in the house. Adding an extra card (technology layer) to the house (overall security) does not necessarily make the house stronger.

Without security policies, standards, procedures, and guidelines, there is no general security framework or foundation. Policies define the behavior that is allowed or not allowed. They are short because they do not explain how to achieve compliance; such is the purpose of procedures and

guidelines. Corporate policy seldom changes because it does not tie to technology, people, or specific processes. Policy establishes technology selection and how it will be configured and implemented. Policies are the consensus between people, especially important between all layers of corporate management. Policy can ensure that the Security Manager and his or her peers apply security technology with the proper emphasis and return on investment for the good of the business as a whole.

In most security audits or reviews, checking, maybe even testing, an organization's security policies, standards, procedures, and guidelines is often listed as the first element in assessing security risk. It is easy to see the published hard-copy policy; but to ensure that policy is practiced, it is necessary to observe the workplace in order to evaluate what is really in operation. Lack of general awareness or compliance with a security policy usually indicates a policy that was not developed with the participation of other company management.

Whether the organization is global or local, there is still expectation of levels of due diligence. As a spin on the golden rule: "Compute unto others as you would want them to compute unto you."

Define the Scope: Objective

> "The first duty of a human is to assume the right functional relationship to society — more briefly, to find your real job, and do it."
>
> — Charlotte Perkins Gilman

Define Security Domain

Every organization has a different perspective on what is within the domain of its Information Security department.

- Does the Information Security domain include both electronic and non-electronic information, printed versus the bytes stored on a computer?
- Does the Information Security department report to IS and have responsibility for only information policies, not telephone, copier, fax, and mail use?
- Does physical security and contingency planning fall into the Information Security Manager's domain?
- Is the Security Manager's responsibility corporate, regional, national, or global?

Information Security's mission statement must support the corporation's business objective. Very often, one can find a security mission stated something like:

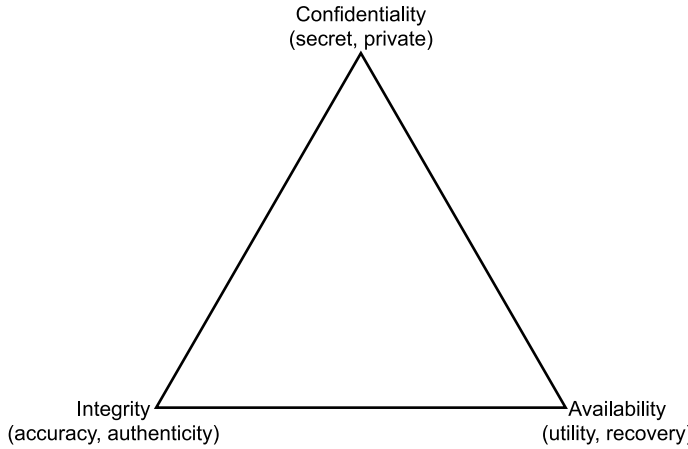

Exhibit 10-1. Basic security triad.

> The mission of the Information Security department is to protect the information assets, the information systems, and networks that deliver the information, from damage resulting from failures of confidentiality, integrity, and availability (CIA) (see Exhibit 10-1).

This mission is quite specific to Information Security and a specific department. A mission like this is a prime reason why defining the Security Manager's domain is critical to the success of policy formation.

Would the mission be more positive and clear by being tied to the business objectives with something like:

> Security's objective is to enhance the productivity of the business by reducing probability of loss through the design and implementation of policies, standards, procedures, and guidelines that enhance the protection of business assets.

Notice how this mission statement does not limit itself to "information." It does not limit the responsibilities to only computer systems and their processing of information. In addition, it ties the success of the mission to the business. It still provides the flexibility to define assets and assign owners to them for accountability. It is important to understand the objectives that security is going to deliver for the business. Exhibit 10-2 outlines some sample objectives.

What will be in the Security Manager's domain: physical security, contingency planning, telephones, copiers, faxes, or mail (especially e-mail)? These technologies process information too, so would they be covered by Information Security Policy? How far reaching will the Security Manager's responsibilities be: corporate, global, national, regional, or local? Is it the

Exhibit 10-2. Questions to help determine security philosophy.

- Do users have expectations relating to security?
- Is it possible to lose customers if security is too restrictive, not restrictive enough, or if controls and policy are so unreasonable that functionality is impaired?
- Is there a history for lost availability or monetary loss from security incidents in the past? What was the cost to the business?
- Who is the primary enemy — employees or outsiders?
- How much confidential information is online, and how is it accessed? What would be the loss if the information was compromised or stolen?
- Is it important to layer security controls for different parts of the organization?
- Are dangerous services that increase vulnerabilities supported by the organization? Is it required that networks and systems meet a security baseline?
- What security guidelines, procedures, regulations, or laws must be met?
- Is there a conflict between business objectives and security?
- Confidentiality, integrity, and availability: how crucial is each to the overall operation?
- Consider business needs and economic reality. What meets due diligence for like companies, the security industry, for this information in other environments?

Security Manager's responsibility to enforce compliance? Is contingency planning or business continuity planning (BCP) a function of physical security? Once the domain has been clearly defined, it becomes easy for responsible areas to form and begin to create their specific policies, standards, procedures, and guidelines.

Traditionally, organizations would refer to different departments for the responsibility of security on such things as telephones, copiers, faxes, or mail. An organization would have to climb quite high in the organizational structure — executive VP, COO, CEO — to find the common management point in the organizational structure where a person responsible for the security of all the disparate resources would come together for central accountability.

Hint: Policies written with the term "electronic" can cover e-mail, (electronic mail), EDI (electronic data interchange), or all the other "E-words" that are becoming popular (i.e., E-commerce, E-marketing, and E-business). Policies not using the term "electronic" can refer to information regardless of technology, storage media, or transportation methods.

In that regard, what used to be called datasecurity, today is referred to as information security. Information security often considers the security of data, information in both electronic and non-electronic forms. The role of the Information Security Manager has either expanded or information security personnel have begun assuming responsibilities in areas that are

often not clearly defined. Some organizations are recognizing the difficulty of separating information dealing with technology from non-technology. With that in mind, Corporate Security Officer (CSO) type positions are being created (other possible name: Chief Security Officer). These positions can be scoped to have responsibility for security, regardless of technology, and across the entire enterprise regardless of geography. This would not necessarily mean that all of the impacted areas report to this position, but this position would provide the enterprise or corporate vision of information security. It would coordinate the security accomplishments for the good of the entire organization, crossing domains and departments. Define "information"; what does it not include?

For years, security purists have argued for information security to report high in the organization as well as not necessarily within the information services (IS) division. Some organizations accomplished this by creating executive-level security positions reporting to the president, COO, or CEO. In differing ways, more organizations are finally making strides to at least put the "corporate" or "enterprise" spin on addressing the security issues of the organization, not just the issues (policy) of IS. An appointment of security personnel with accountability across the organization is a start. Giving them top management and line management support across the organization remains critical to their success, regardless of how high they report in the organization. An executive VP of information security will fail if the position is only a token position. On the other hand, the flunky of information security can be successful if everyone from top down is behind him and the concept of corporate information security.

In this structure, traditional areas can remain responsible for their parts of security and policy definition, their cards in the house, but a corporate entity coordinates the security efforts and brings it all together. That corporate entity is tasked with providing the corporate security vision and could report high in the organization, which is probably the best, or it could be assigned corporate responsibility by executive management. Total and very visual support by all management is obviously critical for success.

Sample roles and responsibilities for this structure include:

- The protection and safety department would continue to contract for guards, handle building access control, ID cards, and other physical building controls, including computer rooms.
- The telecommunications department is still be accountable for the security of phone systems and helps with establishment of policy addressing phone-mail and use of company telephones, probably including fax.
- A corporate mail department deals with internal and external mail, possibly including e-mail.

- IS has accountability for computer-based information processing systems and assists with the establishment of standards for use of them or policy dealing with information processing.
- The corporate legal department would help to ensure that policy meets regulations from a legal perspective and that proper wording makes them enforceable.
- A corporate compliance department can insure that regulatory and legislative concerns are addressed, such as the federal sentencing guidelines.
- Human resources (HR) is still a critical area in identifying employee policies and works closely with the Corporate Security Officer (CSO) on all policies, standards, procedures, and guidelines, as well as proper enforcement.
- The CSO works with all areas to provide high-level security expertise, coordinate and establish employee security awareness, security education programs, along with publication and communication of the security policies, standards, procedures, and guidelines.

SECURITY PHILOSOPHY

> No gain is possible without attendant outlay, but there will be no profit if the outlay exceeds the receipts.
>
> — Plautus

Return on Investment (ROI): What is the basis for security philosophy?

Security is often expected to provide a return on investment (ROI) to justify expenditures. How often is it possible for information security to generate a direct ROI? Which is more expensive, recover from an incident or prevent the incident in the first place? Computer security is often an intangible process. In many instances, the level of security is not evident until a catastrophe happens, at which time the lack of security is all too painfully evident.

Information security should be viewed in terms of the processes and goals of the business. Business risk is different from security risk, but poor security can put the business at risk, or make it risky doing business.

Example

- Would a wise company provide banking services, transmitting credit card numbers and account balances using an unsecured Internet connection? A properly secured infrastructure using encryption or certificates for nonrepudiation can provide the company with a business opportunity that it would not otherwise be likely to engage in. In that situation, the security is an integral part of that business opportunity, minimizing the business risk.

- How can a security manager justify control procedures over program changes or over developers with update access to production data? Assume that 20 percent of problems result from program errors or incorrect updates to data. Maybe inadequately tested code in a program is transferred to production. If controls can reduce the errors and resulting rework to say 10 percent, the payback would be only a few months. In a company that sells its programming services based on quality, this would directly relate to potential business opportunity and increased contracts.
- What about customer privacy? A Harris Poll showed that 53 percent of American adults are concerned about privacy threats from corporations. People have stated in surveys that they would rather do business with a company they feel is going to protect the privacy of their information. Increased business opportunity exists for the company that can show that it protects customer privacy better than its competition, even if it only generates the perception of better. Perception is 90 percent reality. Being able to show how the company enforces sound security policies, standards, and procedures would provide the business advantage.

  Although a mission statement may no longer refer directly to confidentiality, integrity, and availability, the security department cannot ignore CIA (see Exhibit 10-1). As discussed, the base security philosophy must now help improve business productivity. The real life situation is that we can never provide 100 percent security. We can, however, reduce the probability of loss or taking reasonable measures of due diligence consistent with industry norms for how like companies are dealing with like information. Going that extra step ahead to lead the industry can create business opportunity and minimize business risk.

To meet the security business objective, a better order for this triad is probably AIC, but that does not stir as much intrigue as CIA. Studies show AIC to be better matched to the order of priority for many security managers.

WHY?

- *Availability:* A corporation gathers endless amounts of information and in order to effectively produce product, that information must be available and usable when needed. This includes the concept of utility, or that the information must have the quality or condition of being useful. Just being available is not sufficient.
- *Integrity:* For the information to have any value and in order to produce quality product, the data must be protected against unauthorized or inadvertent modification. Its integrity must be of the highest quality and original. If the authenticity of the information is in doubt or compromised, the integrity is still jeopardized.

- *Confidentiality:* The privacy of customer information is becoming more and more important, if not to the corporation, to the customer. Legislation could one day mandate minimum protections for specific pieces of information like health records, credit card numbers, and bank account numbers. Ensuring that only the proper people have access to the information needed to perform their job or that they have been authorized to access it is often the last concern because it can impede business productivity.

MANAGEMENT MYTHS OF SECURITY

1. Security technology will solve all the problems.

Buy the software; now the company is secure. Management has signed the purchase order and the software has arrived. Is management's job finished and the company now secure? Management has done their due diligence, right? Wrong! Remember, software and security technologies are only a piece of the overall security program.

Management must have a concept or philosophy regarding how it wants to address information security, recognizing that technology and software are not 100 percent effective and are not going to magically eliminate all security problems. Does the security software restrict any access to a resource, provide everyone access, or just audit the access until someone steps forward with resources that need to be protected? The security job is not done once the software is installed or the technology is chosen.

Management support for proper security software implementation, configuration, continued maintenance, and the research and development of new security technologies is critical.

2. I have written the policy, so now we are done.

If policies or standards are written but never implemented, or not followed, not enforced, or enforced inconsistently it is worse than not having them at all. Federal Sentencing Guidelines require consistent application of policy and standards.

In an excerpt from the Federal Sentencing Guidelines, it states:

> The standards must have been consistently enforced through appropriate disciplinary mechanisms, including as appropriate, discipline of individuals responsible for the failure to detect an offense. Adequate discipline of individuals responsible for an offense is a necessary component of enforcement; however, the form of discipline that will be appropriate will be case specific.

Management must recognize that policy and standards implementation should be defined as a specific project receiving continued management

support. They may not have understood that there is a cost associated with implementing policy and thought this was only a policy development effort.

Strict enforcement of policy and standards must become a way of life in business. Corporate policy-making bodies should consider adherence to them a condition of employment. Never adopt a policy unless there is a good prospect that it will be followed. Make protecting the confidentiality, integrity, and availability of information "The Law."

3. Publish policy and standards and everyone will comply.

Not only is the job not done once the policy is written, but ensuring that every employee, customer, vendor, constituent, or stockholder knows and understands policy is essential. Training them and keeping records of the training on company policy are critical. Just publishing the policy does not encourage anyone to comply with it.

Simply training people or making them aware (security awareness) is also not sufficient; all one gets is shallow or superficial security. There needs to be motivation to carry out policy; only penalizing people for poor security does not always create positive motivation and is a militaristic attitude. Even child psychologists recommend positive reinforcement.

Security awareness alone can have a negative effect by teaching people how to avoid security in their work. Everyone knows it just slows them down, and they hate it anyway, especially if only penalties are associated with it. Positive reinforcement calls for rewards when people show actions and attitudes toward very good security. Do not eliminate penalties for poor security, but do not let them be the only motivator. Once rewards and penalties are identified, education can include how to achieve the rewards and avoid the penalties, just as for other work motivation. This requires an effectively applied security line item in salary and performance reviews and real rewards and penalties.

4. Follow the vendor's approach: it is the best way to make an organization secure.

An organization's goals should be to build the fences as high as it can. Protect everything; implement every feature of that new software. The organization has paid for those functions and the vendor must know the best way to implement them.

Often, an organization might be inclined to take a generic security product and fail to tailor it to fit its business objectives. Everyone can name an operating system that is not quite as secure as one would like it to be using the vendor defaults. The vendor's approach may go against organization

security philosophy. The product may come out of the box with limited security, open architecture, but the company security philosophy is to allow only access as appropriate, or vice versa.

Should one put all one's eggs in one basket or build one's house all from the same deck of cards? Does using only one security solution from a single vendor open vulnerability to the security architecture? Think about using the best-of-class solution from multiple vendors; this way, one's security architecture is not easily blueprinted by outsiders.

BUILDING THE BRIDGE: SECURITY CONTROLS REACH FOR BUSINESS NEEDS

An information security infrastructure is like a bridge built between the user with a business need to access information and at the other end of the bridge the information they wish to access. Creating gates between the end user and the data are the controls (technology) providing security protection or defining specific paths to the information. Forming the foundation for the security technology to be implemented are policies, standards, and procedures.

Guidelines are not required actions, but provide a map (suggestions of how to comply) or, like the railings of the bridge, help direct end users to their destination so they do not fall off the bridge. Just like the rails of a bridge, if the guidelines are not followed, it is still possible to fall off the bridge (not comply with policy and standards). The river represents unauthorized access, malicious elements (hackers), or unauthorized entities (disgruntled employees) that could affect the delivery of the payloads (information) across the bridge. The river (malicious access) is constantly flowing and often changing faster than security controls can be implemented. The security technology or software are locked gates, toll ways, or speed bumps on the bridge that control and audit the flow of traffic authorized to cross. Exposures or risks that have been accepted by management are represented by holes in the surface of the bridge that are not patched or are not covered by a security technology. Perhaps they are only covered with a see-through mesh, because ignorance is the only protection. The bigger the risk, the bigger the hole in the roadbed.

Build bridges that can get the organization from the "Wild Wild West" of the Internet to the future wars that are yet to be identified. William Hugh Murray of Deloitte and Touche once stated that one should build a solid infrastructure; the infrastructure should be a foundation that will last for 30 years. Work to build a bridge that will handle traffic for a long time and one will have the kind of infrastructure that can be depended upon for many years. Well-written and management-accepted policy should rarely change.

THE RIVER: UNDERSTANDING THE BUSINESS NEED

Understanding what one is protecting the business against is the first place to start. Too often, IS people will build a fantastic bridge — wide, double decked, all out of the best steel in the world — then they begin looking for a river to cross. This could also be called knowing the enemy or, in a more positive light to go with the business concept, understanding the business need.

If the Security Manager does not understand what objectives the end users of the information have, one will not know what is the best security philosophy to choose. One will not know whether availability is more important than integrity or confidentiality, nor which should get the primary focus. It will be difficult to leverage sufficient security technology with administrative procedures, policies, and standards. ROI will be impossible to guage. There will be no way of knowing what guidelines would help the end user follow policy or work best with the technology. Organizations often focus efforts on technical priorities that may not even be where the greatest exposures to the information are (see Exhibit 10-3). Problems for nonexistent exposures will be getting solved; a bridge will be getting erected across a dry river.

Exhibit 10-3. Case study: bank of the world savings.

CASE STUDY:

The Bank of the World Savings (BOWS) organization is dealing daily with financial information. BOWS has security technology fully implemented for protecting information from manipulation by unauthorized people and from people stealing credit card numbers, etc. to the best of its technical ability. Assuming this is equivalent to what all other banks do, BOWS has probably accomplished a portion of its due diligence.

Because no technology can provide 100 percent security, what happens if a person does get by the security technology? BOWS can be damaged just as severely by bad publicity as from the actual loss incurred by circumvention of the technology. Unless the bank has created procedures and policies for damage control, its loss could be orders of magnitude larger in lost business than the original loss.

BOWS does not process information using Internet technology; therefore, the outside element is of less concern. However, the company does have a high employee turnover rate and provides remote access via dial-up and remote control software. No policy exists to require unique user IDs, nor are there any procedures to ensure that terminated employees are promptly removed from system access.

The perpetrator (a terminated employee) is angry with BOWS and wants to get back at the company. He would not even need to use the information for his own financial gain. He could simply publish his ability to penetrate BOWS' defenses and create a consumer scare. The direct loss from the incident was $0, but overall damage to business was likely mega-dollars when the consumer community found out about BOWS bad security practices.

LAYING THE ROADBED: POLICY AND STANDARDS

The roadbed consists of policy and standards. Security policy and standards must have muscle. They must include strong yet enforceable statements, clearly written with no room for interpretation, and most importantly must be reasonable and supported by all levels of management. Avoid long or complex policies. As a rule of thumb, no policy should be more than one page in length; a couple of short paragraphs is preferable. Use words in the policy like must, shall, and will. If a policy is something that will not be supported or it is not reasonable to expect someone to follow it to do their job, it should not be published. (See also Exhibit 10-5.) Include somewhere in policy documentation of the disciplinary measures for anyone who does not comply. Procedures and guidelines can provide detail explaining how personnel can comply. To be valid, policy and standards must be consistently enforced. More information on the structure of policy and standards is available later in this article.

Enforcement procedures are the edges of the roadbed. Noncompliance might result in falling off the bridge, which many can relate to being in trouble, especially if one cannot swim. Enforcement provides the boundaries to keep personnel on the proper road. A sample of a simple enforcement procedure for a security violation might be:

1. On the first occurrence, the employee will be informed and given a warning of the importance to comply with policy.
2. On the next occurrence, the employee's supervisor will be contacted. The supervisor will discuss the indiscretion with the employee.
3. Further violations of the same policy will result in disciplinary actions that might consist of suspension or possible termination, depending on the severity of the incident.

In any case, it might be necessary to publish a disclaimer stating that depending on the severity of the incident, disciplinary actions can result in termination. Remember that, to some degree, common sense must come into the decisions regarding how enforcement procedures should be applied, but they should always be consistently enforced. Also, emphasize the fact that it is all management's responsibility to enforce policy, not just the Security Manager's.

Start with the basics, create baselines, and build on them until one has a corporate infrastructure that can stand years and years of traffic. Policy and standards form the benchmarks or reference points for audits. They provide the basis of evidence that management has acted with due diligence, thus reducing their liability.

THE GATE KEEPERS: TECHNOLOGY

Technology is everywhere. In the simplest terms, the security technology consists of specific software that will provide for three basic elements

of protection: authentication, accountability, and audit. Very specific standards provide the baselines for which technology is evaluated, purchased, and implemented. Technology provides the mechanism to enforce policies, standards, and procedures.

Authentication. Authentication is the process by which access is established and the system verifies that the end user requesting access to the information is who they claim to be. The process involves providing one's personal key at the locked gate to open it in order to be able to cross the bridge using the path guarded by that gate.

Accountability. Accountability is the process of assigning appropriate access and identification codes to users in order for them to access the information. Establishing audit trails is what establishes accountability.

An example of accountability in electronic commerce is the assignment of digital certificates that can provide varying levels of guaranteed accountability (trust). At the least trusted levels, the user has a credit card or cash to buy a certificate. At a middle degree of trust, there is more checking done to validate that the user really is the person who they claim to be. At the highest level of trust, an entity is willing to stand behind the accountability of the certificate assignment to make it legally binding. This would mean a signature document was signed in person with the registrant that assigns certificates for establishing the accountability.

Assigning a personal key to an individual who has provided beyond-doubt proof (DNA test) that they are who they say they are and that they have agreed to guard their key with their life and that any access by that key can only be by them.

Audit. This is the process, on which accountability depends that can verify using system events to show beyond a reasonable doubt, that specific activities, authorized or unauthorized, occurred in the system by a specific user identification at a given point in time. The information is available on request and used to report to management, internal and external auditors, and could be used as legal evidence in a criminal prosecution.

Having the necessary proof that the personal (authentication) key assigned (accountable) to Ken M. Shaurette was used to perform an unauthorized activity such as to modify the payroll system, adding bonus bucks to the salaries of all CISSP personnel.

PROVIDING TRANSPORTATION: COMMUNICATION

Communication is the #1 key to the success of any security infrastructure. Not only do policy, standards, procedures, and guidelines need to be communicated, but proper use and availability of the security technologies and processes also need to be communicated. Communications is like the

racecar or the bus that gets the user across the bridge faster from their business need to the information on the other side. Arguably, the most important aspect of security is informing everyone that they have a responsibility for its effectiveness.

CERT estimates that 80 percent of network security intrusions are a result of users selecting and using passwords that are easy to guess and as such are easy to compromise. If users are unaware that bad password selection is a risk, what incentive is there to make better selections? If they knew of guidelines that could help them pick a more difficult password to compromise, would they not be more inclined to do so? If users are unaware that guidelines exist to help them, how can they follow them?

What makes up communications? Communications involves integrating the policy into the organization using a successful security-training program consisting of such things as:

- new employee orientations
- periodic newsletters
- intranet Web site
- electronic announcements (i.e., banners, e-mail)
- CBT course
- technology lunches, dinners
- informal user group forums
- regular company publications
- security awareness days
- ethics and appropriate use agreements signed annually

EXPERT VERSUS FOOL: IMPLEMENTATION RECOMMENDATIONS

Before beginning policy and standard development, understand that in an established organization, policy and standards may exist in different forms. There is probably official, de jure, less official, *de facto* and proprietary, no choice. Official is the law; they are formal and already accepted. Less official consists of things that get followed but are not necessarily published, but maybe should be. Proprietary are the items that are dictated by an operating system; for example, MVS has limitations of eight-character user IDs and eight-character passwords.

Be the Expert: Implementation Recommendations

Form a team or committee that gets the involvement and cooperation of others. If the policies, standards, procedures, and guidelines are to become enterprisewide, supported by every layer of management, and be reasonable and achievable, representation from all areas — both technology and non-technology — will go a long way toward meeting that goal. Only a team

of the most wise and sage experts from all over the organization will know what may already exist and what might still be necessary.

As the security professional, efforts should be concentrated on providing high-level security expertise, coordination, recommendations, communication, and education in order to help the team come to a consensus. Be the engineer, not the builder; get the team to build the bridge.

Layering Security

Layer protection policies and standards. Support them with procedures and guidelines. Review and select security technology that can be standards. Create guidelines and procedures that help users comply with policy. Establishing policy and adequate standards provides the organization with control of its own destiny. Not doing so provides the potential for auditors (internal or external) or legal actions to set policy.

The following walks the reader through the layers outlined in Exhibit 10-4, from the top down.

Corporate Security Policy. This is the top layer of Exhibit 10-4. There should be as few policies as possible used to convey corporate attitude and the attitude from the top down. Policies will have very distinct characteristics. They should be short, enforceable, and seldom change. See Exhibit 10-5 for tips on writing security policy. Policy that gets in the way of business productivity will be ignored or eliminated. Corporate ethics are a form of policy at the top level. Proper use of computing resources or platforms is another example of high-level policy, such as the statement, "for business use only."

> SAMPLE POLICY:
> Information will be protected based on a need-to-know philosophy. Information will be classified and protected in a manner commensurate with its sensitivity, value, and criticality. Protection of information will apply regardless of the media where the information is stored (printed, electronic, etc.), the systems that process it (PC, mainframes, voice mail systems, etc.), or the transport mechanisms by which it is moved (fax, electronic mail, TCP/IP network, voice conversation, etc.).

Functional Standards

Functional standards (the second layer of Exhibit 10-4) are generally associated to a business area. The Loan department in a bank might have standards governing proper handling of certain loan information. For example, a loan department might have a standard with an associated procedure for the special handling of loans applied for by famous people, or executives of the company. Standards might require that information assigned sensitive classification levels is shredded, or an HR department

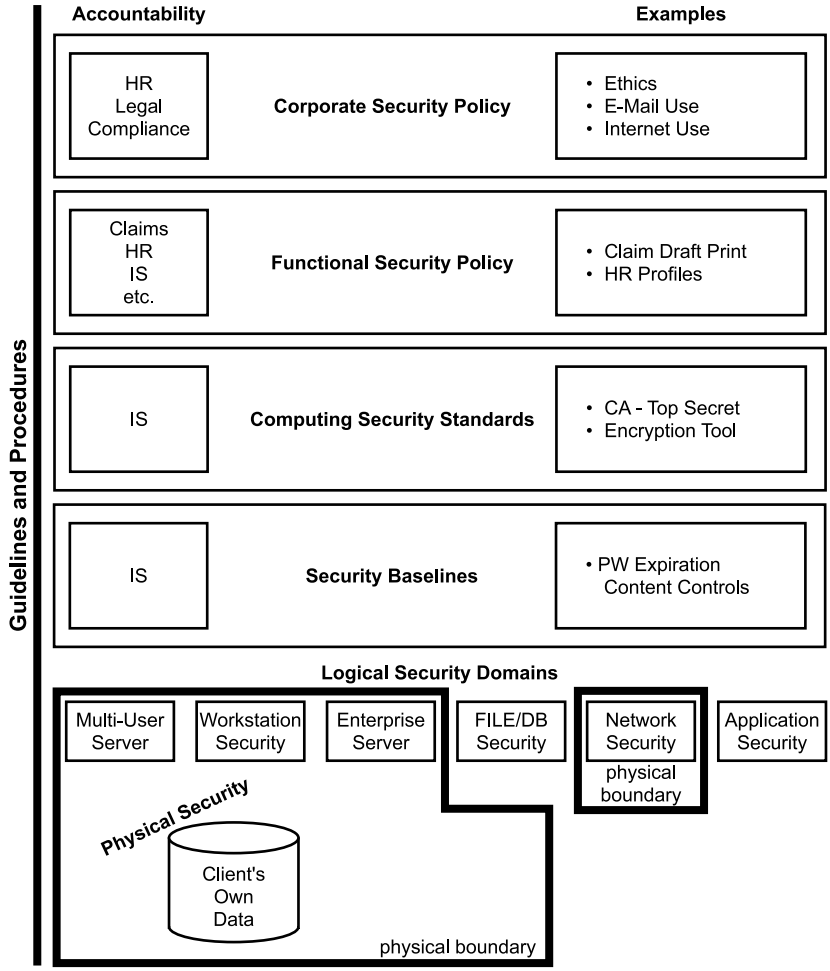

Exhibit 10-4. Layers of security: policies, standards, and procedures.

might require that employee profiles only be printed on secure printers, available and handled only by specific personnel. The Claims department in an insurance company may set standards that require the printing of claim checks on printers local to the office that is handling the claim.

Computing Policy

The computing policies (the third layer in Exhibit 10-4) are tied with technology. These standards establish computing environments such as identifying the standard security software for securing mainframe-computing environments (i.e., CA-Top Secret, RACF, or CA-ACF2), establishing an encryption standard (i.e., PGP, BLOWFISH, DES, 3DES) for every desktop/laptop, or

Exhibit 10-5. Tips on writing security policy.

- Make the policy easy to understand.
- Make it applicable. Does the policy really fit? Does it relate to what actually happens at the company? Does if fit the organizations culture?
- Make it do-able. Can the company still meet business objectives if the policy is implemented?
- Make it enforceable.
- Use a phased-in approach. Allow time for employees to read, digest, and respond to the policy.
- Be pro-active. State what must be done.
- Avoid absolutes; almost never say "never."
- Use wording such as "must," "will," or "shall" — not "would," "should," or "could."
- Meet business objectives. Allow the organization to identify an acceptable level of risk.
- Address all forms of information. (How were the machine names obtained)?
- Obtain appropriate management support.
- Conform. It is important that policy looks like other written company policies.
- Keep it short. Policies are shorter than procedures or practices, usually one or two pages in length maximum.
- What is to be protected?
- When does the policy take effect?
- Where within the organization does the policy reach? Remember the scope.
- To whom does the policy apply? Is there a limitation on the domain?
- Why was the policy developed?
- Who is responsible for enforcement?
- What are the ramifications of noncompliance?
- What, if any, deviations are allowed? If allowed, what are the deviation procedures?
- Are audit trails available and required?
- Who developed, approved, and authorized the policy?
- How will compliance be monitored?
- Are there only penalties for noncompliance, or are rewards available to motivate people toward good practices?
- Who has update and maintenance responsibility for the policies?
- How often will the policy be reviewed and updated if necessary?
- Are there documented approval procedures for new or updated policy?
- Is there an archive of policy, past to present? What was in effect last year at the time of the incident?
- What is the date of the last revision?

transmission of any sensitive information. Information services is most likely establishing the computing security standards that work with information owner requirements, and business needs.

Security Baselines

Security baselines (the fourth layer in Exhibit 10-4) can also be called the minimums. These are tied very closely to the operating environment

and day-to-day functioning of the business. Some baselines might be password expiration intervals, password content controls (six characters must be one numeric or special character), and minimum length of user ID. Another might be requiring that every computing system perform authentication based on a personal identity code that will be assigned to each user and that they use their personal password or alternative authentication (token, biometrics) before access is granted to perform any activities. Audit would also be another baseline requirement.

Technology and Physical Security

Technology and physical security are the components making up the bottom layer of Exhibit 10-4. This is the technology, the security software or hardware, that makes up the various computing platforms that comprise the information processing environment. It is the specific security within an NOS, an application, firewalls for the network, database security, or any other specific technology that provides the actual controls that allow the organization to enforce baselines and standards. An application program may have the security checking that restricts the printing of employee profiles and claim checks or provides alerts and special handling controls for loans by special people.

Procedures and Guidelines

Procedures and guidelines cross all layers of the information security infrastructure, as illustrated in Exhibit 10-4. Guidelines are not required actions, but procedures could fall into either something that must be done or provide help in compliance with security policy, standards, and technology. The best policy and standard can have minimal value if people do not have guidelines to follow. Procedures go that next step in explaining the why and how of policy in the day-to-day business operation to help ensure proper implementation and continued compliance. Policy can only be concise if the guidelines and procedures provide sufficient explanation of how to achieve the business objective. Enforcement is usually spelled out in the form of a procedure; procedures would tell how to and why it is necessary to print to specific printers or handle certain loans in a special way. Guidelines are the hints and tips; for example, sharing one's password does not eliminate one's accountability; choose passwords that are not easily guessed and give sample techniques for password selection. Help personnel find the right path and they will follow it; reminders of the consequences are good incentives.

THE POLICE ARE COMING!

In conclusion, what are the measures that can be taken to protect the company or management from litigation? Security cannot provide 100 percent

protection. There will be a need to accept some risk. Recognize due care methods to reduce and limit liability by minimizing how much risk must be accepted. Computer security is often an intangible process. In many instances, the level of security is not evident until a catastrophe happens, at which time the lack of security is all too painfully evident. Make the protection of corporate information assets "the law." Make adherence to policy and standards a condition of employment. Policy, standards, and procedures must become part of the corporation's living structure, not just a policy development effort. Information security's objective is to enhance the productivity of the business by reducing probability of loss through the design and implementation of policies, standards, procedures, and guidelines that enhance the protection of business assets.

- Information security is not just about technological controls such as software or hardware. Establishing policy and adequate standards provide an organization with control over its own destiny.
- Information security should be viewed in terms of the processes and goals of the business. Business risk is different than security risk, but poor security can put the business at risk; or make it risky doing business.
- Security must become a function of the corporation, and not viewed as an obstacle to business. Policies support the business; put them in business terminology.
- Form a team. Only a team of the most wise and sage experts from all over the organization will know what policy may already exist and what might still be necessary.
- There should be as few policies as possible used to convey corporate attitude and the attitude from the top down. Policies will have very distinct characteristics. They should be short, enforceable, and seldom altered. They must include strong yet enforceable statements, be clearly written with no room for interpretation, and most importantly, must be reasonable and supported by all levels of management. Use words in the policy like must, shall, and will.
- Policy can only be concise if the guidelines and procedures provide sufficient explanation of how to achieve the business objective.
- Test policy and standards; it is easy to know what is published, but is that what is really in operation?
- To be valid, policy and standards must be consistently enforced.
- Carefully define the Security Manager's domain, responsibility, and accountabilities. Clearly identify the scope of their job.
- Communication is the #1 key to the success of any security infrastructure.

> To defeat a strong enemy: Deploy forces to defend the strategic points; exercise vigilance in preparation, do not be indolent. Deeply investigate the true situation, secretly await their laxity. Wait until they leave their strongholds, then seize what they love.
>
> — Sun Tzu

Information security is a team effort; all members in an organization must support the business objectives; and information security is an important part of that objective.

55

The Human Side of Information Security

Kevin Henry, CISA, CISSP

We often hear that people are the weakest link in any security model. That statement brings to mind the old adage that a chain is only as strong as its weakest link. Both of these statements may very well be true; however, they can also be false and misleading.

Throughout this chapter we are going to define the roles and responsibilities of people, especially in relation to information security. We are going to explore how people can become our strongest asset and even act as a compensating strength for areas where mechanical controls are ineffective. We will look briefly at the training and awareness programs that can give people the tools and knowledge to increase security effectiveness rather than be regarded as a liability and a necessary evil.

The Role of People in Information Security

First, we must always remember that systems, applications, products, etc. were created for people — not the other way around. As marketing personnel know, the end of any marketing plan is when a product or service is purchased for, and by, a person. All of the intermediate steps are only support and development for the ultimate goal of providing a service that a person is willing, or needs, to purchase. Even though many systems in development are designed to reduce labor costs, streamline operations, automate repetitive processes, or monitor behavior, the system itself will still rely on effective management, maintenance upgrades, and proper use by individuals. Therefore, one of the most critical and useful shifts in perspective is to understand how to get people committed to and knowledgeable about their roles and responsibilities as well as the importance of creating, enforcing, and committing to a sound security program.

Properly trained and diligent people can become the strongest link in an organization's security infrastructure. Machines and policy tend to be static and limited by historical perspectives. People can respond quickly, absorb new data and conditions, and react in innovative and emotional ways to new situations. However, while a machine will enforce a rule it does not understand, people will not support a rule they do not believe in. The key to strengthening the effectiveness of security programs lies in education, flexibility, fairness, and monitoring.

The Organization Chart

A good security program starts with a review of the organization chart. From this administrative tool, we learn hints about the structure, reporting relationships, segregation of duties, and politics of an organization. When we map out a network, it is relatively easy to slot each piece of equipment into its proper place, show how data flows from one place to another, show linkages, and expose vulnerabilities. It is the same with an organization chart. Here we can see the structure of an organization, who reports to whom, whether authority is distributed or centralized, and who has the ability or placement to make decisions — both locally and throughout the enterprise.

Why is all of this important? In some cases, it is not. In rare cases, an ideal person in the right position is able to overcome some of the weaknesses of a poor structure through strength or personality. However, in nearly all cases, people fit into their relative places in the organizational structure and are constrained by the limitations and boundaries placed around them. For example, a security department or an emergency planning group may be buried deep within one *silo* or branch of an organization. Unable to speak directly with decision makers, financial approval teams, or to have influence over other branches, their efforts become more or less philosophical and ineffective. In such an environment the true experts often leave in frustration and are replaced by individuals who thrive on meetings and may have limited vision or goals.

Do We Need More Policy?

Many recent discussions have centered on whether the information security community needs more policy or to simply get down to work. Is all of this talk about risk assessment, policy, roles and responsibilities, disaster recovery planning, and all of the other *soft* issues that are a part of an information security program only expending time and effort with few results? In most cases, this is probably true. Information security must be a cohesive, coordinated action, much like planning any other large project. A house can be built without a blueprint, but endless copies of blueprints and modifications will not build a house. However, proper planning and methodologies will usually result in a project that is on time, meets customer needs, has a clearly defined budget, stays within its budget, and is almost always run at a lower stress level. As when a home is built, the blueprints almost always change, modifications are done, and, together with the physical work, the administrative effort keeps the project on track and schedules the various events and subcontractors properly.

Many firms have information security programs that are floundering for lack of vision, presentation, and coordination. For most senior managers, information security is a gaping dark hole into which vast amounts of cash are poured with few outcomes except further threats, fear-mongering, and unseen results.

To build an effective program requires vision, delegation, training, technical skills, presentation skills, knowledge, and often a thick skin — not necessarily in that order.

The program starts with a vision. What do we want to accomplish? Where would we like to be? Who can lead and manage the program? How can we stay up-to-date, and how can we do it with limited resources and skills?

A vision is the perception we have of the goal we want to reach. A vision is not a fairy tale but a realistic and attainable objective with clearly defined parameters. A vision is not necessarily a roadmap or a listing of each component and tool we want to use; rather, it is a strategy and picture of the functional benefits and results that would be provided by an effective implementation of the strategic vision.

How do we define our vision? This is a part of policy development, adherence to regulations, and risk assessment. Once we understand our security risks, objectives, and regulations, we can begin to define a practical approach to addressing these concerns.

A recent seminar was held with security managers and administrators from numerous agencies and organizations. The facilitator asked the group to define four major technical changes that were on the horizon that would affect their agencies. Even among this knowledgeable group, the response indicated that most were unaware of the emerging technologies. They were knowledgeable about current developments and new products but were unaware of dramatic changes to existing technologies that would certainly have a major impact on their operations and technical infrastructures within the next 18 months. This is a weakness among many organizations. Strategic planning has been totally overwhelmed by the need to do operational and tactical planning.

Operational or day-to-day planning is primarily a response mechanism — how to react to today's issues. This is kindly referred to as crisis management; however, in many cases the debate is whether the managers are managing the crisis or the crisis is managing the managers.

Tactical planning is short- to medium-term planning. Sometimes, tactical planning is referred to in a period of up to six months. Tactical planning is forecasting developments to existing strategies, upgrades, and operational process changes. Tactical planning involves understanding the growth, use, and risks of the environment. Good tactical plans prevent performance impacts from over-utilization of hardware resources, loss of key personnel, and market changes. Once tactical planning begins to falter, the impact is felt on operational activity and planning within a short timeframe.

Strategic planning was once called long-term planning, but that is relative to the pace of change and volatility of the environment. Strategic planning is preparing for totally new approaches and technologies. New projects,

marketing strategies, new risks, and economic conditions are all a part of a good strategic plan. Strategic planning is looking ahead to entirely new solutions for current and future challenges — seeing the future and how the company or organization can poise itself to be ready to adopt new technologies. A failure to have a strategic plan results in investment in technologies that are outdated, have a short life span, are ineffective, do not meet the expectations of the users, and often result in a lack of confidence by senior management (especially from the user groups) in the information technology or security department.

An information security program is not only a fire-fighting exercise; yet for many companies, that is exactly what they are busy with. Many system administrators are averaging more than five patch releases a week for the systems for which they are responsible. How can they possibly keep up and test each new patch to ensure that it does not introduce other problems? Numerous patches have been found to contain errors or weaknesses that affect other applications or systems. In October 2001, anti-virus companies were still reporting that the LoveLetter virus was accounting for 2.5 percent of all help desk calls — more than a year after patches were available to prevent infection.[1]

What has gone wrong? How did we end up in the position we are in today? The problem is that not any one person can keep up with this rapidly growing and developing field. Here, therefore, is one of the most critical reasons for delegation: the establishment of the principles of responsibility and accountability in the correct departments and with the proper individuals.

Leadership and placement of the security function is an ongoing and never-to-be-resolved debate. There is not a one-size-fits-all answer; however, the core concern is whether the security function has the influence and authority it needs to fulfill its role in the organization.

The role of security is to inform, monitor, lead, and enforce best practice. As we look further at each individual role and responsibility in this chapter, we will define some methods of passing on information or awareness training.

Security Placement

The great debate is where the security department should reside within an organization. There are several historical factors that apply to this question. Until recently, physical security was often either outsourced or considered a less-skilled department. That was suitable when security consisted primarily of locking doors and patrolling hallways. Should this older physical security function be merged into the technical and cyber-security group?

To use our earlier analogy of security being a chain, and the risk that one weak link may have a serious impact on the entire chain, it is probable that combining the functions of physical and technical security is appropriate. Physical access to equipment presents a greater risk than almost any other vulnerability. The trend to incorporate security, risk management, business continuity, and sometimes even audit under one group led by a chief risk officer is recognition both of the importance of these various functions and the need for these groups to work collaboratively to be effective.

The position of chief risk officer (CRO) is usually as a member of the senior management team. From this position, the CRO can ensure that all areas of the organization are included in risk management and disaster recovery planning. This is an extremely accountable position. The CRO must have a team of diligent and knowledgeable leaders who can identify, assess, analyze, and classify risks, data, legislation, and regulation. They must be able to convince, facilitate, coordinate, and plan so that results are obtained; workable strategies become tactical plans; and all areas and personnel are aware, informed, and motivated to adhere to ethics, best practices, policy, and emergency response.

As with so many positions of authority, and especially in an area where most of the work is administrative such as audit, business continuity planning, and risk management, the risk of gathering a team of paper pushers and "yes men" is significant. The CRO must resist this risk by encouraging the leaders of the various departments to keep each other sharp, continue raising the bar, and striving for greater value and benefits.

The Security Director

The security director should be able to coordinate the two areas of physical and technical security. This person has traditionally had a law enforcement background, but these days it is important that this person have a good understanding of information systems security. This person ideally should have certification such as the

CISSP (Certified Information Systems Security Professional administered by ISC² [www.isc2.org]) and experience in investigation and interviewing techniques. Courses provided by companies like John E. Reid and Associates can be an asset for this position.

Roles and Responsibilities

The security department must have a clearly defined mandate and reporting structure. All of its work should be coordinated with the legal and human resources departments. In extreme circumstances it should have access directly to the board of directors or another responsible position so that it can operate confidentially anywhere within the organization, including the executive management team. All work performed by security should be kept confidential in order to protect information about ongoing investigations or erroneously damage the reputation of an individual or a department.

Security should also be a focus point to which all employees, customers, vendors, and the public can refer questions or threats. When an employee receives an e-mail that he suspects may contain a virus or that alleges a virus is on the loose, he should know to contact security for investigation — and not to send the e-mail to everyone he knows to warn them of the perceived threat.

The security department enforces organizational policy and is often involved in the crafting and implementation of policy. As such, this department needs to ensure that policy is enforceable, understandable, comprehensive, up-to-date, and approved by senior management.

Training and Awareness

The security director has the responsibility of promoting education and awareness as well as staying abreast of new developments, threats, and countermeasures. Association with organizations such as SANS (www.sans.org), ISSA (www.issa.org), and CSI (www.gocsi.org) can be beneficial. There are many other groups and forums out there; and the director must ensure that the most valued resources are used to provide alerts, trends, and product evaluation.

The security department must work together with the education and training departments of the organization to be able to target training programs in the most effective possible manner. Training needs to be relevant to the job functions and risks of the attendees. If the training can be imparted in such a way that the attendees are learning the concepts and principles without even realizing how much they have learned, then it is probably ideal. Training is not a "do not do this" activity — ideally, training does not need to only define rules and regulations; rather, training is an activity designed to instill a concept of best practice and understanding to others. Once people realize the reasons behind a guideline or policy, they will be more inclined to better standards of behavior than they would if only pressured into a firm set of rules.

Training should be creative, varied, related to real life, and frequent. Incorporating security training into a ten-minute segment of existing management and staff meetings, and including it as a portion of the new employee orientation process, is often more effective than a day-long seminar once a year. Using examples can be especially effective. The effectiveness of the training is increased when an actual incident known to the staff can be used as an example of the risks, actions, retribution, and reasoning associated with an action undertaken by the security department. This is often called *dragging the wolf into the room*. When a wolf has been taking advantage of the farmer, bringing the carcass of the wolf into the open can be a vivid demonstration of the effectiveness of the security program. When there has been an incident of employee misuse, bringing this into the open (in a tactful manner) can be a way to prevent others from making the same mistakes. Training is not fear mongering. The attitude of the trainers should be to raise the awareness and behavior of the attendees to a higher level, not to explain the rules as if to criminals that they had "better behave or else."

This is perhaps the greatest strength of the human side of information security. Machines can be programmed with a set of rules. The machine then enforces these rules mechanically. If prople are able to slightly modify their activity or use a totally new attack strategy, they may be able to circumvent the rules and attack the machine or network. Also — because machines are controlled by people — when employees feel unnecessarily constrained by a rule, they may well disable or find a way to bypass the constraint and leave a large hole in the rule base. Conversely, a security-conscious person may be able to detect an aberration in behavior or even attitude that could be a precursor to an attack that is well below the detection level of a machine.

Reacting to Incidents

Despite our best precautions and controls, incidents will arise that test the strength of our security programs. Many incidents may be false alarms that can be resolved quickly; however, one of the greatest fears with false alarms is the tendency to become immune to the alarms and turn off the alarm trigger. All alarms should be logged and resolved. This may be done electronically, but it should not be overlooked. Alarm rates can be critical indicators of trends or other types of attacks that may be emerging; they can also be indicators of additional training requirements or employees attempting to circumvent security controls.

One of the tools used by security departments to reduce nuisance or false alarms is the establishment of clipping levels or thresholds for alarm activation. The clipping level is the acceptable level of error before triggering the alarm. These are often used for password lockout thresholds and other low-level activity. The establishment of the correct clipping level depends on historical events, the sensitivity of the system, and the granularity of the system security components. Care must be exercised to ensure that clipping levels are not set too high such that a low-level attack can be performed without bringing in an alarm condition.

Many corporations use a tiered approach to incident response. The initial incident or alarm is recognized by a help-desk or low-level technical person. This person logs the alarm and attempts to resolve the alarm condition. If the incident is too complex or risky to be resolved at this level, the technician refers the alarm to a higher-level technical expert or to management. It is important for the experts to routinely review the logs of the alarms captured at the initial point of contact so that they can be assured that the alarms are being handled correctly and to detect relationships between alarms that may be an indication of further problems.

Part of good incident response is communication. To ensure that the incident is handled properly and risk to the corporation is minimized, a manner of distributing the information about the incident needs to be established. Pagers, cell phones, and e-mail can all be effective tools for alerting key personnel. Some of the personnel that need to be informed of an incident include senior management, public relations, legal, human resources, and security.

Incident handling is the expertise of a good security team. Proper response will contain the damage; assure customers, employees, and shareholders of adequate preparation and response skills; and provide feedback to prevent future incidents.

When investigating an incident, proper care must be taken to preserve the information and evidence collected. The victims or reporting persons should be advised that their report is under investigation.

The security team is also responsible for reviewing past incidents and making recommendations for improvements or better controls to prevent future damage. Whenever a business process is affected, and the business continuity plan is enacted, security should ensure that all assets are protected and controls are in place to prevent disruption of recovery efforts.

Many corporations today are using managed security service providers (MSSPs) to monitor their systems. The MSSP accumulates the alarms and notifies the corporation when an alarm or event of significant seriousness occurs. When using an MSSP, the corporation should still have contracted measurement tools to evaluate the appropriateness and effectiveness of the MSSP's response mechanisms. A competent internal resource must be designated as the contact for the MSSP.

If an incident occurs that requires external agencies or other companies to become involved, a procedure for contacting external parties should be followed. An individual should not contact outside groups without the approval and notification of senior management. Policy must be developed and monitored regarding recent laws requiring an employee to alert police forces of certain types of crimes.

The IT Director — The Chief Information Officer (CIO)

The IT director is responsible for the strategic planning and structure of the IT department. Plans for future systems development, equipment purchase, technological direction, and budgets all start in the office of the IT director. In most cases, the help desk, system administrators, development departments, production support, operations, and sometimes even telecommunications departments are included in his jurisdiction.

The security department should not report to the IT director because this can create a conflict between the need for secure processes and the push to develop new systems. Security can often be perceived as a roadblock for operations and development staff, and having both groups report to the same manager can cause conflict and jeopardize security provisioning.

The IT director usually requires a degree in electrical engineering or computer programming and extensive experience in project planning and implementation. This is important for an understanding of the complexities and challenges of new technologies, project management, and staffing concerns. The IT director or CIO should sit on the senior management team and be a part of the strategic planning process for the organization. Facilitating business operations and requirements and understanding the direction and technology needs of the corporation are critical to ensuring that a gulf does not develop between IT and the sales, marketing, or production shops. In many cases, corporations have been limited in their flexibility due to the cumbersome nature of legacy systems or poor communications between IT development and other corporate areas.

The IT Steering Committee

Many corporations, agencies, and organizations spend millions of dollars per year on IT projects, tools, staff, and programs and yet do not realize adequate benefits or return on investment (ROI) for the amounts of money spent. In many cases this is related to poor project planning, lack of a structured development methodology, poor requirements definition, lack of foresight for future business needs, or lack of close interaction between the IT area and the business units. The IT steering committee is comprised of leaders from the various business units of the organization and the director of IT. The committee has the final approval for any IT expenditures and project prioritization. All proposed IT projects should be presented to the committee along with a thorough business case and forecast expenditure requirements. The committee then determines which projects are most critical to the organization according to risk, opportunities, staffing availability, costs, and alignment with business requirements. Approval for the projects is then granted.

One of the challenges for many organizations is that the IT steering committee does not follow up on ongoing projects to ensure that they meet their initial requirements, budget, timeframes, and performance. IT steering committee members need to be aware of business strategies, technical issues, legal and administrative requirements, and economic conditions. They need the ability to overrule the IT director and cancel or suspend any project that may not provide the functionality required by the users, adequate security, or is seriously over budget. In such cases the IT steering committee may require a detailed review of the status of the project and reevaluate whether the project is still feasible.

Especially in times of weakening IT budgets, all projects should undergo periodic review and rejustification. Projects that may have been started due to hype or the proverbial bandwagon — "everyone must be E-business or they are out of business" — and do not show a realistic return on investment should be cancelled. Projects that can save money must be accelerated — including in many cases a piecemeal approach to getting the most beneficial portions implemented rapidly. Projects that will result in future savings, better technology, and more market flexibility need to be continued, including projects to simplify and streamline IT infrastructure.

Change Management — Certification and Accreditation

Change management is one of the greatest concerns for many organizations today. In our fast-paced world of rapid development, short time to market, and technological change, change management is the key to ensuring that a "sober second thought" is taken before a change to a system goes into production. Many times, the pressure to make a change rapidly and without a formal review process has resulted in a critical system failure due to inadequate testing or unanticipated or unforeseen technical problems.

There are two sides to change management. The most common definition is that change management is concerned with the certification and accreditation process. This is a control set in place to ensure that all changes that are proposed to an existing system are properly tested, approved, and structured (logically and systematically planned and implemented).

The other aspect of change management comes from the project management and systems development world. When an organization is preparing to purchase or deploy a new system, or modify an existing system, the organization will usually follow a project management framework to control the budget, training, timing, and staffing requirements of the project. It is common (and often expected, depending on the type of development life cycle employed) that such projects will undergo significant changes or decision points throughout the project lifetime. The decision points are times when evaluations of the project are made and a choice to either continue or halt the project may be required. Other changes may be made to a project due to external factors — economic climate, marketing forces, and availability of skilled personnel — or to internal factors

such as identification of new user requirements. These changes will often affect the scope of the project (the amount of work required and the deliverables) or timing and budgeting. Changes made to a project in midstream may cause the project to become unwieldy, subject to large financial penalties — especially when dealing with an outsourced development company — or delayed to the point of impacting business operations. In this instance, change management is the team of personnel that will review proposed changes to a project and determine the cutoff for modifications to the project plan. Almost everything we do can be improved and as the project develops, more ideas and opportunities arise. If uncontrolled, the organization may well be developing a perfect system that never gets implemented. The change control committee must ensure that a time comes when the project timeline and budget are set and followed, and refuse to allow further modifications to the project plan — often saving these ideas for a subsequent version or release.

Change management requires that all changes to hardware, software, documentation, and procedures are reviewed by a knowledgeable third party prior to implementation. Even the smallest change to a configuration table or attaching a new piece of equipment can cause catastrophic failures to a system. In some cases a change may open a security hole that goes unnoticed for an extended period of time. Changes to documentation should also be subject to change management so that all documents in use are the same version, the documentation is readable and complete, and all programs and systems have adequate documentation. Furthermore, copies of critical documentation need to be kept off-site in order to be available in the event of a major disaster or loss of access to the primary location.

Certification

Certification is the review of the system from a user perspective. The users review the changes and ensure that the changes will meet the original business requirements outlined at the start of the project or that they will be compatible with existing policy, procedures, or business objectives. The other user group involved is the security department. This group needs to review the system to ensure that it is adequately secured from threats or risks. In this they will need to consider the sensitivity of the data within the system or that the system protects, the reliance of the business process on the system (availability), regulatory requirements such as data protection or storage (archival) time, and documentation and user training.

Accreditation

Once a system has been certified by the users, it must undergo accreditation. This is the final approval by management to permit the system, or the changes to a component, to move into production. Management must review the changes to the system in the context of its operational setting. They must evaluate the certification reports and recommendations from security regarding whether the system is adequately secured and meets user requirements and the proposed implementation timetable. This may include accepting the residual risks that could not be addressed in a cost-effective manner.

Change management is often handled by a committee of business analysts, business unit directors, and security and technical personnel. They meet regularly to approve implementation plans and schedules. Ideally, no change will go into production unless it has been thoroughly inspected and approved by this committee. The main exceptions to this, of course, are changes required to correct system failures. To repair a major failure, a process of emergency change management must be established. The greatest concern with emergency changes is ensuring that the correct follow-up is done to ensure that the changes are complete, documented, and working correctly.

In the case of volatile information such as marketing programs, inventory, or newsflashes, the best approach is to keep the information stored in tables or other logically separated areas so that these changes (which may not be subject to change management procedures) do not affect the core system or critical functionality.

Technical Standards Committee

Total cost of ownership (TCO) and keeping up with new or emerging tools and technologies are areas of major expenditure for most organizations today. New hardware and software are continuously marketed. In many cases a new operating system may be introduced before the organization has completed the rollout of the previous version. This often means supporting three versions of software simultaneously. Often this has resulted

in the inability of personnel still using the older version of the software to read internal documents generated under the newer version. Configurations of desktops or other hardware can be different, making support and maintenance complex. Decisions have to be made about which new products to purchase — laptops instead of desktops, the minimum standards for a new machine, or type of router or network component. All of these decisions are expensive and require a long-term view of what is coming onto the horizon.

The technical standards committee is an advisory committee and should provide recommendations (usually to the IT steering committee or another executive-level committee) for the purchase, strategy, and deployment of new equipment, software, and training. The members of the technical standards committee must be aware of the products currently available as well as the emerging technologies that may affect the viability of current products or purchases. No organization wants to make a major purchase of a software or hardware product that will be incompatible with other products the organization already has or will require within the next few months or years. The members of the technical standards committee should consist of a combination of visionaries, technical experts, and strategic business planners. Care should be taken to ensure that the members of this committee do not become unreasonably influenced by or restricted to one particular vendor or supplier.

Central procurement is a good principle of security management. Often when an organization is spread out geographically, there is a tendency for each department to purchase equipment independently. Organizations lose control over standards and may end up with incompatible VPNs, difficult maintenance and support, loss of savings that may have been available through bulk purchases, cumbersome disaster recovery planning through the need to communicate with many vendors, and loss of inventory control. Printers and other equipment become untraceable and may be subject to theft or misuse by employees. One organization recently found that tens of thousands of dollars' worth of equipment had been stolen by an employee that the organization never realized was missing. Unfortunately for the employee, a relationship breakdown caused an angry partner to report the employee to corporate security.

The Systems Analyst

There are several definitions for a systems analyst. Some organizations may use the term *senior analyst* when the person works in the IT development area; other organizations use the term to describe the person responsible for systems architecture or configuration.

In the IT development shop, the systems analyst plays a critical role in the development and leadership of IT projects and the maintenance of IT systems. The systems analyst may be responsible for chairing or sitting on project development teams, working with business analysts to determine the functional requirements for a system, writing high-level project requirements for use by programmers to write code, enforcing coding standards, coordinating the work of a team of programmers and reviewing their work, overseeing production support efforts, and working on incident handling teams.

The systems analyst is usually trained in computer programming and project management skills. The systems analyst must have the ability to review a system and determine its capabilities, weaknesses, and workflow processes.

Systems analysts should not have access to change production data or programs. This is important to ensure that they cannot inadvertently or maliciously change a program or organizational data. Without such controls, the analyst may be able to introduce a Trojan horse, circumvent change control procedures, and jeopardize data integrity.

Systems analysts in a network or overall systems environment are responsible for ensuring that secure and reliable networks or systems are developed and maintained. They are responsible for ensuring that the networks or systems are constructed with no unknown gaps or backdoors, that there are few single points of failure, that configurations and access control procedures are set up, and that audit trails and alarms are monitored for violations or attacks.

The systems analyst usually requires a technical college diploma and extensive in-depth training. Knowledge of system components, such as the firewalls in use by the organization, tools, and incident handling techniques, is required.

Most often, the systems analyst in this environment will have the ability to set up user profiles, change permissions, change configurations, and perform high-level utilities such as backups or database reorganizations. This creates a control weakness that is difficult to overcome. In many cases the only option an organization has is to trust the person in this position. Periodic reviews of their work and proper management controls are

some of the only compensating controls available. The critical problem for many organizations is ensuring that this position is properly backed up with trained personnel and thorough documentation, and that this person does not become technically stagnant or begin to become sloppy about security issues.

The Business Analyst

The business analyst is one of the most critical roles in the information management environment. A good business analyst has an excellent understanding of the business operating environment, including new trends, marketing opportunities, technological tools, current process strengths, needs, and weaknesses, and is a good team member. The business analyst is responsible for representing the needs of the users to the IT development team. The business analyst must clearly articulate the functional requirements of a project early on in the project life cycle in order to ensure that information technology resources, money, personnel, and time are expended wisely and that the final result of an IT project meets user needs, provides adequate security and functionality, and embraces controls and separation of duties. Once outlined, the business analyst must ensure that these requirements are addressed and documented in the project plan. The business analyst is then responsible for setting up test scenarios to validate the performance of the system and verify that the system meets the original requirements definitions.

When testing, the business analyst should ensure that test scenarios and test cases have been developed to address all recognized risks and test scenarios. Test data should be sanitized to prevent disclosure of private or sensitive information, and test runs of programs should be carefully monitored to prevent test data and reports from introduction into the real-world production environment. Tests should include out-of-range tests, where numbers larger or smaller than the data fields are attempted and invalid data formats are tried. The purpose of the tests is to try to see if it is possible to make the system fail. Proper test data is designed to stress the limitations of the system, the edit checks, and the error handling routines so that the organization can be confident that the system will not fail or handle data incorrectly once in production. The business analyst is often responsible for providing training and documentation to the user groups. In this regard, all methods of access, use, and functionality of the system from a user perspective should be addressed. One area that has often been overlooked has been assignment of error handling and security functionality. The business analyst must ensure that these functions are also assigned to reliable and knowledgeable personnel once the system has gone into production.

The business analyst is responsible for reviewing system tests and approving the change as the certification portion of the change management process. If a change needs to be made to production data, the business analyst will usually be responsible for preparing or reviewing the change and approving the timing and acceptability of the change prior to its implementation. This is a proper segregation of duties, whereby the person actually making the change in production — whether it is the operator, programmer, or other user — is not the same person who reviews and approves the change. This may prevent either human error or malicious changes.

Once in production, business analysts are often the second tier of support for the user community. Here they are responsible to check on inconsistencies, errors, or unreliable processing by the system. They will often have a method of creating trouble tickets or system failure notices for the development and production support groups to investigate or take action.

Business analysts are commonly chosen from the user groups. They must be knowledgeable in the business operations and should have good communication and teamwork skills. Several colleges offer courses in business analysis, and education in project management can also be beneficial.

Because business analysts are involved in defining the original project functional requirements, they should also be trained in security awareness and requirements. Through a partnership with security, business analysts can play a key role in ensuring that adequate security controls are included in the system requirements.

The Programmer

This chapter is not intended to outline all of the responsibilities of a programmer. Instead, it focuses on the security components and risks associated with this job function. The programmer, whether in a mainframe, client/server, or Web development area, is responsible for preparing the code that will fulfill the requirements of the

users. In this regard, the programmer needs to adhere to principles that will provide reliable, secure, and maintainable programs without compromising the integrity, confidentiality, or availability of the data. Poorly written code is the source of almost all buffer overflow attacks. Because of inadequate bounds, parameter checking, or error handling, a program can accept data that exceeds its acceptable range or size, thereby creating a memory or privilege overflow condition. This is a potential hole either for an attacker to exploit or to cause system problems due to simple human error during a data input function.

Programs need to be properly documented so that they are maintainable, and the users (usually business analysts) reviewing the output can have confidence that the program handles the input data in a consistent and reliable manner.

Programmers should never have access to production data or libraries. Several firms have experienced problems due to disgruntled programmers introducing logic bombs into programs or manipulating production data for their own benefit. Any changes to a program should be reviewed and approved by a business analyst and moved into production by another group or department (such as operators), and not by the programmer directly. This practice was established during the mainframe era but has been slow to be enforced on newer Web-based development projects. This has meant that several businesses have learned the hard way about proper segregation of duties and the protection it provides a firm. Often when a program requires frequent updating, such as a Web site, the placement of the changeable data into tables that can be updated by the business analysts or user groups is desirable.

One of the greatest challenges for a programmer is to include security requirements in the programs. A program is primarily written to address functional requirements from a user perspective, and security can often be perceived as a hindrance or obstacle to the fast execution and accessibility of the program. The programmer needs to consider the sensitivity of the data collected or generated by the program and provide secure program access, storage, and audit trails. Access controls are usually set up at the initiation of the program; and user IDs, passwords, and privilege levels are checked when the user first logs on to the system or program. Most programs these days have multiple access paths to information — text commands, GUI icons, and drop-down menus are some of the common access methods. A programmer must ensure that all access methods are protected and that the user is unable to circumvent security by accessing the data through another channel or method.

The programmer needs training in security and risk analysis. The work of a programmer should also be subject to peer review by other systems analysts or programmers to ensure that quality and standard programming practices have been followed.

The Librarian

The librarian was a job function established in a mainframe environment. In many cases the duties of the librarian have now been incorporated into the job functions of other personnel such as system administrators or operators. However, it is important to describe the functions performed by a librarian and ensure that these tasks are still performed and included in the performance criteria and job descriptions of other individuals.

The librarian is responsible for the handling of removable media — tapes, disks, and microfiche; the control of backup tapes and movement to off-site or near-line storage; the movement of programs into production; and source code control. In some instances the librarian is also responsible for system documentation and report distribution.

The librarian duties need to be described, assigned, and followed. Movement of tapes to off-site storage should be done systematically with proper handling procedures, secure transport methods, and proper labeling. When reports are generated, especially those containing sensitive data, the librarian must ensure that the reports are distributed to the correct individuals and no pages are attached in error to other print jobs. For this reason, it is a good practice to restrict the access of other personnel from the main printers.

The librarian accepts the certified and accredited program changes and moves them into production. These changes should always include a back-out plan in case of program or system problems. The librarian should take a backup copy of all programs or tables subject to change prior to moving the new code into production. A librarian should always ensure that all changes are properly approved prior to making a change.

Librarians should not be permitted to make changes to programs or tables; they should only enact the changes prepared and approved by other personnel. Librarians also need to be inoculated against social engineering or pressure from personnel attempting to make changes without going through the proper approval process.

The Operator

The operator plays a key role in information systems security. No one has greater access or privileges than the operator. The operator can be a key contributor to system security or a gaping hole in a security program. The operator is responsible for the day-to-day operations, job flow, and often the scheduling of the system maintenance and backup routines. As such, an operator is in a position that may have serious impact on system performance or integrity in the event of human error, job-sequencing mistakes, processing delays, backup execution, and timing. The operator also plays a key role in incident handling and error recovery. The operator should log all incidents, abnormal conditions, and job completions so that they can be tracked and acted upon, and provide input for corrective action. Proper tracking of job performance, storage requirements, file size, and database activity provides valuable input to forecasting requirements for new equipment or identification of system performance issues and job inefficiencies before they become serious processing impairments.

The operator should never make changes to production programs or tables except where the changes have been properly approved and tested by other personnel. In the event of a system failure, the operator should have a response plan in place to notify key personnel.

The System Owner and the Data Owner

History has taught us that information systems are not owned by the information technology department, but rather by the user group that depends on the system. The system owner therefore is usually the senior manager in the user department. For a financial system this may be the vice president of finance; for a customer support system, the vice president of sales. The IT department then plays the role of supporting the user group and responding to the needs of the user. Proper ownership and control of systems may prevent the development of systems that are technically sound but of little use to the users. Recent studies have shown that the gap between user requirements and system functionality was a serious detriment to business operations. In fact, several government departments have had to discard costly systems that required years of development because they were found to be inadequate to meet business needs.[2]

The roles of system owner and data owner may be separate or combined, depending on the size and complexity of the system. The system owner is responsible for all changes and improvements to a system, including decisions regarding the overall replacement of a system. The system owner sits on the IT steering committee, usually as chair, and provides input, prioritization, budgeting, and high-level resource allocation for system maintenance and development. This should not conflict with the role of the IT director and project leaders who are responsible for the day-to-day operations of production support activity, development projects, and technical resource hiring and allocation. The system owner also oversees the accreditation process that determines when a system change is ready for implementation. This means the system owner must be knowledgeable about new technologies, risks, threats, regulations, and market trends that may impact the security and integrity of a system.

The responsibility of the data owner is to monitor the sensitivity of the data stored or processed by a system. This includes determining the appropriate levels of information classification, access restrictions, and user privileges. The data owner should establish or approve the process for granting access to new users, increasing access levels for existing users, and removing access in a timely manner for users who no longer require access as a part of their job duties. The data owner should require an annual report of all system users and determine whether the level of access each user has is appropriate. This should include a review of special access methods such as remote access, wireless access, reports received, and ad hoc requests for information.

Because these duties are incidental to the main functions of the persons acting as data or system owners, it is incumbent upon these individuals to closely monitor these responsibilities while delegating certain functions to other persons. The ultimate responsibility for accepting the risks associated with a system rests with the system and data owners.

The User

All of the systems development, the changes, modifications, and daily operations are to be completed with the objective of addressing user requirements. The user is the person who must interact daily with the system and

relies on the system to continue business operations. A system that is not designed correctly may lead to a high incidence of user errors, high training costs or extended learning curves, poor performance and frustration, and overly restrictive controls or security measures. Once users notice these types of problems, they will often either attempt to circumvent security controls or other functionality that they find unnecessarily restrictive or abandon the use of the system altogether.

Training for a user must include the proper use of the system and the reasons for the various controls and security parameters built into the system. Without divulging the details of the controls, explaining the reasons for the controls may help the users to accept and adhere to the security restrictions built into the system.

Good Principles — Exploiting the Strengths of Personnel in Regard to a Security Program

A person should never be disciplined for following correct procedures. This may sound ridiculous, but it is a common weakness exploited by people as a part of social engineering. Millions of dollars' worth of security will be worthless if our staff is not trained to resist and report all social engineering attempts. Investigators have found that the easiest way to gather corporate information is through bribery or relationships with employees.

There are four main types of social engineering: intimidation, helpfulness, technical, and name-dropping. The principle of intimidation is the threat of punishment or ridicule for following correct procedures. The person being "engineered" is bullied by the attacker into granting an exception to the rules — perhaps due to position within the company or force of character. In many instances the security-minded person is berated by the attacker, threatened with discipline or loss of employment, or otherwise intimidated by a person for just trying to do their job. Some of the most serious breaches of secure facilities have been accomplished through these techniques. In one instance the chief financial officer of a corporation refused to comply with the procedure of wearing an ID card. When challenged by a new security person, the executive explained in a loud voice that he should never again be challenged to display an ID card. Such intimidation unnerved the security person to the point of making the entire security procedure ineffective and arbitrary. Such a "tone at the top" indicates a lack of concern for security that will soon permeate through the entire organization.

Helpfulness is another form of social engineering, appealing to the natural instinct of most people to want to provide help or assistance to another person. One of the most vulnerable areas for this type of manipulation is the help desk. Help desk personnel are responsible for password resets, remote access problem resolution, and system error handling. Improper handling of these tasks may result in an attacker getting a password reset for another legitimate user's account and creating either a security gap or a denial-of-service for the legitimate user.

Despite the desires of users, the help desk, and administrators to facilitate the access of legitimate users to the system, they must be trained to recognize social engineering and follow established secure procedures.

Name-dropping is another form of social engineering and is often facilitated by press releases, Web page ownership or administrator information, discarded corporate documentation, or other ways that an attacker can learn the names of individuals responsible for research, business operations, administrative functions, or other key roles. By using the names of these individuals in conversation, a hacker can appear to be a legitimate user or have a legitimate affiliation with the corporation. It has been quoted that "The greater the lie, the easier it is to convince someone that it is true." This especially applies to a name-dropping type of attack. Despite the prior knowledge of the behaviors of a manager, a subordinate may be influenced into performing some task at the request of an attacker although the manager would never have contemplated or approved such a request.

Technology has provided new forms of social engineering. Now an attacker can e-mail or fax a request to a corporation for information and receive a response that compromises security. This may be from a person alleging to represent law enforcement or some other government department demanding cooperation or assistance. The correct response must be to have an established manner of contact for outside agencies and train all personnel to route requests for information from an outside source through proper channels.

All in all, the key to immunizing personnel against social-engineering attacks is to emphasize the importance of procedure, the correctness of following and enforcing security protocols, and the support of management for personnel who resist any actions that attempt to circumvent proper controls and may be an incidence of social engineering. All employees must know that they will never lose their job for enforcing corporate security procedures.

Job Rotation

Job rotation is an important principle from a security perspective, although it is often seen as a detriment by project managers. Job rotation moves key personnel through the various functional roles in a department or even between departments. This provides several benefits, such as cross-training of key personnel and reducing the risks to a system through lack of trained personnel during vacations or illnesses. Job rotation also serves to identify possible fraudulent activity or shortcuts taken by personnel who have been in the job for an extended time period. In one instance, a corporation needed to take disciplinary action against an employee who was the administrator for a critically important system, not only for the business but also for the community. Because this administrator had sole knowledge of the system and the system administrator password, they were unable to take action in a timely manner. They were forced to delay any action until the administrator left for vacation and gave the password to a backup person.

When people stay in a position too long, they may become more attached to the system than to the corporation, and their activity and judgment may become impaired.

Anti-Virus and Web-Based Attacks

The connectivity of systems and the proliferation of Web-based attacks have resulted in significant damage to corporate systems, expenses, and productivity losses. Many people recognize the impact of Code Red and Nimda; however, even when these attacks were taken out of the calculations, the incidence of Web-based attacks rose more than 79 percent in 2001.[3] Some studies have documented more attacks in the first two months of 2002 than were detected in the previous year and a half.[4]

Users have heard many times not to open e-mail attachments; however, this has not prevented many infections and security breaches from happening. More sophisticated attacks — all of which can appear to come from trusted sources — are appearing, and today's firewalls and anti-virus products are not able to protect an organization adequately. Instead, users need to be more diligent to confirm with a sender whether they intended to send out an attachment prior to opening it. The use of instant messaging, file sharing, and other products, many of which exploit open ports or VPN tunnels through firewalls, is creating even more vulnerabilities. The use of any technology or new product should be subject to analysis and review by security before the users adopt it. This requires the security department to react swiftly to requests from users and be aware of the new trends, technologies, and threats that are emerging.

Segregation of Duties

The principle of segregation of duties breaks an operation into separate functions so that no one person can control a process from initiation through to completion. Instead, a transaction would require one person to input the data, a second person to review and reconcile the batch totals, and another person (or perhaps the first individual) to confirm the final portion of the transaction. This is especially critical in financial transactions or error handling procedures.

Summary

This is neither a comprehensive list of all the security concerns and ways to train and monitor the people in our organizations, nor is it a full list of all job roles and functions. Hopefully it is a tool that managers, security personnel, and auditors can use to review some of the procedures they have in place and create a better security infrastructure. The key objective of this chapter is to identify the primary roles that people play in the information security environment. A security program is only as good as the people implementing it, and a key realization is that tools and technology are not enough when it comes to protecting our organizations. We need to enlist the support of every member of our companies. We need to see the users, administrators, managers, and auditors as partners in security. Much of this is accomplished through understanding. When the users understand why we need security, the security people understand the business, and everyone respects the role of the other departments, then the atmosphere and environment will lead to greater security, confidence, and trust.

Security Management

Ken Buszta, CISSP

It was once said, "Information is king." In today's world, this statement has never rung more true. As a result, information is now viewed as an asset; and organizations are willing to invest large sums of money toward its protection. Unfortunately, organizations appear to be overlooking one of the weakest links for protecting their information — the information security management team. The security management team is the one component in our strategy that can ensure our security plan is working properly and takes corrective actions when necessary. In this chapter, we address the benefits of an information security team, the various roles within the team, job separation, job rotation, and performance metrics for the team, including certifications.

Security Management Team Justification

Information technology departments have always had to justify their budgets. With the recent global economic changes, the pressures of maintaining stockholder values have brought IT budgets under even more intense scrutiny. Migrations, new technology implementations, and even staff spending have been either been delayed, reduced, or removed from budgets. So how is it that an organization can justify the expense, much less the existence, of an information security management team? While most internal departments lack the necessary skill sets to address security, there are three compelling reasons to establish this team:

1. *Maintain competitive advantage.* An organization exists to provide a specialized product or service for its clients. The methodologies and trade secrets used to provide these services and products are the assets that establish our competitive advantage. An organization's failure to properly protect and monitor these assets can result in the loss of not only a competitive advantage but also lost revenues and possible failure of the organization.
2. *Protection of the organization's reputation.* In early 2000, several high-profile organizations' Web sites were attacked. As a result, the public's confidence was shaken in their ability to adequately protect their clients. A security management team will not be able to guarantee or fully prevent this from happening, but a well-constructed team can minimize the opportunities made available from your organization to an attacker.
3. *Mandates by governmental regulations.* Regulations within the United States, such as the Health Insurance Portability and Accountability Act (HIPAA) and the Gramm-Leach-Bliley Act (GLBA) and those abroad, such as the European Convention on Cybercrime, have mandated that organizations protect their data. An information security management team, working with the organization's legal and auditing teams, can focus on ensuring that proper safeguards are utilized for regulatory compliance.

Executive Management and the IT Security Management Relationship

The first and foremost requirement to help ensure the success of an information security management team relies on its relationship with the organization's executive board. Commencing with the CEO and then working downward, it is essential for the executive board to support the efforts of the information security team. Failure

of the executive board to actively demonstrate its support for this group will gradually become reflected within the rest of the organization. Apathy toward the information security team will become apparent, and the team will be rendered ineffective. The executive board can easily avoid this pitfall by publicly signing and adhering to all major information security initiatives such as security policies.

Information Security Management Team Organization

Once executive management has committed its support to an information security team, a decision must be made as to whether the team should operate within a centralized or decentralized administration environment.

In a centralized environment, a dedicated team is assigned the sole responsibility for the information security program. These team members will report directly to the information security manager. Their responsibilities include promoting security throughout the organization, implementing new security initiatives, and providing daily security administration functions such as access control.

In a decentralized environment, the members of the team have information security responsibilities in addition to those assigned by their departments. These individuals may be network administrators or reside in such departments as finance, legal, human resources, or production.

This decision will be unique to each organization. Organizations that have identified higher risks deploy a centralized administration function. A growing trend is to implement a hybrid solution utilizing the best of both worlds. A smaller dedicated team ensures that new security initiatives are implemented and oversees the overall security plan of the organization, while a decentralized team is charged with promoting security throughout their departments and possibly handling the daily department-related administrative tasking.

The next issue that needs to be addressed is how the information security team will fit into the organization's reporting structure. This is a decision that should not be taken lightly because it will have a long-enduring effect on the organization. It is important that the organization's decision makers fully understand the ramifications of this decision. The information security team should be placed where its function has significant power and authority. For example, if the information security manager reports to management that does not support the information security charter, the manager's group will be rendered ineffective. Likewise, if personal agendas are placed ahead of the information security agenda, it will also be rendered ineffective. An organization may place the team directly under the CIO or it may create an additional executive position, separate from any particular department. Either way, it is critical that the team be placed in a position that will allow it to perform its duties.

Roles and Responsibilities

When planning a successful information security team, it is essential to identify the roles, rather than the titles, that each member will perform. Within each role, their responsibilities and authority must be clearly communicated and understood by everyone in the organization.

Most organizations can define a single process, such as finance, under one umbrella. There is a manager, and there are direct reports for every phase of the financial life cycle within that department. The information security process requires a different approach. Regardless of how centralized we try to make it, we cannot place it under a single umbrella. The success of the information security team is therefore based on a layered approach. As demonstrated in Exhibit 56.1, the core of any information security team lies with the executive management because they are ultimately responsible to the investors for the organization's success or failure. As we delve outward into the other layers, we see there are roles for which an information security manager does not have direct reports, such as auditors, technology providers, and the end-user community, but he still has an accountability report from or to each of these members.

It is difficult to provide a generic approach to fit everyone's needs. However, regardless of the structure, organizations need to assign security-related functions corresponding to the selected employees' skill sets. Over time, eight different roles have been identified to effectively serve an organization:

1. *Executive management.* The executive management team is ultimately responsible for the success (or failure) of any information security program. As stated earlier, without their active support, the information security team will struggle and, in most cases, fail in achieving its charter.
2. *Information security professionals.* These members are the actual members trained and experienced in the information security arena. They are responsible for the design, implementation, management, and review of the organization's security policy, standards, measures, practices, and procedures.

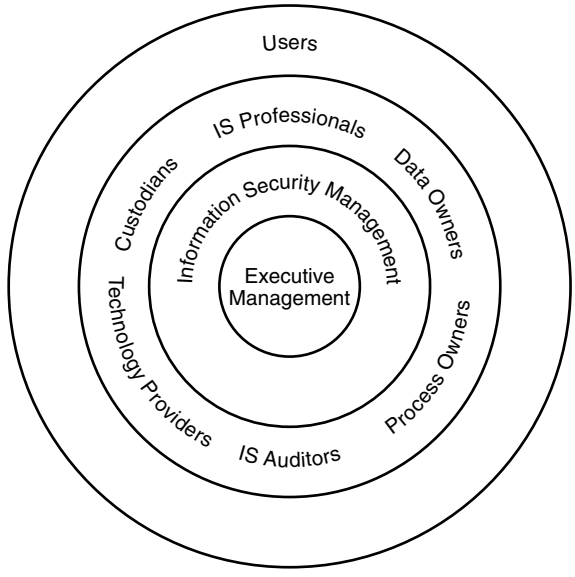

EXHIBIT 56.1 Layers of information security management team.

3. *Data owners.* Everyone within the organization can serve in this role. For example, the creator of a new or unique data spreadsheet or document can be considered the data owner of that file. As such, they are responsible for determining the sensitivity or classification levels of the data as well as maintaining the accuracy and integrity of the data while it resides in the system.
4. *Custodians.* This role may very well be the most under-appreciated of all. Custodians act as the owner's delegate, with their primary focus on backing up and restoring the data. The data owners dictate the schedule at which the backups are performed. Additionally, they run the system for the owners and must ensure that the required security controls are applied in accordance with the organization's security policies and procedures.
5. *Process owners.* These individuals ensure that the appropriate security, consistent with the organization's security policy, is embedded in the information systems.
6. *Technology providers.* These are the organization's subject matter experts for a given set of information security technologies and assist the organization with its implementation and management.
7. *Users.* As almost every member of the organization is a user of the information systems, they are responsible for adhering to the organization's security policies and procedures. Their most vital responsibility is maintaining the confidentiality of all usernames and passwords, including the program upon which these are established.
8. *Information systems auditor.* The auditor is responsible for providing independent assurance to management on the appropriateness of the security objectives and whether the security policies, standards, measures, practices, and procedures are appropriate and comply with the organization's security objectives. Because of the responsibility this role has in the information security program, organizations may shift this role's reporting structure directly to the auditing department as opposed to within the information security department.

Separation of Duties and the Principle of Least Privilege

While it may be necessary for some organizations to have a single individual serve in multiple security roles, each organization will want to consider the possible effects of this decision. By empowering one individual, it is possible for that person to manipulate the system for personal reasons without the organization's knowledge. As such, an information security practice is to maintain a separation of duties. Under this philosophy, pieces of a task are assigned to several people. By clearly identifying the roles and responsibilities, an organization

will be able to also implement the Principle of Least Privilege. This idea supports the concept that the users and the processes in a system should have the least number of privileges and for the shortest amount of time needed to perform their tasks.

For example, the system administrator's role may be broken into several different functions to limit the number of people with complete control. One person may become responsible for the system administration, a second person for the security administration, and a third person for the operator functions.

Typical system administrator/operator functions include:

- Installing system software
- Starting up and shutting down the system
- Adding and removing system users
- Performing backups and recovery
- Mounting disks and tapes
- Handling printers

Typical security administrator functions include:

- Setting user clearances, initial passwords, and other security clearances for new users, and changing security profiles for existing users
- Setting or changing the sensitivity file labels
- Setting security characteristics of devices and communication channels
- Reviewing audit data

The major benefit of both of these principles is to provide a *two-person control* process to limit the potential damage to an organization. Personnel would be forced into collusion in order to manipulate the system.

Job Rotation

Arguably, training may provide the biggest challenge to management, and many view it as a double-edged sword. On the one edge, training is viewed as an expense and is one of the first areas depreciated when budget cuts are required. This may leave the organization with stale skill sets and disgruntled employees. On the other edge, it is not unusual for an employee to absorb as much training from an organization as possible and then leave for a better opportunity. Where does management draw the line?

One method to address this issue is job rotation. By routinely rotating the job a person is assigned to perform, we can provide cross-training to the employees. This process provides the team members with higher skill sets and increased self-esteem; and it provides the organization with backup personnel in the event of an emergency.

From the information security point of view, job rotation has its benefits. Through job rotation, the collusion fostered through the separation of duties is broken up because an individual is not performing the same job functions for an extended period. Further, the designation of additionally trained workers adds to the personnel readiness of the organization's disaster recovery plan.

Performance Metrics

Each department within an organization is created with a charter or mission statement. While the goals for each department should be clearly defined and communicated, the tools that we use to measure a department's performance against these goals are not always as clearly defined, particularly in the case of information security. It is vital to determine a set of metrics by which to measure its effectiveness. Depending upon the metrics collected, the results may be used for several different purposes, such as:

- *Financial.* Results may be used to justify existing or increasing future budget levels.
- *Team competency.* A metric, such as certification, may be employed to demonstrate to management and the end users the knowledge of the information security team members. Additional metrics may include authorship and public speaking engagements.
- *Program efficiency.* As the department's responsibilities are increased, its ability to handle these demands while limiting its personnel hiring can be beneficial in times of economic uncertainty.

While in the metric planning stages, the information security manager may consider asking for assistance from the organization's auditing team. The auditing team can provide an independent verification of the metric results to both the executive management team and the information security department. Additionally, by getting the auditing department involved early in the process, it can assist the information security department in defining its metrics and the tools utilized to obtain them.

Determining performance metrics is a multi-step process. In the first step, the department must identify its process for metric collection. Among the questions an organization may consider in this identification process are:

- Why do we need to collect the statistics?
- What statistics will we collect?
- How will the statistics be collected?
- Who will collect the statistics?
- When will these statistics be collected?

The second step is for the organization to identify the functions that will be affected. The functions are measured as time, money, and resources. The resources can be quantified as personnel, equipment, or other assets of the organization.

The third step requires the department to determine the drivers behind the collection process. In the information security arena, the two drivers that affect the department's ability to respond in a timely manner are the number of system users and the number of systems within its jurisdiction. The more systems and users an organization has, the larger the information security department.

With these drivers in mind, executive management could rely on the following metrics with a better understanding of the department's accomplishments and budget justifications:

- Total systems managed
- Total remote systems managed
- User administration, including additions, deletions, and modifications
- User awareness training
- Average response times

For example, Exhibit 56.2 shows an increase in the number of system users over time. This chart alone could demonstrate the efficiency of the department as it handles more users with the same number of resources.

Exhibit 56.3 shows an example of the average information security response times. Upon review, we are clearly able to see an upward trend in the response times. This chart, when taken by itself, may pose some concerns by senior management regarding the information security team's abilities. However, when this metric is used in conjunction with the metrics found in Exhibit 56.2, a justification could be made to increase the information security personnel budget.

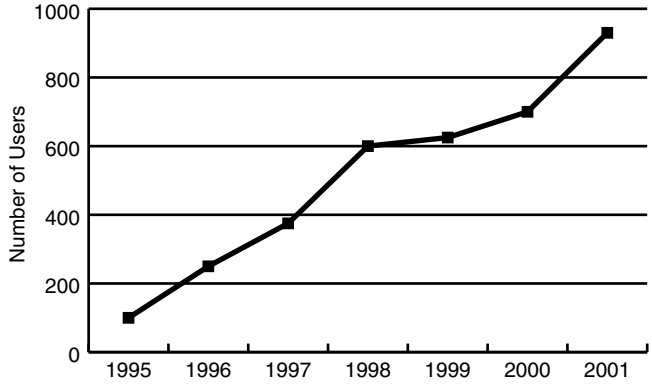

EXHIBIT 56.2 Users administered by information security department.

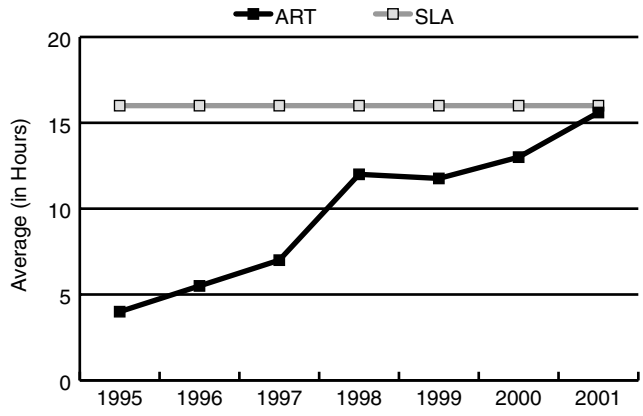

EXHIBIT 56.3 Average information security response times.

While it is important for these metrics to be gathered on a regular basis, it is even more important for this information to be shared with the appropriate parties. For example, by sharing performance metrics within the department, the department will able to identify its strong and weak areas. The information security manager will also want to share these results with the executive management team to perform a formal annual metric review and evaluation of the metrics.

Certifications

Using the various certification programs available is an effective tool for management to enhance the confidence levels in its security program while providing the team with recognition for its experience and knowledge. While there are both vendor-centric and vendor-neutral certifications available in today's market, we will focus only on the latter. (Note: The author does not endorse any particular certification program.)

Presently there is quite a debate about which certification is best. This is a hard question to answer directly. Perhaps the more important question is, "What do I want to accomplish in my career?" If based upon this premise, certification should be tailored to a set of objectives and therefore is a personal decision.

Certified Information Systems Security Professional (CISSP)

The CISSP Certification is an independent and objective measure of professional expertise and knowledge within the information security profession. Many regard this certification as an information security management certification. The credential, established over a decade ago, requires the candidate to have three years' verifiable experience in one or more of the ten domains in the Common Body of Knowledge (CBK) and pass a rigorous exam. The CBK, developed by the International Information Systems Security Certification Consortium $(ISC)^2$, established an international standard for IS security professionals. The CISSP multiple-choice certification examination covers the following ten domains of the CBK:

Domain 1: Access Control Systems and Methodology
Domain 2: Telecommunications and Network Security
Domain 3: Security Management Practices
Domain 4: Applications and Systems Development Security
Domain 5: Cryptography
Domain 6: Security Architecture and Models
Domain 7: Operations Security
Domain 8: Business Continuity Planning (BCP) and Disaster Recovery Planning (DRP)
Domain 9: Law, Investigations and Ethics
Domain 10: Physical Security

More information on this certification can be obtained by contacting (ISC)² through its e-mail address, info@isc2.org.

Systems Security Certified Practitioner (SSCP)

The SSCP certification focuses on information systems security practices, roles, and responsibilities defined by experts from major industries. Established in 1998, it provides network and systems security administrators with independent and objective measures of competence and recognition as a knowledgeable information systems security practitioner. Certification is only available to those individuals who have at least one year's experience in the CBK, subscribe to the (ISC)² Code of Ethics, and pass the 125-question SSCP certification examination, based on seven CBK knowledge areas:

1. Access Controls
2. Administration
3. Audit and Monitoring
4. Risk, Response and Recovery
5. Cryptography
6. Data Communications
7. Malicious Code/Malware

GIAC

In 1999, the SANS (System Administration, Networking, and Security) Institute founded the Global Information Assurance Certification (GIAC) Program to address the need to validate the skills of security professionals. The GIAC certification provides assurance that a certified individual holds an appropriate level of knowledge and skill necessary for a practitioner in key areas of information security. This is accomplished through a twofold process: practitioners must pass a multiple-choice exam and then complete a practical exam to demonstrate their ability to apply their knowledge. GIAC certification programs include:

- *GIAC Security Essentials Certification (GSEC).* GSEC graduates have the knowledge, skills, and abilities to incorporate good information security practice in any organization. The GSEC tests the essential knowledge and skills required of any individual with security responsibilities within an organization.
- *GIAC Certified Firewall Analyst (GCFW).* GCFWs have the knowledge, skills, and abilities to design, configure, and monitor routers, firewalls, and perimeter defense systems.
- *GIAC Certified Intrusion Analyst (GCIA).* GCIAs have the knowledge, skills, and abilities to configure and monitor intrusion detection systems and to read, interpret, and analyze network traffic and related log files.
- *GIAC Certified Incident Handler (GCIH).* GCIHs have the knowledge, skills, and abilities to manage incidents; to understand common attack techniques and tools; and to defend against or respond to such attacks when they occur.
- *GIAC Certified Windows Security Administrator (GCWN).* GCWNs have the knowledge, skills, and abilities to secure and audit Windows systems, including add-on services such as Internet Information Server and Certificate Services.
- *GIAC Certified UNIX Security Administrator (GCUX).* GCUXs have the knowledge, skills, and abilities to secure and audit UNIX and Linux systems.
- *GIAC Information Security Officer (GISO).* GISOs have demonstrated the knowledge required to handle the Security Officer responsibilities, including overseeing the security of information and information resources. This combines basic technical knowledge with an understanding of threats, risks, and best practices. Alternately, this certification suits those new to security who want to demonstrate a basic understanding of security principles and technical concepts.
- *GIAC Systems and Network Auditor (GSNA).* GSNAs have the knowledge, skills, and abilities to apply basic risk analysis techniques and to conduct a technical audit of essential information systems.

Certified Information Systems Auditor (CISA)

CISA is sponsored by the Information Systems and Audit Control Association (ISACA) and tests a candidate's knowledge of IS audit principles and practices, as well as technical content areas. It is based on the results of a practice analysis. The exam tests one process and six content areas (domains) covering those tasks that are routinely performed by a CISA. The process area, which existed in the prior CISA practice analysis, has been expanded to provide the CISA candidate with a more comprehensive description of the full IS audit process. These areas are as follows:

- Process-based area (domain)
- The IS audit process
- Content areas (domains)
- Management, planning, and organization of IS
- Technical infrastructure and operational practices
- Protection of information assets
- Disaster recovery and business continuity
- Business application system development, acquisition, implementation, and maintenance
- Business process evaluation and risk management

For more information, contact ISACA via e-mail: certification@isaca.org.

Conclusion

The protection of the assets may be driven by financial concerns, reputation protection, or government mandate. Regardless of the reason, well-constructed information security teams play a vital role in ensuring organizations are adequately protecting their information assets. Depending upon the organization, an information security team may operate in a centralized or decentralized environment; but either way, the roles must be clearly defined and implemented. Furthermore, it is crucial to develop a set of performance metrics for the information security team. The metrics should look to identify issues such as budgets, efficiencies, and proficiencies within the team.

Securing New Information Technology

Louis Fried

Payoff

New information technologies mean new information security risks. This article helps data center managers to keep up with new information technology and the security risks this technology presents.

Introduction

The job of the IS security specialist has gone from protecting information within the organization to protecting information in the extended enterprise. Controlled offices and plants have given way to a porous, multiconnected, global environment. The pace at which new information technology capabilities are being introduced in the corporate setting also creates a situation in which the potential of new security risks isn't well thought out. Data center managers and must be aware of these threats before adopting new technologies so that they can take adequate countermeasures.

Information security is concerned with protecting:

- The availability of information and information processing resources.

- The integrity and confidentiality of information.

Unless adequate protection is in place when new business applications are developed, one or both of these characteristics of information security may be threatened. Availability alone is a major issue. Among US companies, the cost of systems downtime has been placed by some estimates at $4 billion a year, with a loss of 37 million hours in worker productivity.

The application of information security methods has long been viewed as insurance against potential losses. Senior management has applied the principle that it should not spend more for insurance than the potential loss could cost. In many cases, management is balancing information security costs against the potential for a single loss incident, rather than multiple occurrences of loss. This fallacious reasoning can lead to a failure to protect information assets continuously or to upgrade that protection as technology changes and exposes new opportunities for losses.

Those who would intentionally damage or steal information also follow some basic economic principles. Amateur hackers may not place a specific value on their time and thus may be willing to put substantial effort into penetrating information systems. A professional clearly places an implicit value on time by seeking the easiest way to penetrate a system or by balancing potential profit against the time and effort necessary to carry out a crime. New technologies that create new (and possibly easier) ways to penetrate a system invite such professionals and fail to deter the amateurs.

This article describes some of the potential threats to information security that may arise in the next few years. The article concludes by pointing out the opportunities for employing new countermeasures.

Document Imaging Systems

The capabilities of document imaging systems include:

- Reading and storing images of paper documents.
- Character recognition of text for abstracting or indexing.
- Retrieval of stored documents by index entry.
- Manipulation of stored images.
- Appending notes to stored images (either text or voice).
- Workflow management tools to program the distribution of documents as action steps are needed.

Workflow management is critical to taking full advantage of image processing for business process applications in which successive or parallel steps are required to process the document. Successful applications include loan processing, insurance application or claims processing, and many others that depend on the movement of documents through review and approval steps.

Image processing usually requires a mainframe or minicomputer for processing any serious volume of information, though desktop and workstation versions also exist for limited use. In addition, a full image processing system requires document readers (i.e., scanners), a local area network (LAN), workstations or personal computers, and laser printer as output devices. It is possible to operate image processing over a Wide Area Network; however, because of the bandwidth required for reasonable response times, this is not usually done. As a result, most configurations are located within a single building or building complex.

Two years ago, an insurance company installed an imaging application for processing claims. The system was installed on a LAN linked to a minicomputer in the claims processing area. A manager who had received a layoff notice accessed the parameter-driven work-flow management system and randomly realigned the processing steps into new sequences, reassigning the process steps in an equally random fashion to the hundred or so claims processing clerks using the system. He then took the backup tapes, which were rotated weekly, and backed up the revised system files on all the tapes, replacing them in the tape cabinet. The individual did not steal any information or delete any information from the system. The next morning, he called the personnel department and requested that his final paycheck be sent to his home.

The cost to the insurance company? Tens of thousands of dollars in clerical time wasted and professional and managerial time lost in finding and correcting the problem. Even worse, there were weeks of delays in processing claims and handling the resultant complaint letters. No one at the company can estimate the loss of goodwill in the customer base.

Workflow management's weaknesses.

The very techniques of workflow management that make image processing systems so effective are also their Achilles' heel. Potential threats to image processing systems may come from disruption of the workflow by unauthorized changes to sequence or approval levels in workflow management systems or from the disruption of the workflow by component failure or damage. Information contained on documents may be stolen by the unauthorized copying (downloading of the image to the workstation)and release of document images by users of workstations.

These potential threats raise issues that must be considered in the use of image processing technology. The legal status of stored images may be questioned in court because of the potential for undetectable change. In addition, there are the threats to the business from loss of confidentiality of documents, loss of availability of the system during working hours, damage to the integrity of the images and notes appended to them, and questions about authenticity of stored documents.

Minisupercomputers

Massively parallel minisupercomputers are capable of providing relatively inexpensive, large computational capacity for such applications as signal processing, image recognition processing, or neural network processing.

Massively parallel processors are generally designed to work as attached processors or in conjunction with workstations. Currently available minisupercomputers can provide 4,096 processors for$85,000 or 8,192 processors for $150,000. They can interface to such devices as workstations, file servers, and LANs.

These machines can be an inexpensive computational resource for cracking encryption codes or computer-access codes; consequently, organizations that own them are well advised to limit access control for resource use to authorized users. This is especially true if the processor is attached to a mainframe with wide area network (WAN) connectivity. Such connectivity may allow unauthorized users to obtain access to the attached processor through the host machine.

Even without using a minisupercomputer but by simply stealing unauthorized time on conventional computers, a European hacker group bragged that it had figured out the access codes to all the major North American telephone switches. This allows them to make unlimited international telephone calls at no cost (or, if they are so inclined, to destroy the programming in the switches and deny service to millions of telephone users).

Neural Network Systems

Neural network systems are software (or hardware/software combinations) capable of heuristic learning within limited domains. These systems are an outgrowth of artificial intelligence research and are currently available at different levels of capacity on systems ranging from personal computers to mainframes.

With their heuristic learning capabilities, neural networks can learn how to penetrate a network or computer system. Small systems are already in the hands of hobbyists and hackers. The capability of neural networks programs will increase as greater amounts of main memory and processing power become easily affordable for desktop machines.

Wireless Local Area Networks

Wireless LANs support connectivity of devices by using radio frequency (RF) or infrared (IR) transmission between devices located in an office or office building. Wireless LANs consist of a LAN controller and signal generators or receivers that are either attached to devices or embedded in them. Wireless LANs have the advantage of allowing easy movement of connected devices so that office space can be reallocated or modified without the constraints of hard wiring. They can connect all sizes of computers and some peripherals. As portable computers become more intensively used, they can be easily connected to PCs or workstations in the office for transmission of files in either direction.

Wireless LANs may be subject to signal interruption or message capture by unauthorized parties. Radio frequency LANs operate throughout a transmitting area and are therefore more vulnerable than infrared transmission, which is line-of-sight only.

Among the major issues of concern in using this technology are retaining confidentiality and privacy of transmissions and avoiding business interruption in the event of a failure. The potential also exists, however, for other kinds of damage to wireless LAN users. For example, supermarkets are now experimenting with wireless terminals affixed to supermarket shopping carts that broadcast the price specials on that aisle to the shopper. As this technology is extended to the inventory control function and eventually to other functions in the store, it will not be long before some clever persons find a way to reduce their shopping costs and share the method over the underground networks.

WAN Radio Communications

WAN radio communications enable handheld or portable devices to access remote computers and exchange messages (including fax messages). Wireless wide area network (WAN) may use satellite transmission through roof-mounted antennas or regional radiotelephone technology. Access to wireless Wide Area Network is supported by internal radio modems in notebook and handheld computers or wireless modems/pagers on Personal Computer Memory Card International Association cards for optional use.

Many users think that telephone land lines offer some protection from intrusion because wiretaps can often be detected and tapping into a fiberoptic line is impossible without temporarily interrupting the service. Experience shows that most intrusions results from logical—not physical—attacks on networks. Hackers usually break in through remote maintenance ports on Private Branch eXchange, voice-mail systems, or remote-access features that permit travelers to place outgoing calls.

The threat to information security from the use of wireless wide area network (WAN) is that direct connectivity is no longer needed to connect to networks. Intruders may be able to fake legitimate calls once they have been able to determine access codes. Users need to consider such protective means as encryption for certain messages, limitations on the use of wireless wide area network (WAN) transmission for confidential material, and enforcement for encrypted password and user authentication controls.

Videoconferencing

Travel costs for nonsales activities is of growing concern to many companies. Companies are less concerned about the costs of travel and subsistence than they are about the costs to the company of having key personnel away from their jobs. Crossing the US or traveling to foreign countries for a one-day meeting often requires a key employee to be

away from the job for three days. Videoconferencing is increasingly used to reduce travel to only those trips that are essential for hands-on work.

The capabilities of videoconferencing include slow-scan video for sharing documents or interactive video for conferencing. Videoconferencing equipment is now selling for as little as$30,000 per installation. At that price, saving a few trips a year can quickly pay off. However, videoconferencing is potentially vulnerable to penetration of phone switches to tap open lines and receive both ends of the conferencing transmissions.

Protection against tapping lines requires additional equipment at both ends to scramble communications during transmission. It further requires defining when to scramble communications, making users aware of the risks, and enforcing rules.

Embedded Systems

Embedding computers into mechanical devices was pioneered by the military for applications ranging from autopilots on aircraft to smart bombs and missiles. In the civilian sector, process controls, robots, and automated machine tools were early applications. Manufacturers now embed intelligence and communications capabilities in products ranging from automobiles to microwave ovens. Computers from single-chip size to minicomputers are being integrated into the equipment that they direct. In factory automation systems, embedded systems are linked through LANs to area computers and to corporate hosts.

One security concern is that penetration of host computers can lead to penetration of automated factory units, which could interrupt productive capacity and create potential hazards for workers. In the past, the need for information security controls rarely reached the factory floor or the products that were produced because there was no connection to computers that resided on wide area network (WAN). Now, however, organizations must use techniques that enforce access controls and segment LANs on the factory floor to minimize the potential for unauthorized access through the company's host computers.

Furthermore, as computers and communications devices are used more in products, program bugs or device failure could endanger the customers who buy these products. With computer-controlled medical equipment or automobiles, for example, potential liability from malfunction may be enormous. Information security techniques must extend to the environment in which embedded systems software is developed to protect this software from corruption and the company from potential liability resulting from product failures.

PCMCIA Cards

PCMCIA cards are essentially small computer boards on which chips are mounted to provide memory and processing capacity. They can be inserted (i.e., docked) into slots on portable computers to add memory capacity, processing capacity, data base capacity, or communications functions such as pagers, electronic mail, or facsimile transmission. PCMCIA cards now contain up to 4M bytes of storage; by 1997, they can be expected to provide up to 20M bytes of storage in a 1.8-inch drive, can be inserted into portable devices with double Personal Computer Memory Card International Association card slots.

The small format of PCMCIA cards and their use in portable devices such as notebook or handheld computers makes them especially vulnerable to theft or loss. Such theft or loss can cause business interruption or breach of confidentiality through loss of the information contained on the card. In addition, poor work habits, such as failing to back up the data on another device, can result in the loss of data if the card fails or if the host device fails in a

manner that damages the card. Data recovery methods are notoriously nonexistent for small portable computers.

Smart Cards

Smart cards, consisting of a computer chip mounted on a plastic card similar to a credit card, have limited intelligence and storage compared to Personal Computer Memory Card International Association cards. Smart cards are increasingly used for health records, debit cards, and stored value cards. When inserted into an access device (reader), they may be used in pay telephones, transit systems, retail stores, health care providers, and Asynchronous Transfer Mode, as well as being used to supplement memory in handheld computers.

The risks in using this technology are the same as those for PCMCIA cards but may be exacerbated by the fact that smart cards can be easily carried in wallets along with credit cards. Because smart cards are used in stored value card systems, loss or damage to the card can deprive the owner of the value recorded. Both PCMCIA cards and smart cards must contain means for authenticating the user in order to protect against loss of confidentiality, privacy, or monetary value.

Notebook and Palmtop Computers

Notebook and palmtop computers are small portable personal computers, often supporting wireless connection to LANs and wide area network (WAN) or modems and providing communications capability for docking to desktop computers for uploading or downloading of files (either data or programs).

These devices have flat panel displays and may include 1.8-inch microdisks with 20M- to 80M-byte capacity. Some models support handwriting input. Smart cards, Personal Computer Memory Card International Association cards, or flashcards may be used to add functionality or memory. By the end of the decade, speech recognition capability should be available as a result of more powerful processors and greater memory capacity.

As with the cards that may be inserted into these machines, portable computers are vulnerable to loss or theft—both of the machine and of the information contained in its memory. In addition, their use in public places (such as on airplanes) may breach confidentiality or privacy.

It is vital that companies establish information security guidelines for use of these machines as they become ubiquitous. Guidelines should include means for authentication of the user to the device before it can be used, etching or otherwise imprinting the owner's name indelibly onto the machine, and rules for protected storage of the machine when it is not in the user's possession(as in travel or at hotel stays). One problem is that most hotel safes do not have deposit boxes large enough to hold notebook computers.

Portable computers combined with communications capability may create the single largest area of information security exposure in the future. Portable computers can go wherever the user goes. Scenarios of business use are stressing advantages but not security issues. Portable computers are used in many business functions including marketing, distribution field service, public safety, health care, transportation, financial services, publishing, wholesale and retail sales, insurance sales, and others. As the use of portable computers spreads, the opportunities for information loss or damage increase.

Portable computers, combined with communications that permit access to company data bases, require companies to adopt protective techniques to protect information bases from external access and prevent intelligence from being collected by repeated access. In

addition, techniques are needed for avoiding loss of confidentiality and privacy by device theft and business interruption through device failure.

New uses create new business vulnerabilities. New hospitals, for example, are being designed with patient-centered systems in which the services are brought to the patient (to the extent possible) rather than having the patient moved from one laboratory to another. This approach requires the installation of LANs throughout the hospital so that specialized terminals or diagnostic devices can be connected to the computers processing the data collected. Handheld computers may be moved with the patient or carried by attendants and plugged into the LAN to access patient records or doctors' orders. It is easy to anticipate abuses that range from illegal access to patient information to illegal dispensing of drugs to unauthorized persons.

New Opportunities for Defense

New technology should not, however, be seen solely as a security threat. New technology also holds opportunities for better means of protection and detection. Many capabilities provided by the IT department can support defensive techniques for information or information processing facilities.

Expert systems, neural networks, and minisupercomputers.
Used individually or in combination, these technologies may enable intrusion detection of information systems. These technologies can be used to recognize unusual behavior patterns on the part of the intruder, configure the human interface to suit individual users and their permitted accesses, detect physical intrusion or emergencies by signal analysis of sensor input and pattern recognition, and reconfigure networks and systems to maintain availability and circumvent failed components. In the future, these techniques may be combined with closed-circuit video to authenticate authorized personnel by comparing digitally stored images of persons wishing to enter facilities.

Smart cards or PCMCIA cards.
Used with card readers and carrying their own software data, data cards may enable authentication of a card owner through various means, including recognition of pressure, speed, and patterns of signatures; questions about personal history(the answers to which are stored on the card); use of a digitized picture of the owner; or cryptographic codes, access keys, and algorithms. Within five years, signature recognition capabilities may be used to limit access to penbased handheld computers to authorized users only, by recognizing a signature on log-in.

Personal computer networks (PCNs).
PCNs, enabled by nationwide wireless data communications networks, will permit a personal phone number to be assigned so that calls may reach individuals wherever they (and the instrument) are located in the US. PCNs will permit additional authentication methods and allow call-back techniques to work in a portable device environment.

Voice recognition.
When implemented along with continuous speech understanding, voice recognition may be used to authenticate users of voice input systems—for example, for inquiry systems in banking and brokerages. By the end of this decade voice recognition may be used to limit access to handheld computers to authorized users only by recognizing the owner's voice on log-in.

Wireless tokens.
Wireless tokens used as company identity badges can pinpoint the location of employees on plant sites and monitor restricted plant areas and work check-in and check-out. They may also support paging capability for messages or hazard warnings.

Reducing password risks.
The Obvious Password Utility System (OPUS)project at Purdue University has created a file compression technique that makes it possible to quickly check a proposed password against a list of prohibited passwords. With this technique, the check takes the same amount of time no matter how long the list. OPUS may allow prohibited password lists to be placed on small servers and improve password control so that systems are harder to crack.

Third-party authentication methods.
Systems like Kerberos and Sesame provide a third-party authentication mechanism that operates in an open network environment but does not permit access unless the user and the application are authenticated to each other by a separate, independent computer. (Third-party refers to a separate computer, not a legal entity.) Such systems may be a defense for the threats caused by portable systems and open networks. Users of portable computers may call the third-party machine and request access to a specific application on the remote host. The Kerberos or Sesame machine authenticates the user to the application and the application to the user before permitting access.

Conclusion

To stay ahead of the threats, data center managers must maintain a knowledge of technology advances, anticipate the potential threats and vulnerabilities, and develop the protective measures in advance. In well-run systems development functions, information security specialists are consulted during the systems specification and design phases to ensure that adequate provisions are made for the security of information in applications. Data center managers must be aware of the potential threats implicit in the adoption of new technologies and the defensive measures available in order to critique the design of new applications and to inform their senior management of hazards.

The combination of advanced computer capabilities and communications is making information available to corporate executives and managers on an unprecedented scale. The availability of information mandates its use by decision makers. Corporate officers could find that they are no longer just liable for prudent protection of the company's information assets but that they are liable for prudent use of the information available to the company in order to protect its customers and employees. Such conditions may alter the way systems are designed and information is used and the way the company chooses to protect its information assets.

Configuration Management: Charting the Course for the Organization

Mollie E. Krehnke, CISSP, IAM and David C. Krehnke, CISSP, CISM, IAM

Configuration management (CM) supports consistency, completeness, and rigor in implementing security. It also provides a mechanism for determining the current security posture of the organization with regard to technologies being utilized, processes and practices being performed, and a means for evaluating the impact of change on the security stance of the organization. If a new technology is being considered for implementation, an analysis can determine the effects from multiple standpoints:

- Costs to purchase, install, maintain, and monitor
- Positive or negative interactions with existing technologies or architectures
- Performance
- Level of protection
- Ease of use
- Management practices that must be modified to implement the technology
- Human resources who must be trained on the correct use of the new technology, as a user or as a provider

CM functions serve as a vital base for controlling the present — and for charting the future for an organization in meeting its goals. But looking at CM from a procedural level exclusively might result in the omission of significant processes that could enhance the information security stance of an organization and support mission success.

The Systems Security Engineering Capability Maturity Model (SSE-CMM)[1] will serve as the framework for the discussion of CM, with other long-standing, well-accepted references used to suggest key elements, policies, and procedural examples.

An Overview of the SSE-CMM

The SSE-CMM describes the essential characteristics of an organization's security engineering process that must exist to ensure good security engineering and thereby protect an organization's information resources, including hardware, software, and data. The SSE-CMM model addresses:

- The entire system life cycle, including concept definition, requirements analysis, design, development, integration, installation, operations, maintenance, and decommissioning activities

- The entire organization, including management, organizational, and engineering activities, and their staffs, including developers and integrators, that provide security services
- Concurrent interactions with other disciplines, such as systems, software, hardware, human factors, and testing engineering; system management, operation, and maintenance
- Interactions with other functions, including acquisition, system management, certification, accreditation, and evaluation
- All types and sizes of security engineering organizations — commercial, government, and academia[2]

SSE-CMM Relationship to Other Initiatives

Exhibit 59.1 shows how the SSE-CMM process relates to other initiatives working to provide structure, consistency, assurance, and professional stature to information systems security and security engineering.

EXHIBIT 59.1 Information Security Initiatives

Effort	Goal	Approach	Scope
SSE-CMM	Define, improve, and assess security engineering capability	Continuous security engineering maturity model and appraisal method	Security engineering organizations
SE-CMM	Improve the system or product engineering process	Continuous maturity model of systems engineering practices and appraisal method	Systems engineering organizations
SEI CMM for software	Improve the management of software development	Staged maturity model of software engineering and management practices	Software engineering organizations
Trusted CMM	Improve the process of high-integrity software development and its environment	Staged maturity model of software engineering and management practices, including security	High-integrity software organizations
CMM1	Combine existing process improvement models into a single architectural framework	Sort, combine, and arrange process improvement building blocks to form tailored models	Engineering organizations
Sys. Eng. CM (EIA731)	Define, improve, and assess systems engineering capability	Continuous system engineering maturity model and appraisal method	System engineering organizations
Common criteria	Improve security by enabling reusable protection profiles for classes of technology	Set of functional and assurance requirements for security, along with an evaluation process	Information technology
CISSP	Make security professional a recognized discipline	Security body of knowledge and certification test for security profession	Security practitioners
Assurance frameworks	Improve security assurance by enabling a broad range of evidence	Structured approach for creating assurance arguments and efficiently producing evidence	Security engineering organizations
ISO 9001	Improve organizational quality management	Specific requirements for quality management process	Service organizations
ISO 15504	Improve software process and assessment	Software process improvement model and appraisal methodology	Software engineering organizations
ISO 13335	Improve management of information technology security	Guidance on process used to achieve and maintain appropriate levels of security for information and services	Security engineering organizations

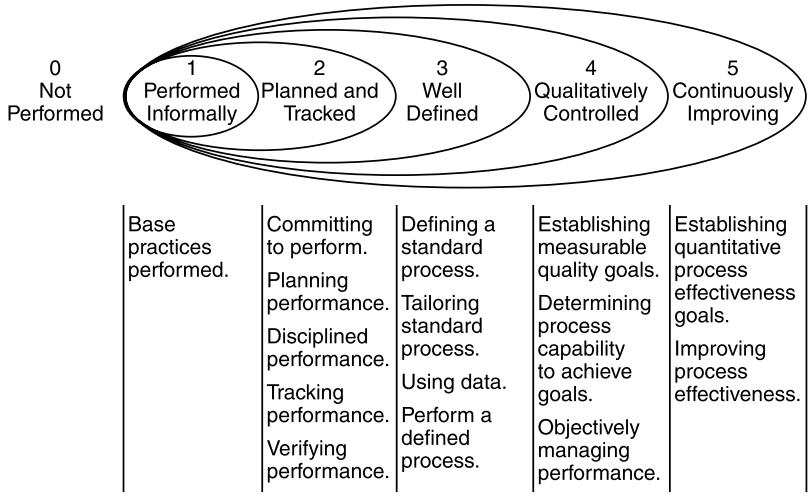

EXHIBIT 59.2 Capability levels of a security engineering organization.

CMM Framework

A CMM is a framework for evolving an security engineering organization from an ad hoc, less organized, less effective state to a highly structured effective state. Use of such a model is a means for organizations to bring their practices under statistical process control in order to increase their process capability. The SSE-CMM was developed with the anticipation that applying the concepts of statistical process control to security engineering will promote the development of secure systems and trusted products within anticipated limits of cost, schedule, and quality.

— SSE-CMM, Version 2.0, April 1, 1999

A process is a set of activities performed to achieve a given purpose. A well-defined process includes activities, input and output artifacts of each activity, and mechanisms to control performance of the activities. A defined process is formally described for or by an organization for use by its security professionals and indicates what actions are supposed to be taken. The performed process is what the security professionals actually do.…[P]rocess maturity indicates the extent to which a specific process is explicitly defined, managed, measured, controlled, and effective. Process maturity implies a potential for growth in capability and indicates both the richness of an organization's process and the consistency with which it is applied throughout the organization.

— SSE-CMM, Version 2.0, April 1, 1999, p. 21

Capability Levels Associated with Security Engineering Maturity

There are five capability levels associated with the SSE-CMM maturity model (see Exhibit 59.2) that represent increasing organizational capability. The levels are comprised of generic practices ordered according to maturity. Therefore, generic practices that indicate a higher level of process capability are located at the top of the capability dimension.

The SSE-CMM does not imply specific requirements for performing the generic practices. An organization is generally free to plan, track, define, control, and improve their processes in any way or sequence they choose. However, because some higher level generic practices are dependent on lower level generic practices, organizations are encouraged to work on the lower level generic practices before attempting to achieve higher levels.

— SSE-CMM, Version 2.0, April 1, 1999

CMM Institutionalization

Institutionalization is the building of an infrastructure and corporate culture that establishes methods, practices, and procedures, even after those who originally defined them are gone. The process capability side of the SSE-CMM supports institutionalization by providing practices and a path toward quantitative management and continuous improvement.[3] A mature, and continually improving, CM process and the associated base practices can result in activities with the following desirable qualities.

- C*ontinuity*: knowledge acquired in previous efforts is used in future efforts
- R*epeatability*: a way to ensure that projects can repeat a successful effort
- E*fficiency*: a way to help both developers and evaluators work more efficiently
- A*ssurance*: confidence that security needs are being addressed[4]

Security Engineering Model Goals

The SSE-CMM is a compilation of the best-known security engineering practices and is an evolving discipline. However, there are some general goals that can be presented. Many of these goals are also supported by the other organizations noted in Exhibit 59.1 that are working to protect an organization's information resources.

- Gain an understanding of the security risks associated with an enterprise.
- Establish a balanced set of security needs in accordance with identified risks.
- Transform security needs into security guidance to be integrated into the activities of other disciplines employed on a project and into descriptions of a system configuration or operation.
- Establish confidence or assurance in the correctness and effectiveness of security mechanisms.
- Determine that operational impacts due to residual security vulnerabilities in a system or its operation are tolerable (acceptable risks).
- Integrate the efforts of all security engineering disciplines and specialties into a combined understanding of the trustworthiness of a system.[5]

Security Engineering

While information technology security is often the driving discipline in the current security and business environment, the more traditional security disciplines should not be overlooked. These other security disciplines include the following:

- Operations security
- Information security
- Network security
- Physical security
- Personnel security
- Administrative security
- Communications security
- Emanation security
- Computer security

Security Engineering Process Overview

The security engineering process is composed of three basic areas: risk management, engineering, and assurance. The risk management process identifies and prioritizes dangers inherent in the developed product or system. The security engineering process works with the other engineering disciplines to determine and implement solutions to the problems presented by the dangers. The assurance process establishes confidence in the security solutions and conveys this confidence to customers or to management. These areas work together to ensure that the security engineering process results achieve the defined goals.

Risk Management

Risk management involves threats, vulnerabilities, and impacts. As an SSE-CMM process, risk management is the process of identifying and quantifying risk, and establishing an acceptable level of risk for the organization. The security practice areas in support of the risk management process are assess security risk, assess impact, and assess vulnerability.[6]

Engineering

Security engineers work with the customer to identify the security needs based on the identified risks, relevant laws, organizational policies, and existing information configurations. Security engineering is a process that proceeds through concept, design, implementation, test, deployment, operation, maintenance, and decommission. This process requires close cooperation and communication with other parts of the system engineering team to coordinate activities in the accomplishment of the required objectives, ensuring that security is an integral part of the process. Once the security needs are identified, security engineers identify and track specific requirements.[7]

The security practice areas in support of the engineering process are specify security needs, provide security input, administer security controls, and monitor security posture. Later in the life cycle, the security engineer is called on to ensure that products and systems are properly configured in relation to the perceived risks, ensuring that new risks do not make the system unsafe to operate.[8]

Assurance

Assurance is the degree of confidence that the security needs are satisfied. The controls have been implemented, will function as intended, and will reduce the anticipated risk. Often, this assurance is communicated in the form of an argument and is evident in documentation that is developed during the normal course of security engineering activities.

Security Engineering Basic Process Areas

The SSE-CMM contains approximately 60 security base practices, organized into 11 process areas that cover all major areas of security engineering, and represent the best existing practices of the security engineering community. Base practices apply across the life cycle of the enterprise, do not overlap with other base practices, represent a best practice of the security community (not a state-of-the-art technique), apply using multiple methods in multiple business contexts, and do not specify a particular method or tool. The 11 SSE-CMM process areas are listed below in alphabetical order to discourage the association of a practice with a life cycle phase.

- Administer security controls
- Assess impact
- Assess security risk
- Assess threat
- Assess vulnerability
- Build assurance argument
- Coordinate security
- Monitor security posture
- Provide security input
- Specify security needs
- Verify and validate security

Security Engineering Project and Organizational Practices

There are also 11 process areas related to project and organizational practices:

- Ensure quality
- Manage configuration
- Manage project risk
- Monitor and control technical effort
- Plan technical effort

- Define organization's system engineering process
- Improve organization's system engineering process
- Manage product line evolution
- Manage systems engineering support environment
- Provide ongoing skills and knowledge
- Coordinate with suppliers[9]

The base practices and the project and organizational practices were presented to provide the reader with a perspective for the focus of this chapter on the utilization and implementation configuration management — the topic of this chapter.

Configuration Management

This chapter follows the base practices associated with SSE-CMM PA 13 — Configuration Management to discuss policies, procedures, and resources that support this process in the establishment, implementation, and enhancement of security of an organization's information resources.

Configuration Management Description

The purpose of CM is to maintain data on and status of identified configuration units, and to analyze and control changes to the system and its configuration units. Managing the system configuration involves providing accurate and current configuration data and status to developers and customers. The goal is to maintain control over the established work product configurations.[10]

Configuration Management Base Practices

The following are the base practices considered essential elements of good security engineering CM:

- Establish CM methodology
- Identify configuration units
- Maintain work product baselines
- Control changes to established configuration units
- Communicate configuration status[11]

Each of these base practices is discussed below. The format presents the SSE-CMM description, example work products, and notes. Then a discussion of other references and resources that can be utilized to implement the base practice is presented.

Establish Configuration Management Methodology

Relationship to Other Security References

Choosing a CM tool to support the CM process will depend on the business processes being supported and the associated resources to be configured (see Exhibit 59.3). "Any information which may impact safety, quality, schedule, cost, or the environment must be managed. Each activity within the supply chain must be involved in the management process…. The best CM process is one that can best accommodate change and assure that all affected information remains clear, concise, and valid."[12]

Electronic Industries Alliance (EIA-649)

The Department of Defense and the Internal Revenue Service have adopted EIA-649 as their CM standard.

The CM process must relate to the context and environment in which it is to be implemented. Related activities include assignment of responsibilities, training of personnel, and determination of performance measurements. The Configuration Management Plan (CMP) can help to correlate CM to the International Standards Organization (ISO) 9000 series of quality systems criteria. The plan can also facilitate the justification of required resources and facilities, including automated tools.[13]

EXHIBIT 59.3 BP.13.01 — Establish CM Methodology

Description

Three primary trade-off considerations will have an impact on the structure and cost of CM, including:

- Level of detail at which the configuration units are identified
- Time when the configuration units are placed under CM
- Level of formalization required for the CM process

Example of Work Products

- Guidelines for identifying configuration units
- Timeline for placing configuration units under CM
- Selected CM process
- Selected CM process description

Notes

Selection criteria for configuration units should address interface maintenance, unique user requirements, new versus modified designs, and expected rate of change.

SSE-CMM, Version 2.0, April 1, 1999, p. 213–214.

Automated Tools

Institute of Configuration Management

There are several tools that have been certified by the Institute of Configuration Management (ICM)[14] because they can support a (new) configuration methodology (indicated as CMII) as defined by the ICM. The tools are listed in Exhibit 59.4.

The ICM certification signifies that:

- The tool supports achievement of the core elements of CMII functionality.
- The tool has the potential to be robust in all areas of functionality needed by that type of tool.
- The developer understands and agrees with the tool's strengths and weaknesses relative to CMII.
- The developer plans to make enhancements that will overcome those weaknesses.
- ICM agrees with the developer's priorities for doing so.[15]

Other Automated Tools

Another automated software management tool that is used in the IBM mainframe environment is ENDEVOR. The product can automate the transfer of all program source code, object code, executable code (load modules), interpretable code, control information, and the associated documentation to run a system. This includes source programs written in high-level programming language, job control or other control language, data dictionary, operating system, database components, online teleprocessing system, and job procedures.[16]

Two other commercially available online CM tools are UNIX's Source Code Control System (SCCS) and Revision Control System (RCS).[17]

EXHIBIT 59.4 ICM's CMII Certified Automated Tools

System Type	System Name	Release/ Version	Provider Name/Site	Date Certified
PDM	Metaphase	3.2	SDRD/Methphase www.SDRD.com	May 12, 2000
PDM	Axalant-CM	1.4	Usb/Eigner + Partner www.usbmuc.com www.ep-ag.com	December 8, 2000

Configuration Management Plan and Configuration Control Board as "Tools"

Computer Security Basics

This reference states that a manual tracking system can also be used for CM throughout a system's life cycle. Policies associated with CM implementation include:

- Assigning a unique identifier to each configuration item
- Developing a CMP
- Recording all changes to configuration items (either online or offline)
- Establishing a Configuration Control Board (CCB)[17]

EIA-649

Configuration identification is the basis of unique product identification, definition, and verification; product and document identification marking; change management; and accountability. The process enables a user to distinguish between product versions and supports release control of documents for baseline management.[18]

Information Systems Security Engineering Handbook

CM is a process for controlling all changes to a system (software, hardware, firmware, documentation, support/testing equipment, and development/maintenance equipment). A CCB should be established to review and approve any and all changes to the system. Reasons for performing CM throughout the life cycle of the information system include:

- Maintaining a baseline at a given point in the system life cycle
- Natural evolution of systems over time — they do not remain static
- Contingency planning for catastrophes (natural or human)
- Keeping track of all certification and accreditation evidence
- Use of the system's finite set of resources will grow through the system's life cycle
- Configuration item identification
- Configuration control
- Configuration accounting
- Configuration auditing[19]

NCSC-TG-006, A Guide to Understanding Configuration Management in Trusted Systems

The CMP and the human resources that support the CM process via the CCB should also be considered "tools." Effective CM should include a well-thought-out plan that should be prepared immediately after project initiation. The CMP should describe, in simple, positive statements, what is to be done to implement CM in the system.[20] CCB participants' roles should also be defined in the CMP. The responsibilities required by all those involved with the system should be established and documented in the CMP to ensure that the human element functions properly during CM.[21] A portion of the CMP should also address required procedures, and include routine CM procedures and any existing "emergency" procedures. Because the CMP is a living document, it should have the capability for additions and changes, but should be carefully evaluated and approved and then completely implemented to provide the appropriate assurances.

Any tools that will be used for CM should be documented in the CMP. These tools should be "maintained under strict configuration control." These tools can include forms used for change control, conventions for labeling configuration items, software libraries, as well as any automated tools that may be available to support the CM process. Samples of any documents to be used for reporting should also be contained in the CMP, along with a description of each.[21]

Information Systems Security Engineering Handbook, National Security Agency, Central Security Service.

Ensuring that a CM process is in place to prevent modifications that can cause an increase in security risk to occur without the proper approval is a consideration in the information system's life cycle, certification/accreditation, and recertification/reaccreditation activities after system activation.[22]

Identify Configuration Units

See Exhibits 59.5 and Exhibit 59.6.

EXHIBIT 59.5 BP.13.02 — Identify Configuration Units

Description

A configuration unit is one or more work products that are baselined together. The selection of work products for CM should be based on criteria established in the selected CM strategy. Configuration units should be selected at a level that benefits the developers and customers, but that does not place an unreasonable administrative burden on the developers.

Example of Work Products

- Baselined work product configuration
- Identified configuration units

Notes

Configuration units for a system that has requirements on field replacement should have an identified configuration unit at the field-replacement unit level.

SSE-CMM, Version 2.0, April 1, 1999, p. 215.

EXHIBIT 59.6 Examples of Configuration Units

The following examples of configuration units are cited in BP.01.02 — Manage Security Configuration:

- *Records of all software updates*: tracks licenses, serial numbers, and receipts for all software and software updates to the system, including date, person responsible, and a description of the change.
- *Records of all distribution problems*: describes any problem encountered during software distribution and how it was resolved.
- *System security configurations*: describes the current state of the system hardware, software, and communications, including their location, the individual assigned, and related information.
- *System security configuration changes*: describes any changes to the system security configuration, including the name of the person making the change, a description of the change, the reason for the change, and when the change was made.
- *Records of all confirmed software updates*: tracks software updates, which includes a description of the change, the name of the person making the change, and the date made.
- *Periodic summaries of trusted software distribution*: describes recent trusted software distribution activity, noting any difficulties and action items.
- *Security changes to requirements*: tracks any changes to system requirements made for security reasons or having an effect on security, to help ensure that changes and their effects are intentional.
- *Security changes to design documentation*: tracks any changes to the system design made for security reasons or having an effect on security, to help ensure that changes and their effects are intentional.
- *Control implementation*: describes the implementation of security controls within the system, including configuration details.
- *Security reviews*: describes the current state of the system security controls relative to the intended control implementation.
- *Control disposal*: describes the procedure for removing or disabling security controls, including a transition plan.

SSE-CMM, Version 2.0, April 1, 1999, p. 115–116.

Relationship to Other Security References

AR25-3, Army Life Cycle Management of Information Systems

CM focuses on four areas: configuration identification, configuration control, configuration status accounting, and configuration audit. CM should be applied throughout the life cycle of configuration items to control and improve the reliability of information systems.[23]

British Standards (BS7799), Information Security Management, Part 1, Code of Practice for Information Security Management Systems

A lack of change control is said to be a "common cause of system or security failures." Formal management and practice of change control are required for equipment, software, or procedures.[24]

Computer Security Basics

CM items also include documentation, test plans, and other security-related system tools and facilities.[25]

DOD-STD-2167A, Defense System Software Development.

Although this military standard has been canceled, the configuration identification units are a familiar concept to many system developers: computer software configuration items (CSCIs) and the corresponding computer software components (CSCs) and the computer software units (CSUs). Documentation established the Functional, Allocated, and Product Baselines. Each deliverable item had a version, release, change status, and other identification details. Configuration control was implemented through an established plan that was documented and then communicated through the implementation of configuration status accounting.

EIA-649

Unique identifiers support the correlation of the unit to a process, date, event, test, or document. Even documents must be uniquely identified to support association with the proper product configuration. The baseline represents an agreed-upon description of the product at a point in time with a known configuration. Intermediate baselines can be established for complex products. Baselines are the tools to match the need for consistency with the authority to approve changes. Baselines can include requirements, design releases, product configurations, operational, and disposal phase baselines.[26]

"Information Classification: A Corporate Implementation Guide," *Handbook of Information Security Management*

Maintaining an audit/history information that documents the software changes, "such as the work request detailing the work to be performed, who performed the work, and other pertinent documentation required by the business" is a vital software control.[17]

Maintain Work Product Baselines

See Exhibit 59.7.

Relationship to Other Security References

EIA-649

Recovery of a configuration baseline (or creation after the fact, with no adequate documentation) will be labor intensive and expensive. Without design and performance information, configuration must be determined via inspection, and this impacts operational and maintenance decisions. Reverse-engineering is a very expensive process.[26]

"Information Classification: A Corporate Implementation Guide," *Handbook of Information Security Management*

This chapter emphasizes the importance of version and configuration control, including "versions of software checked out for update, or being loaded to staging or production libraries. This would include the monitoring of error reports associated with this activity and taking appropriate corrective action."[28]

EXHIBIT 59.7 BP13.03 — Maintain Work Product Baselines

Description

This practice involves establishing and maintaining a repository of information about the work product configuration. …capturing data or describing the configuration units … including an established procedure for additions, deletions, and modifications to the baseline, as well as procedures for tracking/monitoring, auditing, and the accounting of configuration data … to provide an audit trail back to source documents at any point in the system life cycle.

Example of Work Products

- Decision database
- Baselined configuration
- Traceability matrix

Notes

Configuration data can be maintained in an electronic format to facilitate updates and changes to supporting documentation.[38]

SSE-CMM, Version 2.0, April 1, 1999, p. 216.

New Alliance Partnership Model (NAPM)

NAPM is a partnership model that combines security, configuration management, and quality assurance functions with an overall automated information system (AIS) security engineering process. NAPM provides insight into the importance of CM to the AISs of the organization and the implementation of an effective security program.

> CM provides management with the assurance that changes to an existing AIS are performed in an identifiable and controlled environment and that these changes do not adversely affect the integrity or availability properties of secure products, systems, and services. CM provides additional security assurance levels in that all additions, deletions, or changes made to a system do not compromise its integrity, availability, or confidentiality. CM is achieved through proceduralization and unbiased verification, ensuring that changes to an AIS and/or all supporting documentation are updated properly, concentrating on four components: identification, change control, status accounting, and auditing.[29]

Control Changes To Established Configuration Units

See Exhibit 59.8.

Relationship to Other Security References

British Standards (BS7799), Information Security Management, Part 1, Code of Practice for Information Security Management Systems

The assessment of the potential impact of a change, adherence to a procedure for approval of proposed changes, and procedures for aborting and recovering from unsuccessful changes play a significant role in the operational change process.[30] Policies and procedures to support software control and reduce the risk of operational systems corruption include:

- Program library updates by the nominated librarian with IT approval
- Exclusion of nonexecutable code
- In-depth testing and user acceptance of new code
- Updating of program source libraries
- Maintenance of an update audit log for all operational program libraries
- Retention of previous versions of software for contingencies[31]

EXHIBIT 59.8 BP.13.04 — Control Changes to Established Configuration Units

Description

Control is maintained over the configuration of the baselined work product. This includes tracking the configuration of each of the configuration units, approving a new configuration, if necessary, and updating the baseline. Identified problems with the work product or requests to change the work product are analyzed to determine the impact that the change will have on the work product, program schedule and cost, and other work products. If, based on analysis, the proposed change to the work product is accepted, a schedule is identified for incorporating the change into the work product and other affected areas. Changed configuration units are released after review and formal approval of configuration changes. Changes are not official until they are released.

Example of Work Products

- New work product baselines

Notes

Change control mechanisms can be tailored to categories of change. For example, the approval process should be shorter for component changes that do not affect other components.

SSE-CMM, Version 2.0, April 1, 1999, p. 217.

British Standards (BS7799), Information Security Management, Part 2, Specification for Information Security Management Systems

Formal change control procedures should be implemented for all stages of a system's life cycle, and these changes should be strictly controlled.[32]

EIA-649

> The initial baseline for change management consists of the configuration documentation defining the requirements that the performing activity (i.e., the product developer or product supplier) has agreed to meet. The design release baseline for change management consists of the detail design documentation used to manufacture, construct, build, or code the product. The product configuration baseline for change management consists of the detailed design documentation from the design release baseline which defines the product configuration that has been proven to meet the requirements for the product. The product configuration is considered [to be] a mature configuration. Changes to the current requirements, design release, or product configuration baselines may result from discovery of a problem, a suggestion for product improvement or enhancement, a customer request, or a condition dictated by the marketplace or by public law.
>
> Changes should be classified as major or minor to support the determination of the appropriate levels of review and approval. A major change is a change to the requirements of baselined configuration documentation (requirements, design release or product configuration baselines) that has significant impact. It requires coordination and review by all affected functional groups or product development teams and approval by a designated approval authority…. A minor change corrects or modifies configuration documentation (released design information), processes or parts but does not impact…customer requirements.
>
> To adequately evaluate a request for change, the change request must be clearly documented. It is important to accurately describe even minor changes so that an audit trail can be constructed in the event that there are unanticipated consequences or unexpected product failures. Saving the cost of the research involved in one such incident by having accurate accessible records may be sufficient to fully offset diligent, disciplined change processing.[33]

Technical, support, schedule, and cost impacts of a requested change must also be considered prior to approval and implementation. The organizational areas that will be impacted by the change or have the responsibility for implementing the change must be involved in the change process. Those organizations may have significant information (not available to other organizations) that could impact the successful implementation of a change. Change considerations must include the timeline and resource requirements of support organizations, as well as those of the primary client organization (e.g., update of support software, availability of spare and repair parts,

or revisions to operating and maintenance instructions) and urgency of the change. The change must be verified to ensure that the product, its documentation, and the support elements are consistent. The extent to which the verification is implemented will depend on the quantity of units changed and the type of change that is implemented. Records must be maintained regarding the verification of changes and implementation of required support functions. Variances to required configuration must be approved and documented.[33]

FIPS PUB 102, Guideline for Computer Security Certification and Accreditation

The change control process is an implicit form of recertification and reaccreditation. It is required during both development and operation. For sensitive applications, change control is needed for requirements, design, program, and procedural documentation, as well as for the hardware and software itself.

The process begins during development via the establishment of baselines for the products listed above. Once a baseline is established, all changes require a formal change request and authorization. Every change is reviewed for its impact on prior certification evidence.

An entity sometimes formed to oversee change control is the CCB. During development, the CCB is a working group subsidiary to the Project Steering Committee or its equivalent. Upon completion of development, CCB responsibility is typically transferred to an operations and maintenance office. There should be a security representative on the CCB responsible for the following:

- Deciding whether a change is security relevant
- Deciding on a required security review and required levels of recertification and reaccreditation
- Deciding on a threshold that would trigger recertification activity
- Serving as technical security evaluator, especially for minor changes that might receive no other security review

For very sensitive applications, it is appropriate to require approval and testing for all changes. However minor, a record must be kept of all changes as well as such pertinent certification evidence as test results. This record is reviewed during recertification.[33]

> As security features of a system or its environment change, recertification and reaccreditation are needed…. CM is a suitable area in which to place the monitoring activity for these changes.[34]

Information Systems Security Engineering Handbook

> A change or upgrade in the system, subsystem, or component configuration (e.g., incorporation of new operating system releases, modification of an applications program for data management, installation of a new commercial software package, hardware upgrades or swapouts, new security products, change to the interface characteristics of a 'trusted' component) … may violate its security assumptions.[35] The strongest configuration control procedures will include provisions for periodic physical and functional audit on the actual system in its operational environment. They will not rely solely on documentation or known or proposed changes. Changes frequently occur that are either not well known, or not well documented. These will only be detected by direct inspection of the system hardware, software, and resident data.[36]

NCSC-TG-006, A Guide to Configuration Management in Trusted Systems. CM maintains control of a system throughout its life cycle, ensuring that the system in operation is the correct system, and implementing the correct security policy. The Assurance Control Objective can be applied to configuration management as follows:

> Computer systems that process and store sensitive or classified information depend on the hardware and software to protect that information. It follows that the hardware and software themselves must be protected against unauthorized changes that could cause protection mechanisms to malfunction or be bypassed entirely. Only in this way can confidence be provided that the hardware and software interpretation of the security policy is maintained accurately and without distortion.[36]

Communicate Configuration Status

The status of the configuration is vital to the success of the organization (see Exhibit 59.9). The information that an organization uses must be accurate. "What is the sense of building the product to Six Sigma[37] when the blueprint is wrong?"[38] Changes must be documented and communicated in an expeditious and consistent manner.

EXHIBIT 59.9 BP.13.05 — Communicate Configuration Status

Description

Inform affected groups of the status of configuration data whenever there are any status changes. The status reports should include information on when accepted changes to configuration units will be processed, and the associated work products that are affected by the change. Access to configuration data and status should be provided to developers, customers, and other affected groups.

Example of Work Products

- Status reports

Notes

Examples of activities for communicating configuration status include providing access permissions to authorized users, and making baseline copies readily available to authorized users.

SSE-CMM, Version 2.0, April 1, 1999, p. 218.

Relationship to Other Security References

EIA-649

Configuration management information about a product is important throughout the entire life cycle, and the associated CM processes (planning and management, identification, change management, and verification and audit). "Configuration status accounting (CSA) correlates, stores, maintains, and provides readily available views of this organized collection of information…. CSA improves capabilities to identify, produce, inspect, deliver, operate, maintain, repair, and refurbish products."[39] CSA also provides "a source for configuration history of a product and all of its configuration documentation."

This CSA information must be disseminated to those who have a need to know throughout the product's life cycle. Examples of CSA life cycle documentation by phase include the following.

- *Conception phase*: requirements documents and their change history
- *Definition phase*: detailed configuration documents (e.g., specifications, engineering drawings, software design documents, software code, test plans and procedures) and their change history and variance status
- *Build phase*: additional product information (e.g., verified as-built unit configuration) and product changes, and associated variances
- *Distribution phase*: information includes customers and dates of delivery, installation configuration, warranty expiration dates, and service agreement types and expiration
- *Operation phase*: CSA varies, depending on the type of product and the contractual agreements regarding CM responsibilities, but could include product as-maintained and as-modified configurations, operation and maintenance information revision status, change requests and change notices, and restrictions
- *Disposal phase*: CSA information varies with the product and whether disposing of a product could have adverse implications, or if there are legal or contractual statues regarding retention of specific data[40]

"Systems Integrity Engineering," Handbook of Information Security Management

This chapter emphasizes the importance of configuration management plans to convey vital system-level information to the organization. Distributed system CM plans must document:

- System-level and site-level policies, standards, procedures, responsibilities, and requirements for the overall system control of the exchange of data
- The identification of each individual's site configuration
- Common data, hardware, and software
- The maintenance of each component's configuration

Distribution controls and audit checks to ensure common data and application versions are the same across the distributed system in which site-level CM plans are subordinate to distributed-level CM plans. The change control authority(ies) will need to establish agreements with all distributed systems on policies, standards,

procedures, roles, responsibilities, and requirements for distributed systems that are not managed by a single organizational department, agency, or entity.[41]

Conclusions

Change Is Inevitable

Change is inevitable in an organization. Changes in an information system, its immediate environment, or a wider organizational environment can (and probably will) impact the appropriateness of the information system's security posture and implemented security solutions. Routine business actions or events that can have a significant impact on security include:

- A mission or umbrella policy driven change in information criticality or sensitivity that causes a changes in the security needs or countermeasures required
- A change in the threat (e.g., changes in threat motivation, or new threat capabilities of potential attackers) that increases or decreases systems security risk
- A change in the application that requires a different security mode of operation
- A discovery of a new means of security attack
- A breach of security, a breach of system integrity, or an unusual situation or incident that appears to invalidate the accreditation by revealing a security flaw
- A security audit, inspection, or external assessment
- A change or upgrade in the system, subsystem, or component configurations
- The removal or degradation of a configuration item
- The removal or degradation of a system process countermeasure (i.e., human interface requirement or other doctrine/procedure components of the overall security solution)
- The connection to any new external interface
- Changes in the operational environment (e.g., relocation to other facilities, changes in infrastructure/environment-provided protections, changes in external operational procedures)
- Availability of new countermeasures technology that could, if used, improve the security posture or reduce operating costs
- Expiration of the information system's security accreditation statement[42]

Change Must Be Controlled

With the concept of control comes the concept of prior approval before changes are made. The approval is based on an analysis of the implications if the changes are made. It is possible that some changes may inadvertently change the security stance of the information system.

CM that is implemented according to an established plan can provide many benefits to an organization, including:

- Decisions based on knowledge of the complete change impact
- Changes limited to those that are necessary or offer significant benefits
- Effective cost-benefit analysis of proposed changes
- High levels of confidence in the product information or configurations
- Orderly communication of change information
- Preservation of customer interests
- Current system configuration baselines
- Configuration control at product interfaces
- Consistency between system configurations and associated documentation
- Ease of system maintenance after a change[43]

Change control must also be implemented within the computing facility. Every computing facility should have a policy regarding changes to operating systems, computing equipment, networks, environmental facilities (e.g., air conditioning, water, heat, plumbing, electricity, and alarms), and applications.[44]

Configuration Management as a Best Practice

The European Security Forum has been conducting systematic case studies of companies across various economic sectors for a number of years. A recent study addressed organizing and managing information technology (IT) security in a distributed environment. Change management for live systems was the fifth most important security practice worthy of additional study indicated by those organizations queried. Although the practice was well established and deemed of high importance by all respondents — as reported by the IT security manager, the IT manager, and a business manager of a functional area for each company — their comments resulted in the following finding. "While examples of successful practice exist, the general feeling that change management was an area where even the best organization recognized the need for improvement."[45]

Configuration Management as a Value-Adding Process

CM as a process enables an organization to tailor the process to address the context and environment in which the process will be implemented and add value to the resulting product. Multiple references reviewed for this chapter emphasized the need for consistency in how the process is implemented and its repeatability over time. It is better for an organization to consistently repeat a few processes over time than to inconsistently implement a multitude of activities once or twice. With standardization comes the knowledge of the status of that process. With knowledge of the status and the related benefits (and drawbacks), there can be a baseline of the process and its products. Effectively implementing configuration management can result in improved performance, reliability, or maintainability; extended life for the product; reduced development costs; reduced risk and liability; or corrected defects. The attributes of CM best practices include planned, integrated, consistent, rule/workflow-based, flexible, measured, and transparent.[46]

Security advantages of CM include protection against unintentional threats and malicious events. Not only does CM require a careful analysis of the implications of the proposed changes and approval of all changes before they are implemented, but it also provides a capability for reverting to a previous configuration (because previous versions are archived), if circumstances (e.g., a faulty change) require such an action. Once a reviewed program is accepted, a programmer is not permitted to make any malicious changes, such as inserting trapdoors, without going through the change approval process where such an action should be caught.[47]

Implementing Configuration Management

When implementing configuration management, the security professional should:

- Plan CM activities based on sound CM principles
- Choose a CM process that fits the environment, external constraints, and the product's life cycle phases
- Choose tools that support the CM process; tools can be simple and manual, or automated, or a combination of both
- Implement CM activities consistently across project and over time
- Use the CM plan as a training tool for personnel, and a briefing tool to explain the process to customers, quality assurance staff, and auditors
- Use enterprise CM plans to reduce the need for complete CM plans for similar products
- Ensure resources are available to support the process in a timely and accurate manner
- Ensure a security representative is on the CCB to evaluate the security implications of the proposed changes
- Ensure the changed system is tested and approved prior to deployment
- Ensure support/service areas are able to support the change
- Ensure configuration information is systematically recorded, safeguarded, validated, and disseminated
- Perform periodic audits to verify system configurations with the associated documentation, whether hardcopy or electronic in format

Information Classification: A Corporate Implementation Guide

Jim Appleyard

Introduction

Classifying corporate information based on business risk, data value, or other criteria (as discussed later in this chapter), makes good business sense. Not all information has the same value or use, or is subject to the same risks. Therefore, protection mechanisms, recovery processes, etc. are — or should be — different, with differing costs associated with them. Data classification is intended to lower the cost of protecting data, and improve the overall quality of corporate decision making by helping ensure a higher quality of data upon which the decision makers depend.

The benefits of an enterprisewide data classification program are realized at the corporate level, not the individual application or even departmental level. Some of the benefits to the organization inclide:

- Data confidentiality, integrity, and availability are improved because appropriate controls are used for all data across the enterprise.
- The organization gets the most for its information protection dollar because protection mechanisms are designed and implemented where they are needed most, and less costly controls can be put in place for noncritical information.
- The quality of decisions is improved because the quality of the data upon which the decisions are made has been improved.
- The company is provided with a process to review all business functions and informational requirements on a periodic basis to determine priorities and values of critical business functions and data.
- The implementation of an information security architecture is supported, which better positions the company for future acquisitions and mergers.

This chapter will discuss the processes and techniques required to establish and maintain a corporate data classification program. There are costs associated with this process; however, most of these costs are front-end start-up costs. Once the program has been successfully implemented, the cost savings derived from the new security schemes, as well as the improved decision making, should more than offset the initial costs over the long haul, and certainly the benefits of the ongoing program outweigh the small, administrative costs associated with maintaining the data classification program.

Although not the only methodology that could be employed to develop and implement a data classification program, the one described here has been used and proved to work.

EXHIBIT 60.1 Threat/Risk Analysis

Application	Platform	Threat	Risk	Consequences of Loss
Application				

The following topics will be addressed:

- Getting started: questions to ask
- Policy
- Business Impact Analysis
- Establishing classifications
- Defining roles and responsibilities
- Identifying owners
- Classifying information and applications
- Ongoing monitoring

Getting Started: Questions to Ask

Before the actual implementation of the data classification program can begin, the Information Security Officer (ISO) — whom for the purposes of this discussion is the assumed project manager — must ask some very important questions, and get the answers.

Is there an executive sponsor for this project?

Although not absolutely essential, obtaining an executive sponsor and champion for the project could be a critical success factor. Executive backing by someone well respected in the organization who can articulate the ISO's position to other executives and department heads will help remove barriers, and obtain much needed funding and buy-in from others across the corporation. Without an executive sponsor, the ISO will have a difficult time gaining access to executives or other influencers who can help sell the concept of data ownership and classification.

What are you trying to protect, and from what?

The ISO should develop a threat and risk analysis matrix to determine what the threats are to corporate information, the relative risks associated with those threats, and what data or information are subject to those threats. This matrix provides input to the business impact analysis, and forms the beginning of the plans for determining the actual classifications of data, as will be discussed later in this chapter. (See Exhibit 60.1 for an example Threat/Risk Analysis table).

Are there any regulatory requirements to consider?

Regulatory requirements will have an impact on any data classification scheme, if not on the classifications themselves, at least on the controls used to protect or provide access to regulated information. The ISO should be familiar with these laws and regulations, and use them as input to the business case justification for data classification, as well as input to the business impact analysis and other planning processes.

Has the business accepted ownership responsibilities for the data?

The business, not IT, owns the data. Decisions regarding who has what access, what classification the data should be assigned, etc. are decisions that rest solely with the business data owner. IT provides the technology and processes to implement the decisions of the data owners, but should not be involved in the decision-making process. The executive sponsor can be a tremendous help in selling this concept to the organization. Too many organizations still rely on IT for these types of decisions. The business manager must realize that the data is his data, not IT's; IT is merely the custodian of the data. Decisions regarding access, classification, ownership, etc. resides in the business units. This concept must be sold first, if data classification is to be successful.

Are adequate resources available to do the initial project?

Establishing the data classification processes and procedures, performing the business impact analysis, conducting training, etc. requires an up-front commitment of a team of people from across the organization if the project is to be successful. The ISO cannot and should not do it alone. Again, the executive sponsor can

be of tremendous value in obtaining resources such as people and funding for this project that the ISO could not do. Establishing the processes, procedures, and tools to implement good, well-defined data classification processes takes time and dedicated people.

Policy

A useful tool in establishing a data classification scheme is to have a corporate policy implemented stating that the data are an asset of the corporation and must be protected. Within that same document, the policy should state that information will be classified based on data value, sensitivity, risk of loss or compromise, and legal and retention requirements. This provides the ISO the necessary authority to start the project, seek executive sponsorship, and obtain funding and other support for the effort.

If there is an Information Security Policy, these statements should be added if they are not already there. If no Information Security Policy exists, then the ISO should put the data classification project on hold, and develop an Information Security Policy for the organization. Without this policy, the ISO has no real authority or reason to pursue data classification. Information must first be recognized and treated as an asset of the company before efforts can be expended to protect it.

Assuming there is an Information Security Policy that mentions or states that data will be classified according to certain criteria, another policy — Data Management Policy — should be developed which establishes data classification as a process to protect information and provides:

- The definitions for each of the classifications
- The security criteria for each classification for both data and software
- The roles and responsibilities of each group of individuals charged with implementing the policy or using the data

Below is a sample Information Security Policy. Note that the policy is written at a very high level and is intended to describe the "what's" of information security. Processes, procedures, standards, and guidelines are the "hows" or implementation of the policy.

Sample Information Security Policy

> All information, regardless of the form or format, which is created or used in support of company business activities is corporate information. Corporate information is a company asset and must be protected from its creation, through its useful life, and authorized disposal. It should be maintained in a secure, accurate, and reliable manner and be readily available for authorized use. Information will be classified based on its sensitivity, legal, and retention requirements, and type of access required by employees and other authorized personnel.
>
> Information security is the protection of data against accidental or malicious disclosure, modification, or destruction. Information will be protected based on its value, confidentiality, and/or sensitivity to the company, and the risk of loss or compromise. At a minimum, information will be update-protected so that only authorized individuals can modify or erase the information.

The above policy is the minimum requirement to proceed with developing and implementing a data classification program. Additional policies may be required, such as an Information Management Policy, which supports the Information Security Policy. The ISO should consider developing this policy, and integrating it with the Information Security Policy. This policy would:

- Define information as an asset of the business unit
- Declare local business managers as the owners of information
- Establish Information Systems as the custodians of corporate information
- Clearly define roles and responsibilities of those involved in the ownership and classification of information
- Define the classifications and criteria that must be met for each
- Determine the minimum range of controls to be established for each classification

By defining these elements in a separate Information Management Policy, the groundwork is established for defining a corporate information architecture, the purpose of which is to build a framework for integrating

all the strategic information in the company. This architecture can be used later in the enablement of larger, more strategic corporate applications.

The supporting processes, procedures, and standards required to implement the Information Security and Information Management policies must be defined at an operational level and be as seamless as possible. These are the "mechanical" portions of the policies, and represent the day-to-day activities that must take place to implement the policies. These include but are not limited to:

- The process to conduct a Business Impact Analysis
- Procedures to classify the information, both initially after the BIA has been completed, and to change the classification later, based on business need
- The process to communicate the classification to IS in a timely manner so the controls can be applied to the data and software for that classification
- The process to periodically review:
  - — Current classification to determine if it is still valid
  - — Current access rights of individuals and/or groups who have access to a particular resource.
  - — Controls in effect for a classification to determine their effectiveness
  - — Training requirements for new data owners
- The procedures to notify custodians of any change in classification or access privileges of individuals or groups

The appropriate policies are required as a first step in the development of a Data Classification program. The policies provide the ISO with the necessary authority and mandate to develop and implement the program. Without it, the ISO will have an extremely difficult time obtaining the funding and necessary support to move forward. In addition to the policies, the ISO should solicit the assistance and support of both the Legal Department and Internal Audit. If a particular end-user department has some particularly sensitive data, their support would also provide some credibility to the effort.

Business Impact Analysis

The next step in this process is to conduct a high-level business impact analysis on the major business functions within the company. Eventually this process should be carried out on all business functions, but initially it must be done on the business functions deemed most important to the organization.

A critical success factor in this effort is to obtain corporate sponsorship. An executive who supports the project, and may be willing to be the first whose area is analyzed, could help persuade others to participate, especially if the initial effort is highly successful and there is perceived value in the process.

A Study Team comprised of individuals from Information Security, Information Systems (application development and support), Business Continuity Planning, and Business Unit representatives should be formed to conduct the initial impact analysis. Others that may want to participate could include Internal Audit and Legal.

The Business Impact Analysis process is used by the team to:

- Identify major functional areas of information (i.e., human resources, financial, engineering, research and development, marketing, etc.).
- Analyze the threats associated with each major functional area. This could be as simple as identifying the risks associated with loss of confidentiality, integrity, or availability, or get into more detail with specific threats of computer virus infections, denial of service attacks, etc.
- Determine the risk associated with the threat (i.e., the threat could be disclosure of sensitive information, but the risk could be low because of the number of people who have access, and the controls that are imposed on the data).
- Determine the effect of loss of the information asset on the business (this could be financial, regulatory impacts, safety, etc.) for specific periods of unavailability — one hour, one day, two days, one week, a month.
- Build a table detailing the impact of loss of the information (as shown in Exhibit 60.2 — Business Impact Analysis)

EXHIBIT 60.2 Business Impact Analysis

Function	Application	Type Loss (CIA)	Cost after 1 Hour	Cost after 2 Hours	Cost after 1 Day	Cost after 1 Week	Cost after 1 Month
Human Resources	Payroll	Confidentiality					
		Integrity					
		Availability					
	Medical	Confidentiality					
		Integrity					
		Availability					

- Prepare a list of applications that directly support the business function (i.e., Human Resources could have personnel, medical, payroll files, skills inventory, employee stock purchase programs, etc.) This should be part of Exhibit 60.2.

From the information gathered, the team can determine universal threats that cut across all business functional boundaries. This exercise can help place the applications in specific categories or classifications with a common set of controls to mitigate the common risks. In addition to the threats and their associated risks, sensitivity of the information, ease of recovery, and criticality must be considered when determining the classification of the information.

Establish Classifications

Once all the risk assessment and classification criteria have been gathered and analyzed, the team must determine how many classifications are necessary and create the classification definitions, determine the controls necessary for each classification for the information and software, and begin to develop the roles and responsibilities for those who will be involved in the process. Relevant factors, including regulatory requirements, must be considered when establishing the classifications.

Too many classifications will be impractical to implement; most certainly will be confusing to the data owners and meet with resistance. The team must resist the urge for special cases to have their own data classifications. The danger is that too much granularity will cause the process to collapse under its own weight. It will be difficult to administer and costly to maintain.

On the other hand, too few classes could be perceived as not worth the administrative trouble to develop, implement, and maintain. A perception may be created that there is no value in the process, and indeed the critics may be right.

Each classification must have easily identifiable characteristics. There should be little or no overlap between the classes. The classifications should address how information and software are handled from their creation, through authorized disposal. See Exhibit 60.3, Information/Software Classification Criteria.

Following is a sample of classification definitions that have been used in many organizations:

- **Public** — Information, that if disclosed outside the company, would not harm the organization, its employees, customers, or business partners.
- **Internal Use Only** — Information that is not sensitive to disclosure within the organization, but could harm the company if disclosed externally.
- **Company Confidential** — Sensitive information that requires "need to know" before access is given.

It is important to note that controls must be designed and implemented for both the information and software. It is not sufficient to classify and control the information alone. The software, and possibly the

EXHIBIT 60.3 Information/Software Classification Criteria

Classification	Storage Media	Minimum Data Controls	Minimum Software Controls	Transmission Considerations	Destruction Mechanisms
Application					

hardware on which the information and/or software resides, must also have proportionate controls for each classification the software manipulates. Below is a set of minimum controls for both information and software that should be considered.

Information — Minimum Controls

- **Encryption** — Data is encrypted with an encryption key so that the data is "scrambled." When the data is processed or viewed, it must be decrypted with the same key used to encrypt it. The encryption key must be kept secure and known only to those who are authorized to have access to the data. Public/private key algorithms could be considered for maximum security and ease of use.
- **Review and approve** — This is a procedural control, the intent of which is to ensure that any change to the data is reviewed by someone technically knowledgeable to perform the task. The review and approval should be done by an authorized individual other than the person who developed the change.
- **Backup and recovery** — Depending on the criticality of the data and ease of recovery, plans should be developed and periodically tested to ensure the data is backed up properly, and can be fully recovered.
- **Separation of duties** — The intent of this control is to help ensure that no single person has total control over the data entry and validation process, which would enable someone to enter or conceal an error that is intended to defraud the organization or commit other harmful acts. An example would be not allowing the same individual to establish vendors to an Authorized Vendor File, then also be capable of authorizing payments to a vendor.
- **Universal access: none** — No one has access to the data unless given specific authority to read, update, etc. This type of control is generally provided by security access control software.
- **Universal access: read** — Everyone with access to the system can read data with the control applied; however, update authority must be granted to specific individuals, programs, or transactions. This type of control is provided by access control software.
- **Universal access: update** — Anyone with access to the system can update the data, but specific authority must be granted to delete the data. This control is provided by access control software.
- **Universal access: alter** — Anyone with access to the system can view, update, or delete the data. This is virtually no security.
- **Security access control software** — This software allows the administrator to establish security rules as to who has access rights to protected resources. Resources can include data, programs, transactions, individual computer IDs, and terminal IDs. Access control software can be set up to allow access by classes of users to classes of resources, or at any level of granularity required to any particular resource or group of resources.

Software — Minimum Controls

- **Review and approve** — The intent of this control is that any change to the software be reviewed by someone technically knowledgeable to perform this task. The review and approval should be an authorized individual other than the person who developed the change.
- **Review and Approve Test Plan and Results**
  A test plan would be prepared, approved, documented, and followed.
- **Backup and recovery** — Procedures should be developed and periodically tested to ensure backups of the software are performed in such a manner that the most recent production version is recoverable within a reasonable amount of time.
- **Audit/history** — Information documenting the software change such as the work request detailing the work to be performed, test plans, test results, corrective actions, approvals, who performed the work, and other pertinent documentation required by the business.
- **Version and configuration control** — Refers to maintaining control over the versions of software checked out for update, being loaded to staging or production libraries, etc. This would include the monitoring of error reports associated with this activity and taking appropriate corrective action.
- **Periodic testing** — Involves taking a test case and periodically running the system with known data that has predictable results. The intent is to ensure the system still performs as expected, and does not

produce results that are inconsistent with the test case data. These tests could be conducted at random or on a regular schedule.

- **Random checking** — Production checking of defined data and results.
- **Separation of duties** — This procedural control is intended to meet certain regulatory and audit system requirements by helping ensure that one single individual does not have total control over a programming process without appropriate review points or requiring other individuals to perform certain tasks within the process prior to final user acceptance. For example, someone other than the original developer would be responsible for loading the program to the production environment from a staging library.
- **Access control of software** — In some applications, the coding techniques and other information contained within the program are sensitive to disclosure, or unauthorized access could have economic impact. Therefore, the source code must be protected from unauthorized access.
- **Virus checking** — All software destined for a PC platform, regardless of source, should be scanned by an authorized virus-scanning program for computer viruses before it is loaded into production on the PC or placed on a file server for distribution. Some applications would have periodic testing as part of a software quality assurance plan.

Defining Roles and Responsibilities

To have an effective Information Classification program, roles and responsibilities of all participants must be clearly defined. An appropriate training program, developed and implemented, is an essential part of the program. The Study Team identified to conduct the Business Impact Analysis is a good starting point to develop these roles and responsibilities and identify training requirements. However, it should be noted that some members of the original team, such as Legal, Internal Audit, or Business Continuity Planning, most likely will not be interested in this phase. They should be replaced with representatives from the corporate organizational effectiveness group, training, and possibly corporate communications.

Not all of the roles defined in the sections that follow are applicable for all information classification schemes and many of the roles can be performed by the same individual. The key to this exercise is to identify which of the *roles* defined is appropriate for your particular organization, again keeping in mind that an individual may perform more than one of these when the process is fully functional.

- **Information owner** — Business executive or business manager who is responsible for a company business information asset. Responsibilities include, but are not limited to:
  - — Assign initial information classification and periodically review the classification to ensure it still meets the business needs.
  - — Ensure security controls are in place commensurate with the classification.
  - — Review and ensure currency of the access rights associated with information assets they own.
  - — Determine security requirements, access criteria, and backup requirements for the information assets they own.
  - — Perform or delegate, if desired, the following:
    - Approval authority for access requests from other business units or assign a delegate in the same business unit as the executive or manager owner
    - Backup and recovery duties or assign to the custodian
    - Approval of the disclosure of information act on notifications received concerning security violations against their information assets
- **Information custodian** — The information custodian, usually an information systems person, is the delegate of the information owner with primary responsibilities for dealing with backup and recovery of the business information. Responsibilities include the following:
  - — Perform backups according to the backup requirements established by the information owner.
  - — When necessary, restore lost or corrupted information from backup media to return the application to production status.
  - — Perform related tape and DASD management functions as required to ensure availability of the information to the business.
  - — Ensure record retention requirements are met based on the information owner's analysis.

- **Application owner** — Manager of the business unit who is fully accountable for the performance of the business function served by the application. Responsibilities include the following:
  - — Establish user access criteria and availability requirements for their applications.
  - — Ensure the security controls associated with the application are commensurate with support for the highest level of information classification used by the application.
  - — Perform or delegate the following:
    - Day-to-day security administration
    - Approval of exception access requests
    - Appropriate actions on security violations when notified by security administration
    - The review and approval of all changes to the application prior to being placed into the production environment
    - Verification of the currency of user access rights to the application
- **User manager** — The immediate manager or supervisor of an employee. They have ultimate responsibility for all user IDs and information assets owned by company employees. In the case of nonemployee individuals such as contractors, consultants, etc., this manager is responsible for the activity and for the company assets used by these individuals. This is usually the manager responsible for hiring the outside party. Responsibilities include the following:
  - — Inform security administration of the termination of any employee so that the user ID owned by that individual can be revoked, suspended, or made inaccessible in a timely manner.
  - — Inform security administration of the transfer of any employee if the transfer involves the change of access rights or privileges.
  - — Report any security incident or suspected incident to Information Security.
  - — Ensure the currency of user ID information such as the employee identification number and account information of the user ID owner.
  - — Receive and distribute initial passwords for newly created user IDs based on the manager's discretionary approval of the user having the user ID.
  - — Educate employees with regard to security policies, procedures, and standards to which they are accountable.
- **Security administrator** — Any company employee who owns a user ID that has been assigned attributes or privileges associated with access control systems, such as ACF2, Top Secret, or RACF. This user ID allows them to set system-wide security controls or administer user IDs and information resource access rights. These security administrators may report to either a business division or Information Security within Information Systems. Responsibilities include the following:
  - — Understand the different data environments and the impact of granting access to them.
  - — Ensure access requests are consistent with the information directions and security guidelines.
  - — Administer access rights according to criteria established by the Information Owners.
  - — Creat and remove user IDs as directed by the user manager.
  - — Administer the system within the scope of their job description and functional responsibilities.
  - — Distribute and follow up on security violation reports.
  - — Send passwords of newly created user IDs to the manager of the user ID owner only.
- **Security analyst** — Person responsible for determining the data security directions (strategies, procedures, guidelines) to ensure information is controlled and secured based on its value, risk of loss or compromise, and ease of recoverability. Duties include the following:
  - — Provide data security guidelines to the information management process.
  - — Develop basic understanding of the information to ensure proper controls are implemented.
  - — Provide data security design input, consulting and review.
- **Change control analyst** — Person responsible for analyzing requested changes to the IT infrastructure and determining the impact on applications. This function also analyzes the impact to the databases, data-related tools, application code, etc.

- **Data analyst** — This person analyzes the business requirements to design the data structures and recommends data definition standards and physical platforms, and is responsible for applying certain data management standards. Responsibilities include the following:
  - — Design data structures to meet business needs.
  - — Design physical data base structure.
  - — Create and maintain logical data models based on business requirements.
  - — Provide technical assistance to data owner in developing data architectures.
  - — Record metadata in the data library.
  - — Creat, maintain, and use metadata to effectively manage database deployment.
- **Solution provider** — Person who participates in the solution (application) development and delivery processes in deploying business solutions; also referred to as an integrator, application provider/programmer, IT provider. Duties include the following:
  - — Work with the data analyst to ensure the application and data will work together to meet the business requirements.
  - — Give technical requirements to the data analyst to ensure performance and reporting requirements are met.
- **End user** — Any employees, contractors, or vendors of the company who use information systems resources as part of their job. Responsibilities include:
  - — Maintain confidentiality of log-on password(s).
  - — Ensure security of information entrusted to their care.
  - — Use company business assets and information resources for management approved purposes only.
  - — Adhere to all information security policies, procedures, standards, and guidelines.
  - — Promptly report security incidents to management.
- **Process owner** — This person is responsible for the management, implementation, and continuous improvement of a process that has been defined to meet a business need. This person:
  - — Ensures data requirements are defined to support the business process.
  - — Understands how the quality and availability affect the overall effectiveness of the process.
  - — Works with the data owners to define and champion the data quality program for data within the process.
  - — Resolves data-related issues that span applications within the business processes.
- **Product line manager** — Person responsible for understanding business requirements and translating them into product requirements, working with the vendor/user area to ensure the product meets requirements, monitoring new releases, and working with the stakeholders when movement to a new release is required. This person:
  - — Ensures new releases of software are evaluated and upgrades are planned for and properly implemented.
  - — Ensures compliance with software license agreements.
  - — Monitors performance of production against business expectations.
  - — Analyzes product usage, trends, options, competitive sourcing, etc. to identify actions needed to meet project demands of the product.

Identifying Owners

The steps previously defined are required to establish the information classification infrastructure. With the classifications and their definitions defined, and roles and responsibilities of the participants articulated, it is time to execute the plan and begin the process of identifying the information owners. As stated previously, the information owners *must* be from the business units. It is the business unit that will be most greatly affected if the information becomes lost or corrupted; the data exists solely to satisfy a business requirement. The following criteria must be considered when identifying the proper owner for business data:

- Must be from the business; data ownership is *not* an IT responsibility.
- Senior management support is a key success factor.
- Data owners must be given (through policy, perhaps) the necessary authority commensurate with their responsibilities and accountabilities.
- For some business functions, a multi-level approach may be necessary.

A phased approach will most likely meet with less resistance than trying to identify all owners and classify all information at the same time. The Study Team formed to develop the roles and responsibilities should also develop the initial implementation plan. This plan should consider using a phased approach — first identifying from the risk assessment data those applications that are critical or most important by orders of magnitude to the corporation (such as time-critical business functions first, etc.). Owners for these applications are more easily identified and probably are sensitized to the mission criticality of their information. Other owners and information can be identified later by business functions throughout the organization.

A training program must also be developed and be ready to implement as the information owners and their delegates are named. Any tools such as spreadsheets for recording application and information ownership and classification and reporting mechanisms should be developed ahead of time for use by the information owners. Once the owners have been identified, training should commence immediately so that it is delivered at the time it is needed.

Classify Information and Applications

The information owners, after completing their training, should begin collecting the meta data about their business functions and applications. A formal data collection process should be used to ensure a consistency in the methods and types of information gathered. This information should be stored in a central repository for future reference and analysis. Once the information has been collected, the information owners should review the definitions for the information classifications, and classify their data according to that criteria. The owners can use the following information in determining the appropriate controls for the classification:

- Audit information maintained: how much and where it is, and what controls are imposed on the audit data
- Separation of duties required: yes or no; if yes, how is it performed
- Encryption requirements
- Data protection mechanisms; access controls defined based on classification, sensitivity, etc.
- Universal access control assigned
- Backup and recovery processes documented
- Change control and review processes documented
- Confidence level in data accuracy
- Data retention requirements defined
- Location of documentation

The following application controls are required to complement the data controls, but care should be taken to ensure all controls (both data and software) are commensurate with the information classification and value of the information:

- Audit controls in place
- Develop and approve test plans
- Separation of duties practiced
- Change management processes in place
- Code tested, verified for accuracy
- Access control for code in place
- Version controls for code implemented
- Backup and recovery processes in place

Ongoing Monitoring

Once the information processes have been implemented and data classified, the ongoing monitoring processes should be implemented. The internal audit department should lead this effort to ensure compliance with policy and established procedures. Information Security, working with selected information owners, Legal, and other interested parties, should periodically review the information classifications themselves to ensure they still meet business requirements.

The information owners should periodically review the data to ensure that it is still appropriately classified. Also, access rights of individuals should be periodically reviewed to ensure these rights are still appropriate for the job requirements. The controls associated with each classification should also be reviewed to ensure they are still appropriate for the classification they define.

Summary

Information and software classification is necessary to better manage information. If implemented correctly, classification can reduce the cost of protecting information because in today's environment, "one size fits all" will no longer work within the complexity of most corporation's heterogeneous platforms that make up the IT infrastructure. Information classification enhances the probability that controls will be placed on the data where they are needed the most, and not applied where they are not needed.

Classification security schemes enhance the usability of data by ensuring the confidentiality, integrity, and availability of information. By implementing a corporate-wide information classification program, good business practices are enhanced by providing a secure, cost-effective data platform that supports the company's business objectives. The key to the successful implementation of the information classification process is senior management support. The corporate information security policy should lay the groundwork for the classification process, and be the first step in obtaining management support and buy-in.

A Matter of Trust

Ray Kaplan, CISSP, CISA, CISM

There is a continuous stream of security-related bug reports permeating the news these days. With all the noise, it is difficult to spot the core issue, let alone to keep one's eye on it. The simple questions of what one trusts and why one trusts it are often ignored. Moreover, the need to define both inter- and intra-infrastructure trust relationships is often overlooked. The core question of what trust is and its importance is usually forgotten altogether. Security is a matter of trust. This chapter explores the nature of trust and trust relationships, and discusses how one can use trust to build a secure infrastructure.

A Matter of Trust?

Trust is the core issue in security. Unfortunately, simply understanding that is not going to get one very far when one has an infrastructure to secure. The people in an organization, its customers, and their customers are depending on the security of one's infrastructure. Strangely enough (and do not take this personally), they probably should not. The reality is that people make poor decisions about trust all the time, and often engage in relationships based on flawed trust decisions.

Before exploring this further, it is important to understand what trust is and how it is used to build and maintain a trustworthy infrastructure. One can start with the definition of trust — what it is and what it is not. Then this chapter explores how to build and maintain a trustworthy infrastructure.

Trust Defined

The dictionary variously defines trust as a *firm belief or confidence in the honesty, integrity, reliability, justice, etc. of another person or thing*. It goes on to talk about confident expectation, anticipation or hope, imparting responsibility, and engendering confidence. This allows for the development of relationships. Consider committing something or someone to someone else's care, putting someone in charge of something, allowing something to take place without fear, and granting someone credit. All these things are examples of how most people operate — as individuals, as citizens, as organizations, and as a society (locally, nationally, and internationally).

In matters of real-world models of trust for the Internet, law, E-commerce, linguistics, etc., one base definition applies:

> Trust is that which is essential to a communication channel but cannot be transferred from source to destination using that channel.[1]

One can look to information theory as an anchor:

> In Information Theory, information has nothing to do with knowledge or meaning. In the context of Information Theory, information is simply that which is transferred from a source to a destination, using a communication channel.[2]

Think of trust as a value attached to information.

Examples of where people rely on trust in matters of security are everywhere in computing and networking. For example, the scheduler of an operating system trusts the mechanism that is giving it entities to schedule

for execution. A TCP/IP network stack trusts that the source address of a packet can be trusted to be its originator (unless a security mechanism demands proof of the source's identity). Most users trust their browsers and the Web sites they access to automatically "do the right thing" security-wise. In doing so, they trust the operating system schedulers and network stacks on which they rely. The NSA sums it up best when it says that a trusted system or component is one with the power to break one's security policy. However, most organizations do not consider trust in this context.

It is extraordinarily important to understand how this puzzle fits together because everything concerning the security of the distributed systems being developed, deployed, and used depends on it. Consider PKIs and operating systems with distributed trust models such as Windows NT and Windows 2000 as examples.

What Trust Is Not

It is also important to talk about what trust is not. In his works on trust, Dr. E. Gerck explains that trust is not transitive, distributive, associative, or symmetric except in certain instances that are very narrowly defined.[3] Gerck uses simple examples, mathematical proofs, and real-world experience to illustrate trust. Because practical experience in security agrees with him, it is comforting to know that Gerck begins his work with a quote from the Polish mathematician Stanislaw Leshniewski:

> A theory, ultimately, must be judged for its accord with reality.[4]

Because rules regarding trust are regularly ignored, people are going to continue to have heartburn as they deal with trust between UNIX systems, build out Public Key Infrastructures (PKIs) and distributed infrastructures, and deal with the practical aspects of Microsoft Windows 2000's new security model. Note that these are just a few of the problem areas.

Before beginning, a note is in order; this is NOT an exercise in demeaning Windows 2000. However, Windows 2000 provides excellent examples of:

- How trust rules are broken with alacrity
- How detailed things can get when one sets about the task of evaluating a trust model
- The problems presented by trust models that break the rules

Take one of Gerck's assertions at a time, using simple examples based on research, mathematical proofs, and real-world experience — starting with an introduction to the problem with the basic Windows 2000 trust model: transitivity.

Trust Is Not Transitive

If X trusts Y and Y trusts Z, X cannot automatically trust Z. That is, the simple fact that I trust you is not reason for me to trust everyone who you trust. This is a major limiting factor in "web-of-trust" models such as that of PGP. This is quite understandable because PGP was developed as e-mail security software for a close group of friends or associates who would handle trust management issues.[5] Within a "closed group," trust is transitive only to the extent that each group member allows it to be. Outside a "closed group," there is no trust. A problem arises when the group is large and its members do not restrict the trust they place in the credentials presented to them by a "trusted" group member. Consequently, a problem results when systems rely on "relative" references. Windows 2000 is such a system because it has a model based on transitive trust. Simply the way that transitive trust is expected to be used in a Windows 2000 system is problematic, as illustrated by the following descriptions of how it works.

First, excerpts from the Windows NT Server Standards documentation that discuss Primary and Trusted Domains point out the differences between Windows NT 4.0 and Windows 2000:

> ...A trusted domain is one that the local system trusts to authenticate users. In other words, if a user or application is authenticated by a trusted domain, its authentication is accepted by all domains that trust the authenticating domain.

On a Windows NT 4.0 system, trust relationships are one-way and must be created explicitly. Two-way trust is established explicitly by creating two one-way trusts. This type of trust is nontransitive, meaning that if one trusts a domain, one does not automatically trust the domains that domain trusts.

> On a Windows NT 4.0 workstation, a Trusted Domain object is used to identify information for a primary domain rather than for trusted domains...

> ...on a Windows 2000 system, each child domain automatically has a two-way trust relationship with the parent. By default, this trust is transitive, meaning that if you trust a domain, you also trust all domains that domain trusts.[6]

Second, an excerpt from a Microsoft NT Server Standards document:

> Windows 2000 Domains can be linked together into an ADS "tree" with automatic two-way transitive trust relationships. ADS (Active Directory Server) "trees" can also be linked together at their roots into an "enterprise" or "forest," with a common directory schema and global catalog server by setting up static "site link bridges," which are like manual trust relationships.[7]

Finally, an excerpt from the Microsoft 2000 Advanced Server Documentation:

> Because all Windows 2000 domains in a forest are linked by transitive trust, it is not possible to create one-way trusts between Windows 2000 domains in the same forest.
>
> …All domain trusts in a Windows 2000 forest are two-way transitive trusts.[8]

The Microsoft 2000 Advanced Server Documentation explains that all the domains in the forest trust the forest's root domain, and all the interdomain trust paths are transitive by definition. Note that all of this stands in stark contrast to what we know: trust is not transitive except in certain, narrowly defined cases. Suffice it to say, the implications of this dependence on transitive trust and the accompanying default behavior present significant challenges. Consider a classic example: the Human Resources (HR) department's domain. Due to the sensitive nature of HR information, it is not clear that an automatic, blanket, transitive interdomain trust relationship with every other domain in the infrastructure is appropriate. For example, HR may be segregated into its own domain to prevent non-HR network administrators from other domains from accessing its resources and protected objects (such as files.)

Other examples of inappropriate transitive trust abound. Examples of why it is a problem, how it must be handled, and the problems associated with it in the UNIX environment can be found in Marcus Ranum's explanation of transitive trust in the UNIX NFS (Network File System) and rlogin (remote login) facilities.[9]

Trust Is Not Distributive

If W and Y both trust Z, W cannot automatically trust Y and Z as a group.

Suppose your organization and your biggest competitor both get certificates from a Certification Authority (CA). Sometime later, that competitor buys that CA, thereby gaining access rights to all of your information. One cannot automatically trust that your biggest competitor would not revoke your certificate and access all of your information.[10] Practically speaking, such a situation might be met with a lawsuit (if your contract with the CA has been breached, for example). However, this is likely to be difficult because agreements with CAs may not provide for this eventuality.

One could also merely change one's behavior by:

- No longer trusting the offending CA or the credentials that it issued to you
- Ensuring that these, now untrustworthy credentials are revoked
- Getting new credentials from a CA with which one has a viable trust relationship

Trust Is Not Associative

If X trusts the partnership formed with Y and Z for some specific purpose, X cannot automatically trust Y and Z individually.

Just because one trusts a group (that presumably was formed for some specific purpose) does not mean that one can trust each member of that group. Suppose one trusts the partnership formed between two competitors for some specific purpose. That, in and of itself, does not mean that one can trust them individually, even in a matter that has do with the business of the partnership.

Trust Is Not Symmetric

Just because X trusts Y, Y cannot automatically trust X. That is, trust relationships are not automatically bidirectional or two-way. Trust is unidirectional or asymmetric. Just because I trust you, you cannot automatically trust me.

As illustrated several times in the preceding discussion, the trusting party decides the acceptable limits of the trust. The only time trust is transitive, distributive, associative, or symmetric is when some type of "soft

trust" exists — specifically where the trusting party permits it.[11] Practically speaking, many trusting parties do not limit the scope of the trust they place in others. Accordingly, those trust relationships are ill-founded. This is a problem — not a benefit.

Trustworthiness

Whereas trust means placing one's confidence in something, trustworthiness means that one's confidence is well-founded. Trusting something does not make it trustworthy. This is the pay dirt of the trust business.

While many systems and networks can be trusted, few are trustworthy. A simple example will help tease this out. Suppose you live far from your job in a metropolitan area that has little or no mass transit. Chances are that you will commute to work by automobile. You may trust your automobile to get you to and from work just fine without ever experiencing a hitch. However, you may not trust it to get you across Death Valley in the middle of a hot summer day. The reason might be that help is only a cell phone call away in the metropolitan area and you know that a breakdown will not be life-threatening. On the other hand, help might be very difficult to find on the journey across Death Valley, and if you break down, dehydration is a threat. You have decided that your car is trustworthy for commuting to work, whereas it is not trustworthy for long journeys through hostile environments. That is, for the purposes of commuting within your own metropolitan area, you trust your automobile for transportation.

Simply put, trust is situational. That is, one decides to trust something in certain, specific circumstances. Trust is about confidence.

One can consider systems and networks to be trustworthy when they have been shown to perform their jobs correctly in a security sense. That is, one has confidence in them under specific circumstances. Accordingly, this encompasses a wide spectrum of trustworthiness. On one end of this spectrum are the so-called trusted systems that require formal assurance of this assertion based on mathematical proofs. On the other end of this spectrum lie bodies of anecdotal evidence gathered over a long period of time that seems to say "the system is doing its job."

As a practical example of how all this fits together, consider one of Dr. Ed Gerek's notes on the definition of trust, which refers to the American Bar Association's Digital Signature Guidelines:[12]

> Trust is not defined per se, but indirectly, by defining "trustworthy systems" (or, systems that deserve trust) as "Computer hardware, software, and procedures that: (1) are reasonably secure from intrusion and misuse; (2) provide a reasonably reliable level of availability, reliability and correct operation; (3) are reasonably suited to performing their intended functions; and (4) adhere to generally accepted security principles." This definition is unfortunate in that it confuses trust with fault-tolerance, especially so because fault-tolerance is objective and can be quantitatively measured by friends and foes alike — whereas trust is the opposite.[13]

As can be seen, one tries to define trust (trustworthiness) as a measurable quantity in many ways. On the technical side of security, there are several ways to accomplish this, including:

- Formal criteria such as the *Trusted Computer Security Evaluation Criteria* (TCSEC, also known as the *Orange Book*) and its successor the Common Criteria and accompanying formal methods of test
- Less formal testing that is performed by the commercial product testing labs such as those that certify firewalls
- So-called "challenge sites" that seek to prove themselves trustworthy by demonstrating that they can withstand attacks
- Penetration testing that seeks to exhaustively test for all known vulnerabilities
- Assessments that seek to show where vulnerabilities exist past those that can be found using purely technical means
- Alpha, beta, and pre-releases of software and hardware that attempt to identify problems before a final version of a product is shipped

All of these are designed to demonstrate that we can trust systems or networks *under certain circumstances*. The object of all of them is to build trust and confidence and thereby to arrive at a level of trust — circumstances under which the systems or networks are trustworthy. For example, among the many things one finds in the so-called *Rainbow Series* of books that contains the *Orange Book* of the TCSEC are *Guidelines for Writing Trusted Facility Manuals*[14] and *A Guide to Understanding Trusted Facility Management*[15] that discuss how a trusted system must be deployed. Quoting the manual:

Guidelines for Writing Trusted Facility Manuals provides a set of good practices related to the documentation of trusted facility management functions of systems.

"Trusted facility management" is defined as the administrative procedures, roles, functions (e.g., commands, programs, interfaces), privileges, and databases used for secure system configuration, administration, and operation.

Before one can trust a system to be secure, the facility in which the system is deployed must be managed in such a way that it can be trusted. Before giving up on this military-style thinking, consider that commercial systems and network components such as routers must be treated in the same way before one can trust them.

Note that these theories and various testing methods are limited; they do not always work in practice. However, one generally uses adherence to criteria and high scores on tests as measures of trustworthiness.

Another way to look at it is that one mitigates as many risks as one can and accepts the remaining risks as residual risk. Nothing is risk-free, including systems and networks. Hence, our job in security is risk management. Eliminate the risks that one can and accept the rest. The reason for this is that it would be much too expensive to eliminate all risks; even if this were possible, one usually cannot identify absolutely all of them.

Why Is Trust Important?

It is easy to see why trust and trustworthiness are important. Start with a global view. The best articulation of this global view that this author has found is in Francis Fukuyama's *Trust, The Social Virtues & The Creation of Prosperity.* One quote seems to apply to everything we do in life and everything we do in computing and networking, including security:

> A nation's well-being, as well as its ability to compete, is conditioned by a single pervasive cultural characteristic: the level of trust inherent in the society.[16]

Consider that the well-being of our enterprises, including their ability to compete, is conditioned on a single pervasive characteristic of their infrastructures and those on which they depend: the level of inherent trust. Simply put, if one cannot trust one's infrastructure, all bets are off. Consider your own desktop system. How comfortable will you be in using it if you cannot trust it?

As a Ph.D. candidate in 1990, Dr. David Cheriton commented:

> The limit to distributed systems is not performance, it is trust.[17]

Cheriton's statement is especially applicable in an age where everything, including toasters, has computing power and the network accoutrements necessary to connect it to everything else in our lives. The interconnectivity aspect of this developing complexity is best illustrated by the following quote from Robert Morris, Sr.:

> To a first approximation, everything is connected to everything else.[18]

This can be a very scary thought. Increasingly, people are trusting more and more of what they are, have, and know, to parties they may not even know, much less have a basis upon which to establish trust. Trust is becoming increasingly important, but most individuals and organizations do not realize or appreciate this until assets are lost or compromised.

Why Do People Trust?

As previously discussed, there are many reasons why people trust. It is important to note that most people never get to the point where they consider any of the reasons in the trustworthiness spectrum. There is only one reason that most of us trust: blind faith. The reasons seem to include:

- Evidence that "things seem to be doing their jobs"
- Lack of evidence to the contrary
- Anecdotal evidence from others in the community

Moreover, the nature of people in many cultures of the world is to trust first and ask questions later — if ever. This is a little confusing because there is often much evidence to the contrary. Nevertheless, it seems to remain a key part of many cultures.

Why Should People Not Trust?

Perhaps the best way to show the importance of trust is to talk about distrust: the lack of trust, faith, or confidence, doubt or suspicion.

The scary part is that most of what people trust is beyond their control. By way of illustration, consider only one dimension of the problem: complexity. In his musings about complexity, Marcus Ranum observes that Web browsers themselves have become tools for managing complexity. Consider that most every browser is in the business of hiding the complexity of having to deal with the myriad of protocols that most of them support (such as HTTP, FTP, Telnet, etc.). Ranam asks how many of us know all of the features and hooks of the cool, new Web apps that continue to pop up. He posits that probably the only people who know are the ones who coded them. Moreover, the details of the security of such protocols are not published and change from version to version.[19]

As an example that gives life to this, consider this discussion of the "Smart Browsing" feature that showed up in version 4.06 of the Netscape browser:[20]

> Netscape Communications Corporation's release of Communicator 4.06 contains a new feature, 'Smart Browsing,' controlled by a new icon labeled What's Related, a front end to a service that will recommend sites that are related to the document the user is currently viewing. The implementation of this feature raises a number of potentially serious privacy concerns, which we have examined here.
>
> Specifically, URLs that are visited while a user browses the Web are reported back to a server at Netscape. The logs of this data, when used in conjunction with cookies, could be used to build extensive dossiers of individual Web users, even including their names, addresses, and telephone numbers in some cases.

If one is having trouble with this, one can easily make a headache worse by trying to get one's arms around all of the trust questions that surround PKIs and Windows 2000 if not already doing so. Consider that the problem of figuring out how to build and maintain a long-lived trust model with Windows 2000 pales when compared to the problem of figuring out how to trust Windows 2000 itself. This, since it reportedly has 27 to 40 million lines of code,[21] some half or more of which are reportedly new to the initial release. The number of security-related bug fixes is likely to be just as astounding.

Complexity and protocol issues notwithstanding, there is no reason for most people and organizations to trust their infrastructures. The reasons to distrust an infrastructure are legion. Very few infrastructures are trustworthy. Given Marcus Ranum's observation about complexity and what the author of this chapter knows about how things work (or do not work), this author has trouble trusting his own infrastructures much of the time.

Finally, there are the continual reminders of purposeful deceit that confront us every day. These begin with virus, worm, and Trojan horse writers foisting their wares on us, continue through the daily litany of security problems that flood past us on lists such as Bugtraq,[22] and end with the malice of forethought of attackers. Clever competitors, in either business or war, will deceive people at every available opportunity. For an instruction manual, I recommend Sun-Tzu's *On the Art of War* for your study.[23] Your adversaries, be they your competitors in business or those who would attack your infrastructure, are likely out to deceive you at every opportunity.

What justifies the trust placed in an infrastructure? Most of the time, there is only one answer: We have never considered that question. However, the absence of justification for trusting infrastructure does not stop there. Some people — and entire organizations — deceive themselves. *The Skeptic's Dictionary*[24] aptly describes this situation: "The only thing infinite is our capacity for self-deception." Better yet: "There is no accounting for self-delusion."[25]

Securing One's Infrastructure

Now one is down to the nub of the matter. There is only one question left to ask: "Where to from here?" Thankfully, the answer is relatively straightforward. Not to say that it will not take some work. However, it is easy and intuitive to see how to attain trust in one's infrastructure:

1. Decide to approach the problem of gaining trust as an exercise in risk management.
2. Develop a plan.
3. Implement the plan.

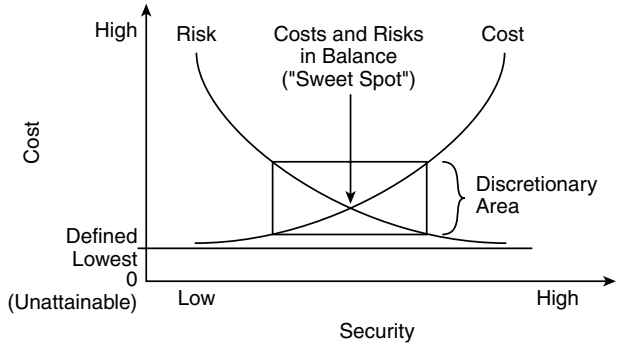

EXHIBIT 61.1 Balancing cost and security.

4. Assess the plan's effectiveness.
5. Modify the plan if necessary.
6. Go to step 1.

This is a sure-fire recipe for success — guaranteed. Barring total disaster outside the control of whomever is following the instructions (e.g., the company going out of business), it has never failed in this author's experience. That is because it is simply a basic problem-solving model. One can fill in the details, starting with risk management.

Risk Management 101

Risk management is an exercise in which one balances a simple equation. Exhibit 61-1 presents a simple picture of how the process of risk management works. A few definitions will help make it readable, starting with security. The *American Heritage Dictionary* offers several definitions, including:

> Freedom from risk or danger; safety.

Accepting this as a starting point presents the first challenge. How does one define risk, danger, and safety for a computing infrastructure? Start with some terminology.

Vulnerabilities, Threats, Risks, and Countermeasures

Sticking with commonly accepted security terminology, one can build a list that is oddly self-referential:

- *Vulnerability*: a weakness that can be exploited. Alternatively, a weakness in system security procedures, design, implementation, internal controls, etc. that could be exploited to violate a security policy.
- *Threat*: anything or anyone that can exploit a vulnerability. Alternatively, any circumstance or event with the potential to cause harm to a system in the form of destruction, disclosure, modification of data, or denial-of-service.
- *Risk*: the likelihood and cost of a particular event occurring. Alternatively, the probability that a particular threat will exploit a particular vulnerability of a system.
- *Countermeasure*: a procedure or mechanism that reduces the probability that a specific vulnerability will be exploited or reduces the damage that can result from a specific vulnerability's exploit. Alternatively, a technique, an action, device, or other measure that reduces an infrastructure's vulnerability. (All of these are risks.)

The game is to balance the expense of incurring risk with the expense of mitigating (not merely mediating) risk by applying just the right amount of countermeasures to offset the vulnerabilities that exist.

Another way to look at this is from the point of view of cost. Exhibit 61.1 illustrates how costs and risk relate to each other. In addition, it shows how one can determine the optimum amount to spend on security. It plots the cost of security against the amount of security one is able to attain for that expenditure.

Perhaps one can now begin to see some of the challenges ahead. All by itself, building a common vocabulary is problematic. One can tackle each of these terms to see how to mold infrastructure security out of them.

These three concepts are logically related and can be grouped together for the sake of discussion. Using them, securing an infrastructure can be as simple as following three simple steps:

1. Identify a vulnerability
2. Identify the threats that can exploit it
3. Design and implement a countermeasure that will reduce the likelihood (risk) that a specific threat can exploit this vulnerability.

Seems simple enough. However, most infrastructures have enough different components in them to make this approach a truly daunting task. Nevertheless, it is an iterative process that uses these steps over and over again. In an ideal situation, every threat, vulnerability, and countermeasure is considered for every infrastructure component in an iterative process. Experience shows that unless one examines every component of an infrastructure in this manner, one simply cannot secure the infrastructure at large.

Practically speaking, however, this is impossible for all but the smallest organizations. Imagine stopping the business of an organization while one goes through this process. After all, the infrastructure is probably in place to support an organization's business needs — not the other way around.

The only exceptions to this rule are where good security is a design goal and there is a resource commitment to go with it. For example, an opportunity certainly exists when brand-new components or entirely new infrastructurea are being installed.

Most people seem to believe that this thinking is restricted to so-called military-grade security. However, most segments of the economy are concerned enough about protecting their information assets to get serious about security. This includes most commercial, industrial, and educational organizations.

One problem is outdated thinking about threats and vulnerabilities. This is being overcome by new thinking that takes a fresh look at them, such as Donn Parker's new framework. It lists several dimensions of threats and vulnerabilities alongside asset categories.[26]

Take a look at how to solve the practical problem of how to complete this risk management exercise without stopping the business of the organization.

Analysis and Quantification

It seems almost obvious to say that the keys to finding and fixing vulnerabilities are analysis and quantification. Only almost, because most organizations do not approach security from a business or technical engineering perspective. Moreover, many organizations run off and buy security technology before they have even identified the problem. Suffice it to say, this sort of thinking is a trap.

To the experienced business or technical problem-solver, there is no other way to proceed. Given a well-stated problem, one simply has to analyze it and quantify the results as the first step.

So, how does one analyze and quantify vulnerabilities, threats, and countermeasures? Were it not for the maturity of the discipline of securing information systems, one would have an impossible task. As it is, this problem is well understood, and there are tools and techniques available. However, it is important to note that no tool is complete. In any case, most successful approaches use another one of the concepts in our basic vocabulary: risk.

Before taking even one step forward from here, a word of caution is in order:

> Quantification of risk is a hard problem.[27] In fact, all attempts to develop reasonable methods in this area have utterly failed over the last several decades. Donn Parker explains exactly how this happened in the 1998 edition of his book *Fighting Computer Crime*.[28] One might succeed in quantifying specific ratings in a narrowly defined area using an arbitrary ranking scale. However, experience shows that reconciling these ratings with others that use equally arbitrary ranking is impossible, especially on the scale of a contemporary, large, highly distributed organization.

One can use quantitative risk assessment methods. However, experience shows that one will end up using some form of qualitative measure in many areas. Consider the evaluation of a security program at large. One will likely want to score it based on an opinion of how well it is able to do its job for its own organization. Clearly, this requires a qualitative rating scale such as one that ranges from "poorly" to "superbly."

Dealing with Risks

Anytime probability or likelihood is mentioned, most people get nervous. After all, there are systems and networks to secure. One does not need to get lost in "the possibilities." However, there is an intuitive appeal to quantifying things — especially when one has to ask for a budget to support one's security-related efforts.

Management and bean counters have little tolerance for pure speculation, and techies and engineers want details. Everyone wants something concrete to work with. Therein lies the rub.

Given ample time and resources, all system and network managers worth their salt can identify security problems. The missing piece is the ability to quantify the effect of identified security problems in terms of their likelihood. This problem is discussed shortly. In the meantime, take a brief look at how risks are analyzed and quantified.

First, one must seek precise problem definition, analysis, and quantification. In addition, experienced problem-solvers will always ask about their goals. A good way to characterize problem solution goals is to rank them according to completeness:

- *Necessary*. These are the essential elements required to solve a problem. Necessary elements can be viewed as fundamental, cardinal, mandatory, or prerequisite.
- *Sufficient*. These are the additional elements that move a problem solution to completeness by making it adequate, ample, satisfactory, and complete.

Experience with security in commercial, industrial, and educational organizations shows that the essence of picking a reasonable security solution is found in the business and technical *artistry* of combining necessity and sufficiency. In this arena, it is not a science. However, high levels of security are only achieved through the rigor of mathematical proof and the application of rigid rules that strictly control their variables. Here, necessity is assumed and sufficiency is a baseline requirement.

The idea of introducing these concepts at this point is to focus on the cost of security. Properly chosen countermeasures mediate risks. However, in the same way that it takes money to make money, it takes money to provide security. Identifying needed countermeasures does no good if those countermeasures cannot be implemented and maintained because they are dismissed as too expensive.

Where the Rubber Meets the Road

There are few — if any — hard numbers surrounding security. This is especially bothersome when a system or network manager tries to explain to management exactly why those extra person-weeks are needed to properly configure or test the security-related aspects of infrastructure components. While a management team can usually quantify what a given information resource is worth to the business, it is nearly impossible for a system or network manager to translate this valuation directly into hard numbers for a security budget. Some relief is found in longtime security pundit Bob Courtney's summary:

You never spend more than something is worth to protect it.

The problem is determining how much something is worth. The answer is achieving an appropriate balance between cost and risk. Exhibit 61.1 presents a time-honored graphic view of how this works in practice.

As one can see, the balance point between the amount of security one has and its cost (the risks or lack of security) is identified as the *Sweet Spot*. Also note that there is a box labeled *Discretionary Area* that includes an area around the *Sweet Spot*. This is the area in which the amount of security and its cost can be in balance. This is based on the fact that perfectly balancing the risk that one incurs with what it costs to maintain that level of security is very difficult, if not impossible. In other words, there is some discretion in the amount of risk one incurs before either the risks or the high costs being incurred would be considered out of hand by some commonly accepted standard.

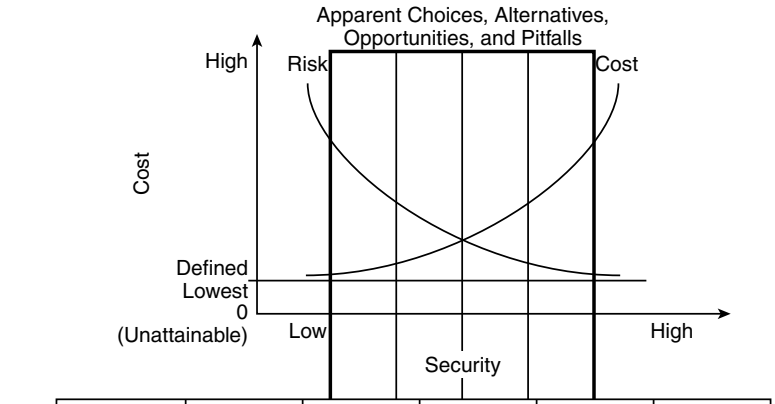
For example, one will never be able to buy a virus scanner that protects against all viruses. Thus, one incurs more risk. On the other hand, one might operate under a conservative policy that severely restricts what can be executed. Thus, one incurs less risk because there are presumably fewer ways for a virus to propagate in one's environment.

Another way to think about this is that the *Discretionary Area* is an area in which both risks and expenditures are "reasonable." Generally speaking, points on the risk curve to the right of the *Sweet Spot* represent overspending (more security than is needed). Points of the risk curve to the left of the *Sweet Spot* represent underspending (less security than is needed).

Limits

A careful inspection of Exhibit 61.1 reveals that neither of the curves ever reach zero and that there are two zeros identified. Two important points about limits explain this:

1. One must define zero points. Infrastructures with absolute zero risk and security with absolute zero cost do not exist and cannot be created.



Sample Risk Evaluation Criteria Categories						
	Expenditure-Based	No Spending	Minimize Costs	Balance Costs and Risks	Invest in the Future	Waste Resources
	Degree of Risk-Based	Maximum Risk	Intolerable Risk	Defined Highest Acceptable Risk	Defined Lowest Acceptable Risk	Zero Risk (Not Attainable)
	Complete-ness-Based	Not Adequate	Not Complete	Necessary	Sufficient	Overkill
	Implementa-tion Style-Based	Haphazard	Expedient	Due Care	Painstaking	Paralized

EXHIBIT 61.2 Risk evaluation criteria.

2. One must define maximums. One can spend as much as one has and still end up with an insecure infrastructure.

Keep it simple. In general, the less one spends, the more risk one incurs. The trick is to identify the level of risk that is acceptable. Again, this is the area Exhibit 61.1 identifies as *Discretionary.*

All of this begs the questions: how does one know what is reasonable?, and how does one determine the risks that exist? Take a look at one time-honored approach.

A Do-It-Yourself Kit

Exhibit 61.2 adds several ways to evaluate risk to the x-axis (security level) of Exhibit 61.1. These risk evaluation criteria are alternative scales on which to measure risk. Each scale includes labels that suggest how the cost of mitigating risk at this level is thought of by commonly accepted standards of due care.

Note that the additional information under the x-axis (security level) is in a box labeled *Apparent Choices, Alternatives, Opportunities, and Pitfalls*. This box encloses the acceptable ranges of risk (listed horizontally on the bottom of the diagram), just as the box labeled *Discretionary Area* did in Exhibit 61.1. These ranges are determined by various risk evaluation criteria (listed next to the right of their respective risk ranges on the bottom of the diagram).

For example, look at *Expenditure-Based* risk evaluation criteria. To judge how much risk is acceptable, one can see that *No Spending* and *Waste Resources* are both outside of the box. N*o Spending* is underkill, and *Waste Resources* is considered overkill — just as one would expect them to be. Using *Implementation Style Based* risk evaluation criteria, one can see that the *Apparent Choices, Alternatives, Opportunities, and Pitfalls* box encloses the range from *Expedient* to *Due Care* to *Painstaking*. Again, this is just as one would expect it to be.

One can add most any criteria one chooses. These are only examples to get started.

A note of caution is in order:

> Attempts to come up with a method to quantify risks have been largely unsuccessful and those that exist are problematic to use, at best. This is not an attempt to provide a quantitative approach to risk analysis past what is necessary for you to see how all of the factors affecting risk interact. In fact, one

can see that the risk evaluation criteria that are listed below the x-axis (level of security) are actually a mix of quantitative and qualitative measures.

Asking what is important and how it will be measured is the best place to start. Once that is done, one can consider the various risk evaluation criteria that are available. While there are many considerations to choose from, those that matter to a particular organization are the most important.

Surrounding an organization's unique concerns, there are standards of due care, common practice, and compliance that can be used as risk evaluation criteria — both from the point of view of industry-specific measures and measures that are common to all organizations. Auditors and other security professionals practiced in doing audits and assessments for a particular industry can provide the industry-specific standards that are important to an organization, as well as what is considered to be due care and common practice in general. For example, some industries such as defense contracting are required to do certain things and there is wide agreement in the security industry about what it takes to protect specific systems such as NT, UNIX, routers, etc. in general.

One will also have to find risk evaluation criteria that match the management style and culture of one's organization. Certainly, one would like to have risk evaluation formulae, models that implement them, and tools that automatically do all this according to Exhibit 61.2 suggestions. However, the state-of-the-art for analysis and quantification in security is quite far from point-and-click tools that do everything. No point-and-click tools do it all. Most of the tools that exist are basically spreadsheets that are elaborately scripted. Unfortunately, these tools help maintain a facade of value for quantitative risk assessment methods.

For now, risk assessment is still very much a job that falls to creative and experienced security professionals to sort out — one little, ugly detail at a time.

The Bottom Lines

Despite the apparent complexity, the process of securing one's infrastructure is quite well-understood and widely practiced. There is hope. The trick is to look at the information system and network infrastructures from a business point of view with a plan. Here are the steps to take and a framework in which one can operate — a time-tested way to approach the problem:

1. Identify the vulnerabilities and threats that the infrastructure faces.
2. Translate these vulnerabilities and threats into statements about the risks that they represent.
3. Organize the risks in a hierarchy that reflects the business needs of the organization.
4. Identify the countermeasures that are required to balance them.
5. Start working on a plan of attack for this list of risks.
6. Start working on reducing the biggest risks — today.

Now that one has a handle on risk, one can proceed to discuss how to gain trust in an infrastructure.

Gaining Trust

The reader will be happy to know that gaining trust in an infrastructure is a well-understood process. It is well-documented and widely practiced. In fact, the literature is ripe with examples. A good reference to the process is found in *Learning from Leading Organizations*.[29] Do not let the fact that it is a government document turn you away. It is an excellent reference, based on processes successfully applied by leading private-sector and government organizations. This author has used a modified version of this model to do security assessments (that is how I know it works so well). This GAO model has been extended to include some of the steps that precede one of the steps in the process. This is represented in Exhibit 61.3 as part of a methodology that works in practice.

In examining Exhibit 61.3, one sees that it includes an iterative loop. The assessment phase of the model has been expanded into a risk assessment and the parts that feed it:

- *Legal, Regulatory, and Business Requirements:* the process of sorting through an organization to identify its constraints (e.g., laws and oversight that determine how it must behave)
- *Identify Assets and Threats:* the process of sorting through an organization's priorities to find what is important and then isolating the threats to those assets
- *Security Advisories and Results of Audits and Monitoring:* the process of identifying the infrastructure's vulnerabilities

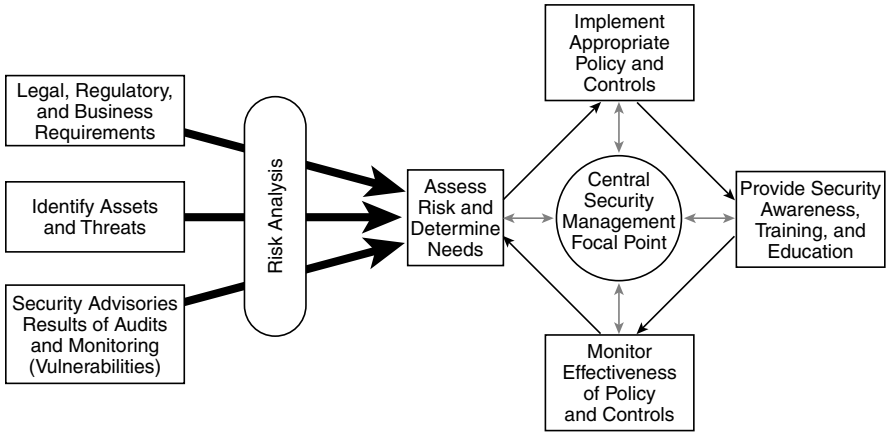


EXHIBIT 61.3 A plan for gaining trust.

The gory details of gaining trust in specific components of the infrastructure are a story for another dissertation. Suffice it to say, following a model such as that presented in the GAO report (as presented in Exhibit 61.3) to identify and mediate risks is a tried and true way to gain trust in one's infrastructure.

Acknowledgments

This chapter was originally an Invited Paper for the *Spring 2000 Internet Security Conference,* http://tisc.core-com.com/. Charlie Payne, Tom Haigh, Steve Kohler, Tom Markham, Rick Smith, Dan Thompson, and George Jelatis of Secure Computing; Randy Keader, Lori Blair, Bryan Koch, and Andrea Nelson of Guardent, Inc.; and Dave Piscitello of Core Competence, Inc., contributed to this paper.

Trust Governance in a Web Services World

Daniel D. Houser, CISSP, MBA, e-Biz+

The problem space of trust governance is discussed, and five business drivers for trust governance are detailed, including the rise of Web Services, SAML, and Cross-Company Authentication. Xota[SM], a protocol for providing lightweight standards-based trust assertions, is introduced, as well as a framework for utilizing trusted third parties for generating trust assertions. With these in place, enterprise and division security postures can be dynamically evaluated for trustworthiness at the time each transaction or connection is made.

Introduction

Web Services are rapidly changing the face of E-business, while the trust models we use for conducting commerce remain largely unchanged. Cross-company authentication and portals are also increasing interdependence on business partner trustworthiness, while many trust models are built on houses of cards. Many organizations have little means of determining and evaluating the trustworthiness of business partners and their divisions aside from error-prone, expensive, and time-consuming processes. This chapter further outlines the business drivers in this space, and includes analysis of how hacker insurance and changing security attack patterns will likely lead to a regulated industry. With business drivers firmly in place and the problem space defined, a new open protocol for establishing trustworthiness at the transaction and message level is provided (Xota), which permits a dynamic assessment of a business partner's trust status at business application execution time, instead of months earlier. To deliver this protocol, a framework for utilizing trusted third-party assertions is also detailed, along with likely implementation plans for dynamic trust analysis in the B2B and B2C environment.

Prologue: A Story of E-Business and Trust Governance

The thought came to me one day as I reflected on meetings I had attended that morning. In two consecutive meetings, I was asked to provide a time estimate for my team's involvement to secure a data feed to a business partner. This straightforward, everyday IT project meeting had two very different outcomes because of a simple but significant difference. In the first meeting, I asked the business partner what kind of cryptography he provided to protect the data stream. His clear-cut answer described secure, well-proven means for protecting data. We heard names we trusted: PGP, SSL, RSA, VeriSign. I asked a few more questions and determined the protocols and modes he supported, and got solid answers. Finally, he was forthcoming with a vulnerability assessment from a reputable information security consulting firm, which included an assessment of the application. In five questions, I had determined enough to permit a comfortable level of trust in the strength of his data protection, because trusted third parties had done most of the work for us.

In the next meeting, it was "déjà vu all over again," to quote Yogi Bera. We had a similar discussion about a virtually identical product and process, and I asked the same questions but received starkly different answers. The second business partner had developed proprietary cryptography using its own homegrown algorithms.

It had also spurned using a cryptographic toolkit for development, and used native C++ code, with its own random number generator. From a security perspective, this was a disaster! Proprietary cryptography is usually a very poor substitute for the real thing, and often easy to break. The costs to hire a cryptographer, plus our team's involvement of 180 to 250 hours to certify the proprietary cryptography, would cost more than the expected profits. We could not trust this cryptography.

As I reflected back on these events at the end of the day, the stark contrast between the two meetings struck me. The first partner had enabled me to determine the risk of the transaction with just a few questions. By using protocols, toolkits, and a certificate authority that met our standards, and then wrapping it in a completed assessment delivered by a reliable third party, we had enough information to make a decision about the trustworthiness of their application. Then it hit me — what if trust assertions, during E-business transactions, could be driven down to this level of simplicity? How might that change the process for determining vendor trustworthiness?

Business Driver 1: Acceleration of E-Business through Web Services

In case you have been asleep for the past ten years, business acceleration through technology is moving at an incredible rate. Where formerly a typesetter could produce a book in three to six months, the same book can now be printed on-demand and bound in five minutes. Business formerly done through a handshake over dinner at the club is now brokered autonomously through EDI. Massive diversification, outsourcing, insourcing, and merger and acquisition fragmentation constantly shift the way industries and partners connect their networks together. In this arena, the latest force that promises to revolutionize the speed and ease of doing business is Web Services.

Consider the business and trust decisions that are made through conducting E-business in a Web Services transaction. Web Services offerings provide a near "instant-on" delivery of services and information through interoperable lightweight protocols: largely HTML, XML, and SOAP. Web Services transactions are ideally conducted through flexible interfaces that permit corporations to provide adaptable and extensible access portals for their legacy business logic and processes. Read the previous sentence again. It is not rhetoric; it is sincere. Consider the power of being able to broker a Web Service to a partner by providing an interface to the same object model that rests at the core of your business application. When you roll out new business functions for your business application, providing that same interface through your Web Service portal is a relatively simple operation. Imagine how quickly your business could pivot and respond to market changes if you remove the need to create and update yet another presentation and application layer each time you make a change. At long last, object technology is making a difference on the bottom line as competitive advantage is achieved by slashing time-to-market. This is a powerful force that is driving business to the speed of thought.

However, it is not just B2B (business-to-business) reaping the benefits of Web Services. Since mobile computing is driving the computing power of the individual to this ubiquitous edge, Web Services promise to deliver instant menus on-demand to handhelds when standing down the street, or perhaps instant call-ahead reservations for your table two minutes from now. These, however, are low-trust transactions, as there is little harm in a menu item being left off, or a reservation for four being dropped to two. In contrast, consider the trust necessary to conduct stock trades through the same device. This type of transaction requires a starkly different trust model for conducting instant business, particularly in B2C (business-to-commerce).

The need to provide stated trust levels for instant services executed on behalf of others is one of the driving forces behind the Security Assertions Markup Language (SAML), although it may not be immediately apparent. Most consumers do not have digital certificates, so consumers cannot easily assert their identity through a third party. Consumers' authentication is necessarily going to be brokered for B2B2C transactions for the foreseeable future. If you need that translated, brokered authentication equates to cross-realm authentication, or cross-company authentication. This is also referred to in some industry groups as "federated identity." With apologies to entities and organizations that do not call themselves a "company" (e.g., the FBI, the Republican Party, and UCLA), I will refer to this authentication as cross-company authentication, or CCA. Although CCA can carry substantial risks, because you are permitting another organization to manage the authentication credentials to your site, CCA is one of the drivers promising single sign-on between business partners and portals. There are already a substantial number of CCA projects that have been implemented in finance, government, and other industries, largely through proprietary (expensive) protocols. As an example, when consumers connect to Travelocity to book airfare on America West Airlines, they do not have to log in to Sabre

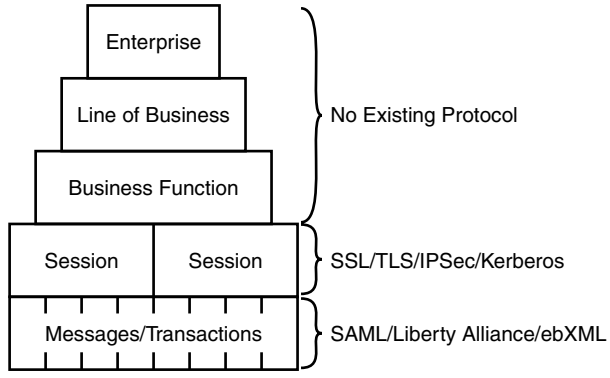

EXHIBIT 62.1 Protocols providing trust.

or America West. Rather, Travelocity provides that authentication for them, as a brokered authentication session for that transaction conducted on their behalf. Through proprietary protocols, Travelocity asserts the identity of the consumer to Sabre, and Sabre asserts the identity of Travelocity to America West. This is a familiar model, but expensive to replicate, due to the proprietary protocols. Resolving this expensive implementation is the promise of SAML, as it provides the ability to ensure that the trust inherent in transactions is asserted through an interoperable authentication assertion protocol. Because it is interoperable, it is repeatable.

Web Services and cross-company authentication drive business to the cusp of instantaneous trust decisions because E-business and E-commerce trust decisions must be delivered within a very short click-stream. Remember: your customers may only tolerate ten seconds of Internet lag before they jump to a competitor's site, and connecting with the Web Service interface has already spent 15 percent of that time, so your model must be able to make a trust decision in two seconds or less.

Before you make that trust decision, there are some things to consider, not least of which is determining what you are trusting. Smart and well-meaning IT and business professionals are often far too loose with how they use the term "trust." If you listen to the Root Certificate Authorities discuss trust, many of them call their certificates "trust," which is over-simplified. Trust, at its core, is derived from "trustworthiness." The trust extended by a digital certificate through SSL is merely trust in the identification of the party on the other end of the SSL tunnel, which is *session trust.*

There are multiple levels of trust that must be embraced to conduct E-business, and digital certificates cannot provide trust in individual transactions/messages, business functions, or corporations (see Exhibit 62.1). Unfortunately, there are many companies that have trustworthy digital certificates about untrustworthy transactions or their untrustworthy corporations. I am sure that WorldCom stockholders can help sharply differentiate the "trust" embodied in the SSL session that the lock icon in their browser assured them of as they connected to AOL and the trust they had in WorldCom after news of their financial scandal was made public.

It is this core differentiation, between the trustworthiness of a session and the trustworthiness of an organization, that is so problematic in the paradigm of Web Services, where instant trust decisions are necessary for trusted transactions. If this trust decision is further permitting outsourced authentication through CCA, the criticality of this trust is even more acute. How is it that you can determine, instantly, at the moment a Web Service transaction is occurring, if you can trust the security and privacy posture of a business partner or vendor?

If you do not think this is a problem, there are even stronger business drivers for trust governance.

Business Driver 2: Death by 1000 Cuts

When establishing new business relationships, companies must determine a number of things about their new partner, including their security posture, financial strength, and a number of other factors that help measure the trustworthiness of the organization. Because of the need to attest to the security of a partner organization, most organizations have reverted to making determinations of security posture through large proprietary checklists of questions that are exchanged and completed. Typically, after asking hundreds (or thousands) of probing questions, security and privacy analysts review the answers, score the organization's security posture,

and make some report of findings. Based on the report, management is able to make some basic decision regarding the trustworthiness of the organization. As organizations become more interconnected with business partners and vendors, these stacks of checklists arrive more frequently. Many organizations have had to hire multiple employees to do nothing more than manage incoming and outbound ad-hoc security assessments. Furthermore, the margin of error after completing hundreds of manual and subjective assessments makes it likely that a few untrustworthy organizations were given a clean bill of health. However, that is only a small part of the problem. If the security policy of your company changes, many of your assessments are no longer valid. If your policy is strengthened, all the assessments you performed were measured against an old standard that was weaker, so your trust models are no longer valid. Your business practices at that point could be construed as no longer providing due diligence in protecting your information assets, because your effective security policy is less than your stated policy. If you have instead relaxed your security policy, all the assessments you provided to other organizations have been invalidated, which could represent liability.

Business Driver 3: Trust Erosion

Imagine that you moved to a new city six months ago, and your car's air conditioning goes out. How do you find a mechanic you can trust? Of course, you ask your neighbor, a friend at work, or a buddy at the gym where you can find a trustworthy mechanic. Five years later, their recommendation is now stale. If you did not return to the garage for five years, how would you know that that garage could still be trusted? This is one of the problems of trust, which degrades over time.

Security assessments, like any audit function, are out-of-date the minute they are performed. Simply put, an assessment from yesterday or last year cannot provide any trustworthiness in a vendor's current or future security posture. Assessments are also largely undertaken during the intense scrutiny brought about through purchasing, merger and acquisition, and contract negotiation activities, and may never be conducted again at that level of diligence. Very few organizations will undertake the expense of performing monthly, quarterly, or even annual audits of all business partners and vendors, so their partners' security postures are unknown at any given point. You certainly have a contract with various vendors who manage some of your customer, employee, or financial data. If one of those vendors eliminates employee bonding and drug testing, removes most firewalls, moves its hosting servers from a data center to a warehouse, and converts long-term debt into junk bonds, would your organization ever know?

At this point, lawyers will interject that contracts should protect the organization, if they have required that the business partner provide a stated level of security. This is true, but contracts can rarely provide adequate compensation for reputation and consequential damages from a serious security breach. There is no monetary salve that can erase your company's name from bad press.

Business Driver 4: Lack of Common Standards

Corporations today are inundated with a variety of organizations asking them to attest to their level of security in dozens of unique and proprietary ways, and there is no single security standard used in all organizations to provide a measurement of trust. Although many fine standards exist, such as ISO 17799, COBIT, GASSP, and the Common Criteria, they are so massive and stringent that few organizations can be 100-percent compliant with any one of them, and could never hope to achieve compliance with more than one. Some of these standards, such as the Common Criteria, make generalities about a corporation's recommended security stance, regardless of industry, which is patently false. To expect that all industries could (or should) have similar security standards and policies is ludicrous. While most U.S. financial organizations conduct drug tests and background checks when hiring, most higher education institutions would likely consider such measures heavy-handed, and might instead focus on evaluating employee curriculum vitae and transcripts. At the other end of the spectrum, the CIA, NSA, and defense contractors commonly use lifestyle polygraph tests on employees holding sensitive positions, security measures that would certainly not be viable for most organizations.

By contrast, other standards, such as GASSP, are such a generalized framework that compliance with GASSP is largely subjective. An assessment that asserted compliance with GASSP would not be useful to another entity because the underlying principles of best practice necessary to ensure compliance with GASSP are largely open to interpretation.

Clearly, a common standard or framework is needed so that assessments, conducted by one company's auditors, can be easily evaluated by partner companies to save expense and provide a better determination of trust.

Business Driver 5: Security Standard Regulation

At the RSA 2002 Conference, Bruce Schneier proposed a vision of the future that I found startling. It took several months for me to realize his vision was sound, although I disagreed with his forecasted end-result. Schneier related the following timeline, which I present with my revisions:

- The "hacker insurance" market will continue to grow as CEOs look for ways to transfer risk.
- Small security events, such as the SQL Slammer attack of February 2003, will dramatically increase interest in acquiring hacker insurance.
- Many insurers will aggressively enter the hacker insurance market, seeking lucrative policies.
- Massive security events like Melissa and Code Red are evolving to resemble worldwide weather patterns and acts of God, rather than focused or targeted attacks. Just like weather-induced floods and earthquakes, these massive security events will attack quickly, universally, and cause widespread damage.
- A massive security event of Code Red proportion will overwhelm networks worldwide, and cause widespread, actual damage to corporate information through a destructive payload. Billions in damages will be registered, and several insurance companies will face crippling losses or go out of business.
- Just as insurers formed Underwriters Laboratories (UL) in the 1890s because they were tired of paying for electrical fires, insurers will again turn to UL and ask them to establish security standards that will be required for hacker insurance coverage.
- UL standards for security best practice will be published, and will start to appear in contracts as a base requirement to protect participants, just as ISO 9000 showed substantial growth through pressure by Fortune 500 companies on their supply chains.
- Eventually, UL standards will become codified by various government bodies and gain the rule of law, similar to the adoption of UL wiring and fire suppression standards that have been codified through municipal building codes.

Although some industries might welcome this regulation of security standards, many others would rather develop and police their own standards to ensure they were meeting their particular needs, rather than the needs of the insurers. We must either develop our own standards (soon!) and police ourselves, or the choices on how we secure our company data may be forced upon us, just as privacy law has done.

The Trust Governance Answer: Certified Trust Assertions

We return now to the original story, about the two business partners with starkly different cryptography solutions, and the idea it sparked in my brain.

I realized that if industries developed a simplified set of standards, perhaps they could simply state, with 100 to 300 statements, enough indicators about their security posture to enable others in the same industry to determine their trust status. They might be able to say six things about how they secure firewalls, five things about their host server hardening, five statements about their CIRT, three statements about hiring practices, etc. Once you have these answers, you can readily determine the high-level trustworthiness of a partner in the same industry. Perhaps 50 common questions could be established across all industries, and several more questions would provide the industry-specific standards.

This industry-specific security standard solves the problem of a common standard that can be evaluated, but does not address the timeliness of trust decisions. However, that model is even easier to provide. The same consortium that establishes the standard 100 to 300 questions also establishes the standards that certified auditors must meet in testing and reporting compliance with those standards. When an assessment is completed, the auditor, likely a major accounting firm, would generate a score and statement of scope. With this information, an organization would only need to know the answer to five questions to determine trustworthiness:

1. Who provided the audit?
2. What standard was used?
3. What was the score?
4. What was the scope of the audit?
5. What date was the audit conducted?

EXHIBIT 62.2 Example of What a Xota Assertion Would Look Like

Standard:	ISO17799-ABCDE
Score:	6.7.19.22.8.5.9.4.2.5.6.x.x.x.x.x.x.x.x.x
Score (Raw):	CACEADD9F7BFF7FDFF7B6D90E7D8CA04106C8B70
ORG:	O = EXAMPLE ORG; C = US; OU = BANKING;CN = CCU_APP
Included:	OU = BANKING
Excluded:	NONE
Date:	20020103101411.2Z

EXHIBIT 62.3 Answers to the Five Questions

Q1: Who provided the audit?
A1: "PDQ Audit Solutions" provided the audit.
Our business accepts them. Passed.

Q2: What standard was used?
A2: The standard was ISO 17799-ABCDE.
That's a standard we support. Passed.

Q3: What was the score?
A3: The score was 6.7.19.22.8.5.9.4.2.5.6.
Minimum for ISO 17799-ABCDE is 5.5.17.22.8.2.9.3.2.3.3. Passed.

Q4: What was the scope of the audit?
A4: The scope was the OU = Banking.
Business app is in Banking Division. Passed.

Q5: What date was the audit conducted?
A5: The date was 1/3/2002.
Maximum age is 18 months. Failed. Untrusted state.

These questions cover everything a relying party needs to know, provided they trust the standard and the auditor, and have established scoring criteria for their organization. However, the real power is yet to come. As a required deliverable of the assessment, the auditing party would issue a digital signature that contains these five fields of information, and is issued by a trusted Root Certificate Authority. Because an X.509 certificate can be readily verified, such credentials would be nearly impossible to forge.

When connecting to a business application, part of the connection negotiation would require exchange of digital certificates to establish secure communications, and the trust assertion certificate could be included in this handshake (see Exhibit 62.2). The relying party can then extract the information, verify the public key, ensure that the integrity of the information is intact, and that the digital certificate has not been revoked. That process takes sub-seconds to perform, and is a time-honored process currently used in SSL.

For each business application, all organizations taking part in the transaction would establish minimal scoring standards for that application, aligned with the stipulations in the contractual agreement. The trust assertion analysis process then checks those baseline standards against the assertions, represented as the answers to those five questions detailed above (see Exhibit 62.3).

Again, because these standards are an extension of contractual obligations stipulated in the agreement between the two companies, the terms should be clear to all involved, and the trust analysis merely reflects the trust embodied in the contract. Because the standard and scope are flexible, each business application can determine what level and scope are required for the trust posture necessary for the application. Scope can readily be defined through embedded XML in the certificate, providing a pointer to LDAP-compliant Fully Distinguished Names (FDNs) and Relative Distinguished Names (RDNs). This would permit the application to determine how much of the infrastructure was covered by the auditor's assessment.

In addition to providing scoring ranges for quick compliance scoring, the answer to each compliance question would also be communicated in hexadecimal notation (00-FF), providing a compact means of conveying assessment information, to facilitate very granular compliance analysis. For example, "FC" represents scoring answers of 11111100, which indicates the company is compliant with requirements 1 through 6, but is not compliant with standards 7 and 8.

Basing Certified Trust Assertions on X.509 is not an accident, because Certificate Revocation List (CRL) checking becomes an integral control of the methodology. If a security score downgrade is determined through an audit, event, or discovery, the auditor would be required to revoke the prior certificate and reissue the new one (which is a simple process). For a security score upgrade, a new certificate would be issued without revoking the "weaker" assertion, to avoid a denial-of-service in ongoing transactions using trust assertions. Checking certificate revocation against Certificate Revocation Lists ensures that the trust rating is still viable, and provides protection against fraud. Further, it permits all other parties relying on that trust assertion to know, near instantaneously, that the trust model has changed for that transaction.

This methodology, of determining trustworthiness through exchange of standards-based assertions of trust from third parties, is the core of the recently developed Xota protocol. Xota — eXtensible Organizational Trust Assertions — is the combination of the methodology and practices, which use trusted third parties, with the lightweight protocol to report the scope and standard used during the assessment, and the "score" of that assessment.

Because the trust assertion is provided via lightweight and ubiquitous X.509 digital certificates, nearly any system designed to provide authentication could readily request and analyze trust assertions. Both traditional client/server E-commerce and Web Services business applications can dynamically determine session trust, application trust, and entity trust, all at execution time. The same technology could be embedded in SSH to determine trustworthiness for logins, to protect file transfers and terminal emulation sessions. By placing trust assertion processing in e-mail gateways, spam can be deflected or routed based on the trust assertions embedded with the message, either by mail router trust assertions or those from the author's systems.

Trustworthiness of executables could also be governed if a secure kernel would not only verify the integrity against known, signed hashes, but would also perform trust assertion validation. By performing an assessment of the executable's Xota trust assertion, most importantly by assessing the viability of the certificate against a CRL, the kernel would be able to determine if the executable had lost its certification, perhaps because vulnerabilities had been published against that version of the application. Implementing such a methodology would require some serious shoring up of the certification and vetting process to ensure that a bogus CRL did not cause a massive denial-of-service attack, but still presents useful extensions for a trustworthy computing environment, particularly in a government or military application requiring certified executables.

Xota trust modeling is also viable for the B2C environment, and could be built into a browser quite easily to provide a security assessment automatically, just as PGP does for privacy. Java applets, ActiveX controls, JavaScript, VBScript, and embedded components could be required not only to be signed, but also to include a trust assertion for the application. Consumers would be able to determine the trustworthiness of the application, company, and privacy controls automatically at download, which could be a very powerful tool for consumers to identify malicious payloads, spyware, and untrustworthy companies.

Conclusion

The technical challenges to building a Xota-compliant trust assertion model are minimal, as all the necessary components exist today. Common standards would be helpful, but merely provide implementation lubrication to remove barriers and expense from implementation. Most of the assessments are already being conducted as part of vulnerability assessments, SAS 70 audits, and regulatory compliance assessments. The process could technically be implemented tomorrow by using an existing standard (e.g., ISO 17799), although it will almost certainly take the establishment of a consortium to develop standards that will evoke trust by participants. Additionally, the consortium should develop auditing standards and auditing certification processes to ensure that issuers of trust assertions follow the standards.

The benefits realized from developing this system speak directly to the five business drivers introduced earlier. Presuming adoption of the Xota protocol by business partners within one or more industries, what might trust governance look like within these paradigms?

Acceleration of E-Business through Web Services

By utilizing Xota trust assertions as an integral component of their Web Services offerings, business partners can now interconnect their Web Services very quickly. UDDI and WSDL are two protocols that permit Web Services and their interfaces to be published in a meta-directory, and hold the promise of "drag-and-drop"

Web Services interface deployment. However, they are currently only used for referencing low-value transactions, due to the lack of trust and contractual assurances. By utilizing Xota trust assertions, UDDI and WSDL could also be used for high-value Web Services transactions. This would mean that the only remaining barrier for instant-on Web Services is contract negotiation. Business partners can now react very quickly to market changes by rolling out Web Services interfaces to existing and new partners in days instead of months, because the security and interface barriers can be identified within minutes instead of weeks.

Several consortiums and business groups are currently working to create "circles of trust" within industries, to permit Single Sign-on through federated identity management. However, these circles of trust are constrained when they cross industry, country, and other trust barriers. If these business trust models use Xota trust assertions to provide a common language and framework for trust modeling, these circles of trust may no longer be constrained to single industries or circles, but can now enable the rapid deployment of cross-industry E-business.

Death by 1000 Cuts

The most striking effect from implementation of trust governance lies in the compliance and assessment functions within organizations. By implementing rapid assessments with the Xota protocol, the tasks of establishing, assessing, and governing business trust models becomes an automated process. Further, by moving the trust assessments to the transaction point, compliance with the business trust model is provided automatically and proactively. Trust assertions can easily be forwarded to a central repository for further compliance analysis.

Once Xota trust modeling is implemented, compliance organizations can shift compliance workers from a cost to a revenue basis. Instead of the drudgery of assessing and reporting on security models, security knowledge workers can focus on building and extending trust models. Security assessments become a key business enabler, rather than a cost sink. Further, the hidden costs of continuous assessments and governance are converted into hard-dollar infrastructure and application costs that can be included in budgets for projects that implement those risks, rather than being borne by the security and compliance organizations as overhead. The risk posture of partnerships can also be determined and evaluated at the point of project initiation, rather than weeks later. By attaching costs and risks to the projects that generate them, senior management can make more-informed decisions on project return on investment (ROI) and return on risk.

Trust Erosion

Although most contracts today include verbiage that permits a periodic or unscheduled on-site visit by one or both parties of the contract, this assessment is rarely executed, due to the high cost of such assessments. However, with the availability of continuous determinations of trust compliance, these components of contract compliance are now verified automatically. If the contracts are structured to require periodic third-party assessments and Xota assertions, the trust models can be self-regulated through ongoing analysis of the trust assertions.

Common Standards

Through the creation of a common framework and language for discussing standards compliance, Xota permits translations of assessments across international and industry boundaries. If an assessment was provided against the Common Criteria standard, but the organization has based its policies and trust models on BS 7799, the assessment can still be used by the business partners. The relying organization would have to assess the individual answers to all the questions of the "new" standard, and then determine what its requirements would be within that business context. Once completed, the organization would have a template that can be used to translate Common Criteria to BS 7799, and this could be extended to other trust models in the organization. Although Xota does not provide a common standard, it does provide a common language for interpreting standards, and permits wide reuse of assessments across many isolated contexts.

Security Regulation

Security regulatory proponents primarily cite the need for regulation to establish and enforce common standards. With industry-wide adoption of Xota and the underlying standards, regulators can assess the compliance of organizations within their jurisdictional purview without the need to create yet another security standard. Insurers could likewise determine the risk posture of policyholders, and reward security diligence (or punish poor security) through a tiered pricing structure. By moving industries to a common language for communicating compliance with existing standards, the need to regulate security evaporates. Governing and regulatory bodies are able to provide compliance metrics and oversight without the need to enforce monolithic standards across the industry, and organizations are able to report their security posture without necessarily migrating to yet another security standard.

The power of Xota as the language of trust governance extends from the ability to make a clear determination of trustworthiness with five simple questions that can be dynamically assessed. The instant payoff from implementation is the ability to determine the trustworthiness of business partners without long checklists and expensive manual processes; and by ensuring that businesses, divisions, and applications are trustworthy at the point that messages and transactions are processed.

Risk Management and Analysis

Kevin Henry, CISA, CISSP

Why risk management? What purpose does it serve and what real benefits does it provide? In today's overextended work environments, it can easily be perceived that "risk management and analysis" is just another hot buzzword or fashionable trend that occupies an enormous amount of time, keeps the "administrative types" busy and feeling important, and just hinders the "technical types" from getting their work done.

However, risk management can provide key benefits and savings to a corporation when used as a foundation for a focused and solid countermeasure and planning strategy.

Risk management is a keystone to effective performance and for targeted, proactive solutions to potential incidents. Many corporations have begun to recognize the importance of risk management through the appointment of a Chief Risk Officer. This also recognizes that risk management is a key function of many departments within the corporation. By coordinating the efforts and results of these many groups, a clearer picture of the entire scenario becomes apparent. Some of the groups that perform risk management as a part of their function include security (both physical and information systems security groups), audit, and emergency measures planning groups.

Because all of these areas are performing risk analysis, it is important for these groups to coordinate and interleave their efforts. This includes the sharing of information, as well as the communication of direction and reaction to incidents.

Risk analysis is the science of observation, knowledge, and evaluation — that is, keen eyesight, a bit of smarts, and a bit of luck. However, it is important to recognize that the more a person knows, the harder they work, often the luckier they get.

Risk management is the skill of handling the identified risks in the best possible method for the interests of the corporation.

Risk is often described by a mathematical formula:

$$\text{Risk} = \text{Threat} * \text{Vulnerability} * \text{Asset value}$$

This formula can be described and worked quite readily into the business environment using a common practical example. Using the example of the bully on the playground who threatens another child with physical harm outside the school gates after class, one can break down each component as follows:

- The threat is that of being beat up, and one can assign a likelihood to that threat. In this case, say that it is 80 percent likely that the bully will follow up on his threat unless something else intervenes (a countermeasure — discussed later).
- The vulnerability is the other child's weakness. The fact that the other child is unable to defend himself adequately against this physical attack means that the child is probably 100 percent likely to be harmed by a successful attack.

- The asset value is also easy to calculate. The cost of a new shirt or pants, because they will probably be hopelessly torn or stained as a result of an altercation and the resultant bloody nose, puts the value of the assets at $70.00.

Therefore, the total risk in this scenario is:

$$\text{Risk} = 80\% * 100\% * \$70.00.$$

$$\text{Risk} = \$56.00$$

Now one can ask: what is the value of this risk assessment? This assessment would be used to select and justify appropriate countermeasures and to take preventative action. The countermeasures could include hiring a bodyguard (a firewall) at a cost of $25.00, not going to school for the day (like shutting the system down and losing business), or taking out insurance to cover losses. The first of these primarily deals with strengthening the weakness(es) or vulnerabilities, while the third protects the asset value. Preventative action would include methods of reducing the threats, perhaps by befriending the bully, working out or learning karate, or moving out of town.

Thus, from this example, it is easy to describe a set of definitions in relation to risk management.

- Risk is any event that could impact a business and prevent it from reaching its corporate goals.
- Threat is the possibility or likelihood that the corporation will be exposed to an incident that has an impact on the business. Some experts have described a threat both in a positive sense as well as in a negative sense. Therefore, it is not certain that a threat will always have a negative impact; however, that is how it is usually interpreted.
- A vulnerability is the point of weakness that a threat can exploit. It is the soft underbelly or Achilles' heel where, despite the tough armor shielding the rest of the system, the attack is launched and may open the entire system or network to compromise. However, if risk is viewed as a potentially positive scenario, one should replace the term "vulnerability" with the term "opportunity" or "gateway." In this scenario, the key is to recognize and exploit the opportunity in a timely manner so that the maximum benefit of the risk is realized.
- The asset is the component that will be affected by the risk. From the example above, the asset was described as the clothing of the individual. This would be a typical quantitative interpretation of risk analysis. Quantitative risk analysis attempts to describe risk from a purely mathematical viewpoint, fixing a numerical value to every risk and using that as a guideline for further risk management decisions.

Quantitative Risk Analysis

Quantitative risk analysis has several advantages. It provides a rather straightforward result to support an accounting-based presentation to senior managers. It is also fairly simple and can easily follow a template type of approach. With support and input from all of the experts in the business groups and supporting research, much of the legwork behind quantitative analysis can be performed with minimal prior experience. Some of the steps of performing risk analysis are addressed later in this chapter.

However, it is also easy to see the weaknesses of quantitative risk analysis. While it provides some value from a budget or audit perspective, it disregards many other factors affected by an incident. From the previous example, how does one know the extent of the damage that would be caused by the bully? An assumption was made of generally external damage (clothing, scrapes, bruises, bloody nose), but the potential for damage goes well beyond that point. For example, in a business scenario, if a computer system is compromised, how does one know how far the damage has gone? Once the perpetrator is into a system and has the mind to commit a criminal act, what limits the duration or scope of the attack? What was stolen or copied? What Trojan horses, logic bombs, or viruses were introduced. What confidential information was exposed? And in today's most critical area, what private customer details or data were released. Because these factors are unknown, it is nearly impossible to put a credible number on the value of the damage to the asset.

This chapter, like most published manuscripts these days, is biased toward the perception of risk from a negative standpoint. On the other hand, when risk is regarded in a potentially positive situation, there is the difficulty of knowing the true benefit or timing of a successful exploitation of an opportunity. What would be the effect on the value of the asset if a person reacts today rather than tomorrow, or if the opportunity is

missed altogether and the asset (corporation) thereby loses its leading-edge initiative and market presence? A clear example of this is the stock market. It can be incredibly positive if a person or company knows the ideal time to act (seize a risk); however, it can be devastating to wait a day or an hour too long.

Some of the factors that are difficult to assess in a quantitative risk analysis include the impact on employees, shareholders or owners, customers, regulatory agencies, suppliers, and credit rating agencies.

From an employee perspective, the damage from a successful attack can be severe and yet unknown. If an attack has an effect on morale, it can lead to unrealized productivity losses, skilled and experienced employee retention problems, bad reactions toward customers, and dysfunction or conflict in the workplace. It can also inhibit the recruitment of new, skilled personnel.

Shareholders or owners can easily become disillusioned with their investments if the company is not performing up to expectations. Once a series of incidents occur that prevent a company from reaching its goals, the attraction to move an investment or interest into a different corporation can be overpowering. Despite the best excuses and explanations, this movement of capital can significantly impact the financial position of the corporation.

Customers are the key to every successful endeavor. Even the best product, the best sales plans, and the best employees cannot overcome the failure to attract and retain customers. Often, the thought can be that the strength of a company can rest in a superior product; however, that is of little value if no one is interested in the services or products a company is trying to provide. A company with an inferior product will often outperform the company with superior products that gets some "bad press" or has problems with credibility. A lifetime warranty is of no value if the company fails because the billing system being used is insecure.

Regulatory agencies are often very vulnerable to public pressure and political influence. Once a company has gained a reputation for insecure or vulnerable business processes, the public pressure can force "kneejerk" reactions from politicians and regulatory agencies that can virtually handcuff a firm and cause unreasonable costs in new controls, procedures, reports, and litigation.

One of the best lessons learned from companies that have faced serious disasters and incidents is to immediately contact all major customers and suppliers to reassure them that the company is still viable and business processes are continuing. This is critical to maintaining confidence among these groups. Once a company has been exposed to a serious incident, the reluctance of a supplier to provide new raw materials, support, and credit can cripple a firm from re-establishing its market presence.

Because of the possible impact of an incident on all of these groups, and the difficulty in gauging a numerical value for any of these factors, it has been asserted by many experts that a purely quantitative risk analysis is not possible or practical.

Qualitative Risk Analysis

The alternative to quantitative risk analysis is qualitative risk analysis. Qualitative risk analysis is the process of evaluating risk based on scenarios and determining the impact that such an incident would have.

For qualitative risk analysis, a number of brief scenarios of potential incidents are outlined and those scenarios are developed or researched to examine which areas of the corporation would be affected and what would be the probable extent of the damage experienced by those areas in the event that this scenario ever occurred. This is based on the best estimates of the personnel involved.

Instead of a numerical interpretation of a risk as done in a quantitative risk analysis, a ranking of the risk relative to the affected areas is prepared. The risk analysis team will determine what types of incidents may occur, based on the best knowledge they can gain about the business environment in which the company operates. This is similar to the financial modeling done by strategic planning groups and marketing areas. By rolling out the scenario and inputting the variables that influence the event, the risk analysis team will attempt to identify every area that might be affected by an incident and determine the impact on that group based on a simple graph like "High Impact," "Medium Impact," "Low Impact" — or through a symbolic designation like 3,2,1 or 0 for no impact. When all of the affected areas are identified, the value for each area is summarized to gauge the total impact or risk to the company of that scenario occurring. In addition to purely financial considerations, some of the areas to include in this analysis are productivity, morale, credibility, public pressure, and the possible impact on future strategic initiatives.

Whenever doing a risk analysis of an information system, it is important to follow the guidelines of the AIC triad. The risk analyst must consider the availability requirements of the system. Is it imperative that it operates continuously, or can it be turned down for maintenance or suffer short outages due to system failure without

causing a critical failure of the business process it supports? The integrity of the data and process controls and access controls around the systems and the underlying policies they are built on also need a thorough review. Probably no area has received as much negative publicity as the risk of data exposure from breaches of confidentiality in the past few years. A large, well-publicized breach of customer private information may well be a fatal incident for many firms.

One of the best methods to examine the relationship between the AIC triad and risk analysis is to perform general computer controls checks on all information systems. A short sample of a general computer controls questionnaire appears in Exhibit 63.1. This is a brief survey compiled from several similar documents available on the Internet. A proper general computer controls survey (see Exhibit 63.1) will identify weakness such as training, single points of failure, hardware and software support, and documentation. All of these are extremely valuable when assessing the true risk of an incident to a system.

However, qualitative risk analysis has its weaknesses just like quantitative risk analysis does. In the minds of senior managers, it can be too loose or imprecise and does not give a clear indication of the need or cost-benefit analysis required to spur the purchase of countermeasures or to develop or initiate new policies or controls.

For this reason, most companies now perform a combination of these two risk analysis methodologies. They use scenario-based qualitative risk analysis (see Exhibit 63.2) to identify all of the areas impacted by an incident, and use quantitative risk analysis to put a rough dollar figure on the loss or impact of the risk according to certain assumptions about the incident. This presumes, of course, a high level of understanding and knowledge about the business processes and the potential risks.

The Keys

If one were to describe three keys to risk analysis, they would be knowledge, observation, and business acumen.

Knowledge

Effective risk analysis depends on a thorough and realistic understanding of the environment in which a corporation operates. The risk manager must understand the possible threats and vulnerabilities that a corporation faces. These managers must have a current knowledge of new threats, trends, and system components, tools, and architectures in order to separate the hype and noise from the true vulnerabilities and solutions to their organization. To gain the cooperation of the business areas to perform risk analysis, and to be able to present the resulting credible recommendations to senior managers, the manager must be able to portray a realistic scenario of possible threats and countermeasures. This knowledge is gained through the continuous review of security bulletins, trade journals, and audits. For this reason, a Chief Risk Officer should also sit on the senior management team so that he or she has knowledge of corporate strategic direction and initiatives. The Chief Risk Officer should also receive regular updates of all ongoing incidents that may have an impact on the corporation.

Observation

Observation is the second key. We live in an age of overwhelming data and communication. Observation is the ability and skill to see through all of the outside influences and understand the underlying scenarios. Observation is to review all tools and reports routinely to notice if any abnormal conditions are being experienced. It is noteworthy that many excellent audit logs and output reports from tools are sitting unused on shelves because it is too difficult and time-consuming for most individuals to pick out the details. When a person first installs an intrusion detection system on his home PC, he suddenly becomes aware of the number of scans and hits he is exposed to. Did those just commence when he installed his IDS? No, it is just that he was able to observe them once he had purchased the correct tools. Therefore, observations and the use of tools are critical to understanding the characteristics and risks of the environment in which they operate.

Business Acumen

The main reason for risk analysis is to get results. Therefore, the third key is business acumen, that is, the ability to operate effectively in the business world — to sense and understand the methods and techniques to

EXHIBIT 63.1 General Computer Controls Guideline Questionnaire

Objective:

When an Auditor is involved in the analysis of a system or process that involves a software tool or computer system or hardware that may be unique to that department, we are requesting that the Auditor fill out this questionnaire, if possible, during the performance of the audit.

This will allow us to identify and monitor more of the systems in use throughout the company, and especially to assess the risk associated with these systems and indicate the need to include these systems in future audit plans.

Thanks for your assisance; if you have any questions, please contact either Alan or myslf.

System Name and Acronym: _____

Key Contact Person: _____

Area where system is used: _____

Questions for initial meeting:

Please describe the system function for us: _____

_____

What operating platform does it work on (hardware)? _____

Is it proprietary software? Yes ☐ No ☐ Who is the supplier? _____

Does MTS have a copy of the source code? Yes ☐ No ☐

In which department? _____

Who can make changes to the source code?_____

Are backups scheduled and stored offsite? Yes ☐ No ☐

How can we obtain a list of users of the systems and their privileges? _____

Is there a maintenance contract for software and hardware? Yes ☐ No ☐

Can we get a copy? Yes ☐ No ☐

Separation of Duties:

Can the same person change security and programming or perform data entry? Yes ☐ No ☐

Completeness and accuracy of inputs/processing/outputs:

Are there edit checks for inputs and controls over totals to ensure that all inputs are entered and processed correctly? Yes ☐ No ☐

Who monitors job processing and would identify job failures? _____

Who receives copies of outputs/reports? _____

Authorization levels

Who has high-level authorization to the system? _____

Security — physical and configuration

Are the hardware and data entry terminals secure? Can just anyone get to them, especially high-level user workstations? Yes ☐ No ☐

Maintenance of tables

Are there any tables associated with the system (i.e., tax tables, employee ID tables)? Yes ☐ No ☐

Who can amend these tables? _____

EXHIBIT 63.1 General Computer Controls Guideline Questionnaire (continued)

Documentation

Is the entire system and process documented? Yes ☐ No ☐

Where are these documents stored? _____

Training of end users

Who trains the users? _____

Who trains the system administrator? _____

Is there a knowledgeable backup person? _____

DRP of System

Has a Disaster Recovery Plan for this system been prepared and filed with Corporate Emergency Management? Yes ☐ No ☐

Please provide an example of an input/output. _____

Any other comments:

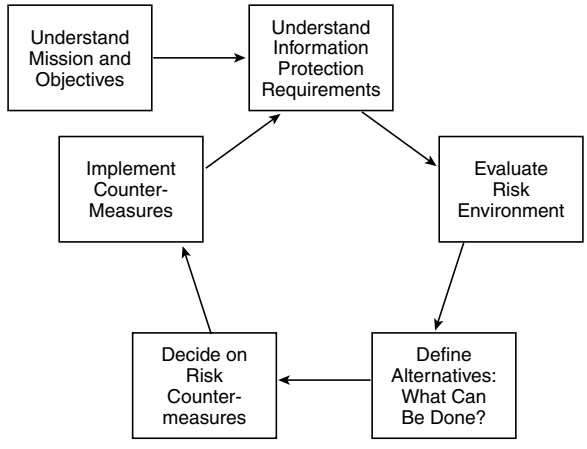

EXHIBIT 63.2 Risk analysis/management process.

use to achieve the desired results. Business acumen separates the average manager from the effective manager. With business acumen, they know how to get things done, how to make powerful and credible presentations, when to cry wolf, and when to withdraw. Because the whole foundation of risk analysis is based on understanding and addressing the mission of the business, risk managers must have the ability to set aside their traditional biases and understand the perspective of the business area managers at the same time they are evaluating risk and countermeasures. An ideal risk management solution requires the support of the users, the business area managers, and effective administration. This means that the solution must not be seen as too intrusive or cumbersome for the users nor having a significant performance or productivity impact on the supporting business systems or processes.

Risk Management

This is where the science of risk management comes into effect. Risk management is the careful balance between placing controls into the business processes and systems to prevent, detect, and correct potential incidents, and the requirement that the risk management solution not impede or restrict the proper flow and timeliness of the business.

Once the risk assessment has been completed, the result should be a concise overview of all possible threats to the organization. Included in this review will be a listing of all identified threats, areas potentially impacted by a threat, estimated cost or damage from an exposure (a threat actually being realized or occurring), and the key players in each business group.

From this assessment, the risk managers must evaluate whether or not the risk identified supports the adoption of some form of countermeasure. Usually, these countermeasures can be grouped into three categories: reduce, assign, and accept.

Reduce

To reduce the risk, most often some new control is adopted. These controls can be either administrative (balancing, edits, ID control, process change, or physical access rules) or technical (intrusion detection systems, firewalls, architecture, or new tools). By evaluating the true extent of the risk and the business requirements, the risk manager will develop a list of possible solutions to the risks. These solutions will then be evaluated on the basis of cost, effectiveness, and user acceptance before being presented for approval and implementation.

By this time in the risk analysis and management process, some of the initial fear or excitement that was driving the risk analysis process may be starting to wane. Personnel are moving on to new issues and can become desensitized to the threats that caused them sleepless nights only a few weeks before. This is where many risk management processes become derailed. Solutions are proposed and even purchased, but now the impetus to implement them dries up. The new tools sit ignored because no one has the time to look at them and learn all of their features. The controls are relaxed and become ineffective, and the budget does not provide the funding to continue the administrative support of the controls effectively. These can be dark days for the risk manager, and the result is often an incomplete risk analysis and management process. Now, at the very verge of implementation, the project silently subsides.

This is a challenge for the risk manager. The manager must rise to the occasion and create an awareness program, explain the importance of the new controls, and foster an understanding among the user community of how this risk solution can play a critical role in the future health of their department and the corporation.

Outsourcing

One alternate solution being explored by many companies today is a hybrid between the adoption of risk management tools and the assignment of risk management. This is the concept of outsourcing key areas of the risk management process. It is difficult for a corporation to maintain a competent, knowledgeable staff to maintain some of the tools and products needed to secure an information system. Therefore, they leverage the expertise of a vendor that provides risk management services to several corporations and has a skilled and larger staff that can provide 24-hour support. This relieves the corporation from a need to continually update and train an extensive internal staff group and at the same time can provide some proof of due diligence through the independent evaluation and recommendations of a third party. This does have significant challenges, however. The corporation needs to ensure that the promised services are being delivered, and that the knowledge and care of the corporate network entrusted to a third party are kept secure and confidential. Nothing is worse than hiring a fox to guard the chicken house. Through an outsourcing agreement, the risk manager must maintain the competence to evaluate the performance of the outsourcing support firm.

Assign

To assign the risk is to defer or pass some of the risk off to another firm. This is usually done through some insurance or service level agreement. Insurers will also require a fairly thorough check of the risks to the corporation they are ensuring to verify that all risks are acknowledged and that good practices are being followed. Such insurance should be closely evaluated to confirm that the corporation understands the limita-

tions that could affect a reimbursement from the insurer in the event of a failure. Some of the insurance that one will undoubtedly be seeing more of will be denial-of-service, E-business interruption, and Web site defacement insurance.

Accept

When a risk is either determined to be of an insignificant level, or it has been reduced through countermeasures to a tolerable level, acceptance of the residual risk is required. To accept a level of risk, management must be apprised of the risk analysis process that was used to determine the extent of the risk. Once management has been presented with these results, they must sign off on the acceptance of the risk. This presumes that a risk is defined to be at a tolerable level, either because it is of insignificant impact, countermeasure costs or processes outweigh the cost of the impact, or no viable method of risk prevention is currently available.

Summary

Risk analysis and management is a growing and exciting area. The ability of a corporation to identify risks and prevent incidents or exposures is a significant benefit to ensuring continued business viability and growth even in the midst of increasing threats and pressures. The ability of the risk managers to coordinate their efforts alongside the requirements of the business and to keep abreast of new developments and technologies will set the superb risk managers apart from the mundane and ineffective.

For further research into risk analysis and management, see the Information Assurance Technical Framework (IATF) at www.iatf.net.

64

New Trends in Information Risk Management

Brett Regan Young, CISSP, CBCP

Corporations have increased their investment in information security because critical business systems have moved into increasingly hostile territory. As the enterprise has embraced new technologies such as EDI/EFT, remote access, and sales automation, confidential data has gradually found itself in ever-riskier venues. Moving to the Internet is the latest — and riskiest — frontier. Nevertheless, forward-looking companies are willing to face the growing and unpredictable body of risks on the Internet to create competitive advantage.

Management of information risk is a new discipline, following on the heels of electronic information systems in general. To date, in the majority of organizations, information risk management has been done largely with a "seat of the britches" approach. The opinions of experts are often sought to assist with current protection needs while divining future threats. Electronic fortifications have been erected to improve an organization's defensive position. These measures, while allowing businesses to operate within the delicate balance of controls and risks, have had mixed success. This is not to say that organizations have not been hit by computer crime. The extent and frequency of such crimes have been historically low enough to give the impression that IS departments and security teams were managing information risk sufficiently well.

A Traditional Approach

Conventional risk analysis is a well-defined science that assists in decision support for businesses. The most common use of risk analysis is to lend order to apparently random events. By observing the frequency of an event factored by the magnitude of the occurrences, one can predict, with more or less accuracy, when and to what degree something might happen. Thus, one might expect ten earthquakes of a 7 magnitude to strike Yokohama within 100 years. When information is available to indicate the projected expense of each episode, then one can ascertain the ALE (annual loss expectancy). Conventional risk analysis is a powerful tool for managing risk, but it works best when analyzing static or slowly evolving systems such as human beings, traffic patterns, or terrestrial phenomena. Incidents that cause the loss of computing functions are difficult to map and even more difficult to predict. Two reasons for this are:

1. Trends in computing change so rapidly that it is difficult to collect enough historical data to make any intelligent predictions. A good example of this can be found in the area of system outages. An observer in California might predict that a server farm should suffer no more than one, three-hour outage in ten years. In 1996, that was plausible. Less than five years later and after an extended power crisis, that estimate was probably off by a factor of ten.
2. There is a contrarian nature to computer crime. Criminals tend to strike the least protected part of an enterprise. Because of the reactive nature of information security teams, it is most likely that one will

add protection where one was last hit. This relationship between attackers and attacked makes most attempts to predict dangerously off-track.

While information risk shares aspects with other types of business risks, it is also unique, making it difficult to analyze and address using conventional methods.

Doing Our Best

To protect their E-commerce operations, most businesses have relied primarily on an "avoidance" strategy, focusing on components such as firewalls and authentication systems. Daily reports of Internet exploits have shown that these avoidance measures, while absolutely essential, are not a sufficient defense. Avoidance strategies offer little recourse when incursions or failures do occur. And despite an organization's best efforts to avoid intrusions and outages, they will occur. In the high-stakes world of E-commerce, would-be survivors must understand this and they need to prepare accordingly.

Reports of Internet intrusions are frequent — and frightening enough to get the attention of management. Tragically, the most common response from corporate management and IS directors is a simple redoubling of current efforts. This reaction, largely driven by fear, will never be more than partially successful. It is simply not possible to out-maneuver Internet thugs by tacking new devices onto the perimeter.

The most telling metric of failed security strategies is financial. According to one source, funding for defensive programs and devices will increase an estimated 55 percent during the two years leading up to 2004, growing to a projected $19.7 billion for U.S. entities alone.[1] Keeping pace with rising computer security budgets are the material effects of computer crime. Dramatic increases in both the frequency and extent of damage were reported in the most recent annual Computer Security Institute (CSI)/FBI computer crime survey. The 273 respondents reported a total of $265 million in losses. These figures were up from the $120 million reported the previous year.[2] While the survey results are not an absolute measure of the phenomenon, it is a chilling thought to imagine that the enormous increases in security spending may not be keeping up with 50 percent and greater annual increases in material damage suffered as a result of computer-related crime.

The composite picture of rising costs for security chasing rising damages casts a dark shadow on the future of electronic commerce. Left unchecked, security threats coupled with security mismanagement could bring otherwise healthy companies to ruin. The ones that escape being hacked may succumb to the exorbitant costs of protection.

Common Sense

Who Let the Cows Out?

During the 1990s, a trend emerged among IS management to focus intensely on prevention of negative security events, often to the exclusion of more comprehensive strategies. There were three distinct rationales behind this emphasis:

1. *Experience has consistently shown that it is cheaper to avoid a negative incident than to recover from it.* This is most often expressed with a barnyard metaphor: "like shutting the gate after the cows are gone." The implication is that recovery operations (i.e., rounding up livestock after they have gotten loose) is infinitely more trouble than simply minding the latch on the gate.
2. *Loss of confidentiality often cannot be recovered, and there is, accordingly, no adequate insurance for it.* Valuing confidential information poses a paradox. All of the value of some types of confidential information may be lost upon disclosure. Conversely, the value of specific information can shoot up in certain circumstances, such as an IPO or merger. Extreme situations such as these have contributed to an "all-or-nothing" mentality.
3. *The "bastion" approach is an easier sell to management than recovery capability.* Information security has always been a hard sell. It adds little to the bottom line and is inherently expensive. A realistic approach, where contingencies are described for circumvented security systems, would not make the sale any easier.

The first argument makes sense: avoidance is cheaper than recovery in the long run. In theory, if new and better defenses are put in place with smarter and better-trained staff to monitor them, then the problem should

be contained. The anticipated results would be a more secure workplace; however, precisely the opposite is being witnessed, as evidenced by the explosive growth of computer crime.

The bastion approach has failed to live up to its expectations. This is not because the technology was not sufficient. The problem lies in the nature of the threats involved. One constant vexation to security teams charged with protecting a corporation's information assets is the speed with which new exploits are developed. This rapid development is attributable to the near-infinite amount of volunteer work performed by would-be criminals around the world. Attacks on the Internet are the ultimate example of guerilla warfare. The attacks are random, the army is formless, and communication between enemy contingents is almost instantaneous. There is simply no firewall or intrusion detection system that is comprehensive and current enough to provide 100 percent coverage. To stay current, a successful defense system would require the "perps" to submit their exploits before executing them. While this may seem ludicrous, it illustrates well the development cycle of defensive systems. Most often, the exploit must be executed, then detected, and finally understood before a defense can be engineered.

Despite the media's fascination with electronic criminals, it is the post-event heroics that really garner attention. When a high-volume E-commerce site takes a hit, the onlookers (especially affected shareholders) are less interested in the details of the exploit than they are in how long the site was down and whether there is any risk of further interruption. Ironically, despite this interest, spending for incident response and recovery has historically been shorted in security and E-commerce budgets.

It is time to rethink information protection strategies to bring them more in line with current risks. Organizations doing business on the Internet should frequently revise their information protection strategies to take into account the likelihood of having to recover from a malicious strike by criminals, a natural disaster, or other failures. Adequate preparation for recovery is expensive, but it is absolutely necessary for businesses that rely on the Internet for mission-critical (time-critical) services.

Exhibit 64.1 illustrates a simple hierarchy of information security defenses. The defenses garnering the most attention (and budget dollars) are in the lower three categories, with avoidance capturing the lion's share. Organizations will need to include recovery and bolster assurance and detection if they are to successfully protect their E-commerce operations.

A Different Twist: Business Continuity Management

Business continuity management (BCM) is a subset of information security that has established recovery as its primary method of risk management. Where other areas of information security have been preoccupied with prevention, BCM has focused almost exclusively on recovery. And just as security needs to broaden its focus on post-event strategies, business continuity needs to broaden its focus to include pre-event strategies. BCM in the E-commerce era will need to devise avoidance strategies to effectively protect the enterprise. The reason for this is time.

A review of availability requirements for Internet business reveals an alarming fact: there often is not enough time to recover from an outage without suffering irreparable damage. Where BCM has historically relied heavily on recovery strategies to maintain system availability, the demands of E-commerce may make recovery an unworkable option. The reason for this is defined by the fundamental variable of maximum tolerable downtime (MTD). The MTD is a measure of just how much time a system can be unavailable with the business still able to recover from the financial, operational, and reputational impacts.

EXHIBIT 64.1 Information Protection Model

Level	Examples
Recovery	Incident response, disaster recovery
Detection	Intrusion detection
Assurance	Vulnerability analysis, log reviews
Avoidance	Firewalls, PKI, policy and standards

Courtesy of Peter Stephenson of the Netigy Corporation.

E-commerce has shortened the MTD to almost nil in some cases. A few years back, a warehousing system might have had the luxury of several days' recovery time after a disaster. With the introduction of 24/7 global services, an acceptable downtime during recovery operations might be mere minutes. In this case, one is left with a paradox: the only workable alternatives to recovery are avoidance strategies.

Referring again to the information protection model, shown in Exhibit 64.1, BCM now requires more solutions at the lower avoidance area of the hierarchy. Discussing these solutions is not within the scope of this chapter, but examples of enhancing availability include system redundancy, duplexing, failover, and data replication across geographical distances. Another indication of the shift in focus is that business continuity now requires a greater investment in assurance and detection technologies. In 2002, was likely that a company's Web presence would fail as a result of a malicious attack because it is from a physical failure. Business continuity teams once relied on calls from end users or the helpdesk for notification of a system failure; but today, sophisticated monitoring and detection techniques are essential for an organization to respond to an attack quickly enough to prevent lasting damage.

The makeup of business continuity teams will likewise need to change to reflect this new reality. A decade ago, business continuity was largely the domain of subject matter experts and dedicated business continuity planners. The distributed denial-of-service attacks witnessed in February 2000 spawned ad hoc teams made up of firewall experts, router jocks, and incident management experts. The teams tackled what was, by definition, a business continuity issue: loss of system availability.

Reworking the Enterprise's Defenses

One only needs to look back as far as the mid-1990s to remember a time when it seemed that we had most of the answers and were making impressive progress in managing information risk. New threats to organizational security were sure to come, but technological advances would keep those in check — it was hoped. Then the rigorous requirements of protecting information within the insecurity of a wired frontier jarred us back to reality. Waves of malicious assaults and frequent outages suggest that it may be a long time before one can relax again. But one should take heart. A thorough review of the current risk terrain, coupled with renewed vigilance, should pull us through. It is quite clear, however, that organizations should not expect to improve the protection of their environments if they continue to use the same strategies that have been losing ground over the past several years. Coming out on top in the E-commerce age will require one to rethink positions and discard failed strategies.

It should be encouragement to us all that reworking the enterprise's defenses requires more rethinking than retooling. Many of the requisite techniques are already resident in the enterprise or can be readily obtained. In recommending a review of an organization's defensive strategy, four principal areas of analysis need to be applied. They are presented below.

Security Architecture

Building an appropriate security architecture for an organization requires a thorough understanding of the organization's primary business functions. This understanding is best obtained through interviews with business leaders within the organization. Once discovered, the primary business functions can be linked to information technology services. These, in turn, will require protection from outside attack, espionage, and systems outage. Protecting IS services and systems is accomplished using security practices and mechanisms. Thus, the results of a security architecture study relate the activities of the information security group back to the primary business of the company.

The results of a security architecture study are particularly enlightening to businesses that have recently jumped onto the Internet. Quite often, businesses will have security processes and mechanisms protecting areas of secondary criticality while new business-critical areas go unprotected. Devising an effective architecture model allows an organization to allocate sufficient resources to the areas that need the most protection.

An additional benefit of the results of a security architecture study lies in its bridging function. Security architecture tracks relationships between information security and business functions that it protects, demonstrating the value of information security to the enterprise. The resultant insights can prove quite valuable as a support tool for budgetary requests.

Business Impact Analysis

Business impact analysis (or BIA) has been used as an essential component of business continuity planning for some years. The BIA estimates the cost per time unit of an outage of a specific system. Once this cost is known for a specific system (e.g., $100,000 per day), then informed decisions can be made concerning the system's protection. In addition to the practical uses for such information, the cost of a potential outage is the type of information that makes corporate management less reluctant to budget for protective measures.

The BIA has been a tool employed almost exclusively by business continuity planners until very recently. As malicious attacks on E-commerce availability have become a costly form of computer crime, the BIA is receiving a broader base of attention.

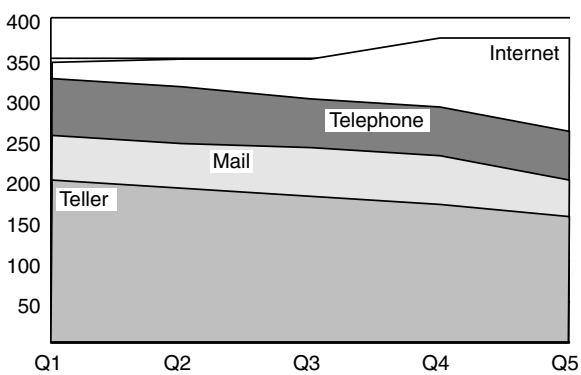
Two points must be made with respect to doing a BIA on E-commerce systems. First, as the MTD approaches zero, the potential business impact will appear absolute and infinite — much like an asymptote. Some understanding of the actual workings of the system may be indicated here. Unfortunately, because so many systems connected to the Internet host real-time activities, such as stock trading, the impact of a specific system outage may indeed be immediately devastating. This might be the case with a back-office, host-based system that previously had a more relaxed recovery requirement. Moving to a real-time Internet business model may put 7×24 requirements on legacy systems. The resulting dilemma may force decisions regarding the ability of the enterprise to run its business on certain platforms.

Second, a BIA that uses multiple revenue streams as a source of potential lost profit will need to be updated frequently as business shifts to the Internet. This is to say, for example, that a company trying to replace a telephone center with an Internet-based alternative should weight impacts to the telephone center with decreasing importance. This can be accomplished by frequently updating the BIA or by extrapolating future numbers using projections. An example for a bank transitioning to online services is shown in Exhibit 64.2.

The results of a BIA fasten perceived risks to a concrete anchor — money. As with a security architecture review, the information returned suggests a very potent tool. Obtaining resources to protect a business-critical system or process is far easier when the costs of an outage have been tallied and presented to management.

Risk Analysis

Risk analysis isolates and ranks individual risks to a specific system or process. In the past, quantitative risk analysis was time-consuming and not terribly accurate. In the area of E-commerce, risk analysis needs to be swift and decisive to be useful. In industries where marketing goals and production are expected to shift quickly to maximize profitability, risk analysis is the key to avoiding dangerous situations. It can provide the candid observations and raw ideas necessary to devise strategies to avoid and to resist threats.



A bank's transaction totals are shown in millions of dollars per quarter. Four types of transactions are added to obtain the total. As revenue streams shift from one revenue source to another, material impacts to the bank for failed systems in each of the four areas should increase or decrease in proportion to the change. Thus, the numbers used in a BIA must be extrapolated in anticipation of the changes.

EXHIBIT 64.2 Banking services over time.

The method known as facilitated risk analysis, taught by the CSI, offers a rapid, straightforward approach to ascertaining risks without getting bogged down in unnecessary details. Using this approach, a facilitator directs a small group (usually six to twelve people) through a series of questions designed to evoke the participant's impression of the threats to a particular system. Ideally, those participating will represent a diverse group of people, each having a unique view of the system. The process resembles a group interview, in that real-time peer review of each person's comments takes place. The results are a synthesized picture of the system's significant risks and a number of suggested controls for mitigating the risks.

As a process, the facilitated risk analysis is sufficiently lightweight that it could be repeated as often as required without overly taxing the affected group. Effective information security management depends on having a current, realistic assessment of risks to the enterprise's information. It also serves as a check to ensure that the mission of the information security team is in line with the customer's expectations.

Incident Response

Twenty years ago, incident response was exclusively the domain of disaster recovery and corporate (physical) security. If the incident was a massive system failure, the recovery team invoked a detailed, formal plan to recover the information asset. Had there been a reason to suspect wrongdoing, a fraud investigator would be enlisted to investigate the alleged crime.

Client/server and PC networks brought in their wake a wide range of vulnerabilities requiring proactive mechanisms to protect internal networks and hosts. As IS shops raced forward in the waves of new technologies, avoidance remained the preferred strategy — but ad hoc recovery became the new reality. In truth, most organizations make a dreadful mess of recovering from incidents.

In most shops today, incident response is the weakest tool of information defense. Incident recovery is the ability to detect and respond to an unplanned, negative incident in an organization's information systems. Most companies are woefully unprepared to respond to an incident because of their unwavering faith in avoidance. The approach of building an invincible wall around a trusted network was sold so well in the past decade that many organizations felt that spending on detection and recovery from computer crime was a frivolous waste of money. This is the same mix of technological faith and naiveté that supplied lifeboats for only half the passengers on the Titanic.

The appalling lack of incident response capability in most corporate environments is especially salient when one looks at a particularly embarrassing segment of computer crime: insider crime. The CSI/FBI computer crime survey presents an alarming picture of corporate crime that has not deviated very much over the past few years. The survey indicates that corporate insiders perpetrate approximately 70 percent of incidents reported in the survey. Even if overstated, the numbers underscore the need for increased detection and response capabilities. The criminals in these cases were found on the "friendly" side of the firewall. These threats are largely undeterred by the recent increases in funding for Internet security, and they require mechanisms for detection and response expertise to resolve.

Incident response brings an essential element to the arsenal of information security; that is, the organizational skill of having a group rapidly assess a complex situation and assemble a response. Properly managed, an incident response program can save the organization from disaster. The team needs a wide variety of experts to be successful, including legal, networking, security, and public relations experts. And the organization needs to exercise the team with frequent drills.

Conclusion

While the demand for security goods and services is experiencing boundless growth, the total cost of computer crime may be outpacing spending. This should prompt a thorough review of defensive strategies; instead, corporate IS managers seem prepared to increase funding to still higher levels in a futile attempt to build stronger perimeters. There is little reason for optimism for this program, given recent history.

The Internet now hosts live transaction business processes in almost every industry. Hitherto unthinkable exposures of technical, financial, and corporate reputations are the daily grist of the 21st-century information workers. Information risk management was once feasible with a small number of decision makers and security

technicians. Those days are gone. Risk management in an atmosphere that is so fraught with danger and constantly in flux requires clear thought and a broad base of experience. It requires that one take extraordinary measures to protect information while preparing for the failure of the same measures. It also requires wider participation with other groups in the enterprise.

It is incumbent on those who are in a position of influence to push for a more comprehensive set of defenses. Success in the Internet age depends on building a robust infrastructure that avoids negative incidents and is positioned to recover from them as well. Risk management in the 21st-century will require adequate attention to both pre-event (avoidance and assurance) measures as well as post-event (detection and recovery) measures. While the task seems daunting, success will depend on application of techniques that are already well-understood — but lamentably underutilized.

Information Security in the Enterprise

Duane E. Sharp

The value of information to an organization cannot be overemphasized, particularly in today's knowledge-based economy. Information is probably *the* most valuable single asset of many organizations.

Corporate data assets are more distributed than in the past, both from a management and geographic location perspective. As well, the number of internal users requiring access to corporate data has increased and the traditionally solid IT perimeter has become much more easily accessed.

One objective of IT management is to provide high-value information services to its end users — its customers — in a timely fashion. Information is valuable in proportion to its timely availability and, in most cases, to its *secure* availability.

With a dizzying array of products and technologies available to provide secure information in various forms and in complex IT environments, the best solution is to develop a comprehensive security framework. This framework will integrate security in a cost-effective manner, subject to the needs of the entire enterprise.

Among the topics to be discussed in this chapter are the following:

- The need for security
- The requirements for implementing security
- Characteristics of an optimal security framework
- Key technology solutions to meet security requirements
- Building an effective security framework that matches technologies with requirements

The Need for Security: Accessing Corporate Data

In a number of geographic sectors of the globe, underground networks of hackers have developed and shared publicly some very sophisticated tools for intercepting and modifying data being transmitted over the Internet. These tools have even enabled successful interception of data behind the relative safety of the walls of corporate office buildings.

Some of the tools used for sniffing, hijacking, and spoofing are freely available on the Internet, a vast, loosely interconnected (and unsecured) network. Initially created as an open, accessible medium for the free exchange of information, it offers numerous opportunities to access data flowing through its global network. For example, a single e-mail message from one individual to a co-worker, buyer, vendor, client, doctor, patient, friend, or relative at a remote location may "hop" through several intermediate "nodes" before arriving at its final destination. At any point along the way, the contents of that e-mail could be visible to any number of people, including competitors, their agents, or individuals who would access the data for fraudulent purposes.

Over the past several years, the threat to organizations from hackers on the Internet has received wide publicity, as several major hacking incidents have interrupted the operations of both business and government. The fact is that although earlier surveys indicated that more than 50 percent of all intrusions occurred from *within* an organization, this trend seems to be reversing according to more recent analyses of hacking incidents.

These studies indicate that the majority of attacks are coming from *outside* the organization. It is not uncommon for such attacks to go unnoticed or unreported, so the statistics probably understate the seriousness of the threat.

In one recent analysis of 2213 Web sites of widely differing content, conducted by the Computer Security Institute, it was found that 28 percent of some commonly used sites were "highly vulnerable" to attack, 30 percent were somewhat vulnerable, and only 42 percent were considered safe. The sites surveyed were grouped into six categories: banks, credit unions, U.S. federal sites, newspapers, adult sites, and a miscellaneous group.

In another more recent study, companies reported annual increases of more than 35 percent in data or network sabotage incidents from 1997 to 1999. In this same survey, organizations reported annual increases of more than 25 percent in financial fraud perpetrated online. Insider abuse of network access increased by over 20 percent, resulting in losses of more than $8 million.

These studies point to the seriousness of the threat to organizations from financial fraud, through unauthorized access and use of corporate data flowing through the Internet and internal networks, and underline the requirement to provide a secure network environment.

Information Security Requirements

While security is a requirement at several levels in the handling of information, many security implementations focus on addressing a particular problem, as opposed to considering *all* levels. For example, most implementations have attempted to address problems such as authentication (ensuring that the users are who they say they are) or on protecting a specific resource such as the customer database. Taken by themselves, these solutions are often quite good at the job they do.

However, as with any assembly of unintegrated point products, these solutions will most likely be less than perfect, as well as being expensive to use and maintain due to their dissimilar user and administrative interfaces.

So, what should an information manager do to reduce the likelihood of significant loss from one of the enterprise's most valuable assets, without disrupting users, delaying current deliverables, and breaking the budget? The simple answer is: implement a comprehensive information security framework for the enterprise, one that stresses seamless integration with the existing IT environment; and implement it incrementally where it is most needed first.

Some of the specifics of a security framework are described later in this chapter. First, this chapter examines some of the requirements of an effective security framework and provides an overview of some of the techniques used to meet these requirements.

Primary Security Functions

The five primary functions of a good security framework include:

1. *Authentication*: to verify with confidence the identities of the users
2. *Access control*: to enable only authorized users to access appropriate resources
3. *Privacy*: to ensure confidentiality of communication among authorized parties and of data in the system
4. *Data integrity*: to ensure that communications, files, and programs are not tampered with
5. *Non-repudiation*: to provide undeniable proof that a certain user sent a certain message and to prevent the receiver from claiming that a different message was received

Functions such as virus protection are not specifically addressed because these are often combined with integrity, access control, and authentication functions.

Authentication

Authentication, the process of verifying the identity of a party or parties to an electronic communication, forces the party to produce proof of identity: something they know, something they have, or something they are. In situations where an individual is physically present to provide identification, these attributes can be provided through biometrics, a physical characteristic of the individual; for example, a fingerprint, voice print, or retinal scan. The first two categories are most commonly used because they are relatively inexpensive to implement.

In other situations where electronic communications are occurring without the facility to acquire a biometric form of identification, the easiest mechanism to implement is a simple password scheme. This mechanism forces the user to provide a known password in order to authenticate. To be effective, password authentication

requires the use of a secure channel through the network to transmit the encrypted password; otherwise, the password might be compromised by electronic eavesdroppers.

Passwords by themselves are not very secure. They are usually short and often easy to guess or observe, and they have been proven to be the weakest link in any system where a user participates in some form of digital commerce. Moreover, because users are increasingly being required to set numerous passwords for various systems, the tendency is to use a single password for all access requirements. They invariably either select from a very short list of known passwords or simply write down all passwords on a piece of paper near their computers. In either case, it is possible for someone to compromise several systems at once.

A cost-effective authentication scheme is to combine a password (something one knows) with an inexpensive smart-card token (something one has). A common example of this is the ATM (automatic teller machine) card. The ATM card is something an individual carries on their person, and the PIN (personal identification number) is something the individual knows. The combination provides improved protection (two-factor authentication) over just one or the other.

An important aspect of authentication is whether it is unilateral (sender authenticates to a server) or bilateral (user and server authenticate to each other). For example, using an ATM at a bank branch assumes that the ATM is legitimate. But can one be as confident when using an ATM sitting alone in a parking lot? There have been well-documented cases of thieves constructing extremely convincing but fraudulent ATMs in parking lots. Dozens of ATM card numbers and PINs, as well as cash, have been taken from unsuspecting customers. While these cases are admittedly rare, they do demonstrate the importance of *bilateral* authentication.

In an electronic environment, public key cryptography systems (usually referred to as PKI, for public key infrastructure), combined with digital certificates, provide a straightforward, secure mechanism for bilateral authentication. The success of public/private key systems and the trustworthiness of digital certificates lie in keeping the private key secret. If an individual's private key is stolen or accessed by an unauthorized party, then all communications to or from that person are compromised. The storage of private keys on PCs throughout an organization becomes a serious security risk. Because the private key is held on an individual's PC, the user must be authenticated on that PC to achieve security. The strongest security systems will store this information on a smart card and will require a PIN for access.

Access Control

Access control (or authorization), as the name implies, deals with ensuring that users only have access to appropriate resources (systems, directories, databases, even records) as determined by the security policy administrator. Technologies commonly used to enforce access control include trusted operating systems through the use of access control lists (ACLs), single sign-on products, and firewalls. Single sign-on products enable a user to authenticate to the environment once per session. The user will thus be authorized to access any of the appropriate resources without the need for additional authentication during that session.

Privacy

Privacy is the cornerstone of any security environment. Although the definition of privacy can vary significantly between users and owners, privacy issues are important for data with financial, personnel, or research value. Even on a corporate intranet, the privacy issue is important. However, extranet sites often face the greatest challenge in handling data because individuals and corporate data must be protected while multiple corporate entities are provided with some level of access to the data.

Depending on its sensitivity, information must be rendered indecipherable to unauthorized people, whether stored on disk or communicated over a network. Privacy can be implemented through physical isolation. In today's computing environments, however, this is generally too inefficient for most users. The ideal solution for most enterprises is to implement a decentralized cryptographic environment enabling users to maintain and exchange encrypted information.

The entire set of trust requirements for E-security (security of electronic data) builds on the foundation of encryption. There are numerous cryptographic systems available, both asymmetric and symmetric. However, asymmetric coding procedures typically have a severe disadvantage: they are computationally very expensive in comparison with symmetric procedures.

To minimize this problem, fast symmetric coding systems are usually combined with slower asymmetric ones, and a combination of public and private keys is used to decode and decrypt the message. In a secure environment, each user is assigned a user name, together with a public and private key. The public key is

published, that is, made available to all interested parties, together with the user name; the private key is only known to its key holder.

There are also efficient procedures to protect the integrity of information, by generating and verifying electronic signatures, combining asymmetric encoding with checksum algorithms, which are efficiently and easily implemented.

An interested partner can now authenticate the key holder through the capability of adding an electronic signature to data elements. However, this only ensures that the partner corresponds to that key; authentication of the partner by name requires a mechanism to guarantee that names and public keys belong together. The problem is comparable to that of a personal identity card, in that a match between the partner and the photo on the identity card does not mean that the partner's name is actually that shown on the identity card.

The idea of the identity card can be carried over to an electronic form. The corresponding "identity cards" are called certificates, which attest to the public key-name pair. It is also possible to distribute pairs of names and keys to the partners via secure channels and store them with write protection. If there are few subscribers, the names and public keys of all possible communication partners can be stored in a table in the electronic message handling system. To avoid a man-in-the-middle attack, it is necessary to ensure that the names and public keys actually belong together. In practice, this means that the pairs of names and keys must be distributed via secure channels and stored in the systems with write protection.

Data Integrity

Integrity involves the protection of data from corruption, destruction, or unauthorized changes. This requirement also extends to the configurations and basic integrity of services, applications, and networks that must be protected. Maintaining the integrity of information is critical. When information is communicated between two parties, the parties must have confidence that it has not been tampered with. Conceptually similar to checksum information, most cryptographic systems provide an efficient means for ensuring integrity.

Non-repudiation

This requirement is important for legal reasons. As more and more business, both internal and external, is conducted electronically, it becomes necessary to ensure that electronic transactions provide some form of legal proof of sender and message received when they are completed. This requirement goes hand-in-hand with the need to verify identity and control access.

IT Requirements

A good security framework must implement the functions discussed in the preceding chapter section, while at the same time supporting the following requirements:

- The varying security robustness requirements throughout the enterprise
- Integration with point security products such as security gateways and firewalls already in place in the IT infrastructure
- The heterogeneous platforms, applications, networks, networking equipment, and tools found in all IT departments
- The availability and performance requirements of the users and system administrators
- Cross-departmental, cross-geographical, and potentially inter-enterprise interaction
- The ease-of-use requirements of the users
- Flexible and cost-effective implementation under the control of the IT organization
- Stepwise implementation and deployment throughout the enterprise

The best security is transparent to the user community. When a dignitary makes a public visit, the security agents one actually sees are generally only a small fraction of the security forces deployed for that person's protection. Information security should also be largely invisible to the user community and most of the security framework should be behind the scenes.

In the open system environments commonly found in IT departments, transparency can be problematic. Consuming technology from multiple vendors enhances the value of a solution by enabling selection of best-of-breed technology and by creating competition. It is important, however, that technologies from multiple vendors fit together seamlessly, based on open standards, or this benefit is lost in the integration effort.

Ultimately, the IT organization "owns the problem." Rather than buying a number of unintegrated security "point" products such as firewalls and smart cards, it is better to implement an integrated security framework. Framework components would be designed to inter-operate seamlessly, using standard programming interfaces, with each other and with the existing IT application base. The products may still come from multiple sources, but they should plug into a framework that represents the requirements of the entire enterprise.

In today's electronic economy, organizations need to communicate transparently with other organizations, a factor that has contributed to the commercial explosion of the Internet. The world's networking environment is now laced with intranets and extranets, many of which are interwoven with the Internet, that enhance the capabilities of organizations to communicate with each other. Throughout all of these networking environments, the security of data must be maintained.

The following components form the essential framework of an integrated, comprehensive, security system, designed to protect corporate data from unauthorized access and misuse.

Encryption: The Key to Security

Encryption refers to the process of transforming messages and documents from cleartext to ciphertext using a secret code known only to the sender and the intended recipient. Decryption is the inverse process — restoring the cleartext from the ciphertext. There are a number of methods available for document encryption. These generally fall into the categories of symmetric and asymmetric cryptography.

Symmetric key structures, such as the Data Encryption Standard (DES), use a single key shared between sender and receiver. This key, when applied to the cleartext, yields the ciphertext and, when applied to the ciphertext, yields the cleartext. With symmetric keys, both the sender and receiver must share the same key. Symmetric keys tend to perform well, but the sharing protocol may not scale well in a large environment as more and more users need to communicate encrypted information to one another.

Asymmetric key structures use a public and private key-pair, a different key to encrypt and decrypt. The significance of public key encryption technology is that only the user has access to his private key; that user gives out his public key to others. Other people encrypt documents with the public key for communication to the user, and the user encrypts the documents with his private key.

There is a strict inverse mathematical relationship between public and private keys that ensures that only the user with his private key can decrypt messages encrypted with his public key. As well, with that private key, the user with his private key could have encrypted messages, while other people can decrypt with his public key. This characteristic enables the use of keys to "sign" documents digitally.

Strong Encryption: A Necessary Requirement

One security technology in widespread use today, so much so that it has become a *de facto* standard, is the RSA strong public/private key-pairs with digital certificates. Strong encryption refers to the use of encryption technology that is nearly impossible to break within an amount of time that would enable the information to be of any value. The distinction is made between strong and weak encryption, due in part to the running debate over restrictions the U.S. Government has placed on the exportability of message encryption technologies.

The technology of providing strong encryption is considered a munition and its export from the United States is, for the most part, prohibited. The export of weaker encryption is permitted with certain restrictions.

Cleartext e-mail messages and other documents sent over the Internet can be intercepted by hackers, as experience shows. If encryption is the solution, then what prevents a hacker from guessing someone's key and being able to decrypt that person's encrypted messages? In most cases, nothing more than time.

One method used by hackers is to take a sample of cleartext and corresponding encrypted text and repeatedly try random bit sequences by brute force to reconstruct the key used to encrypt the text. Therefore, all the hacker needs is a fast computer or network of computers working together and samples of the clear and encrypted texts. To protect against these brute-force attacks, cryptographic keys must be "strong."

Assessing the Strength of an Encryption System

In a strong encryption scenario, the hacker's strategy will be to use high-powered computing resources to try to crack the encryption key. The solution to this hacking process is to generate sufficiently large keys such that it will take the hacker too long to break them. It is important to remember that computing speeds are doubling roughly every 18 months. The size of a key must be large enough to prevent hacking now and in the future. Also, one does not want to have to change one's key very often.

How large should a key be? Strong encryption means encryption based on key sizes large enough to deter a brute-force attack. Thus, hackers using even a large number of powerful computers should not be able to break the key within a useful amount of time; that is, on the order of many, many years. Key sizes of 56 bits or less are considered weak. Key sizes in excess of 128 bits are considered very strong. One rule of thumb for key sizes is that keys used to protect data today should be at least 75 bits long. To protect information adequately for the next 20 years in the face of expected advances in computing power, keys in newly deployed systems should be at least 90 bits long.

Key Management

Managing keys securely is extremely important and there are a number of products from the security industry that address this issue. Most attacks by hackers will involve an attempt to compromise the key management versus the keys themselves, because a brute-force attack would require a long time to break a key with 128 or more bits.

There are several key management considerations for users. They must be able to:

- Create or obtain their own keys in a highly secure and efficient manner.
- Distribute their keys to others.
- Obtain other people's keys with confidence in the identity of the other party.

Without secure key management, a hacker could tamper with keys or impersonate a user. With public/private key-pairs, a form of "certification" is used, called digital certificates, to provide confidence in the authenticity of a user's public key.

Using Keys and Digital Certificates

Digital certificates must be secure components in the security framework. That is, it must not be possible to forge a certificate or obtain one in an unsecured fashion. Nor should it be possible to use legitimate certificates for illegitimate purposes. A secure infrastructure is necessary to protect certificates, which in turn attest to the authenticity of public keys.

One of the important functions of the certificate infrastructure is the revocation of certificates. If someone's private key is lost or stolen, people communicating with that individual must be informed. They must no longer use the public key for that individual nor accept digitally signed documents from that individual with the invalid private key. This is analogous to what happens when one loses, or someone steals, a credit card.

When keys are generated, they receive an expiration date. Keys need to expire at some point or they can be compromised due to attrition. The expiration date must be chosen carefully, however, as part of the set of security policies in force in the environment. Because other users must be made aware of the expiration, having keys expire too frequently could overload the certificate and key management infrastructure.

Digital Signatures and Certification

Encryption works to ensure the privacy of communication; but how is authentication handled? That is, how can a person, as the receiver of a document, be sure that the sender of that document really is who he says he is? And vice versa? The authentication of both parties is accomplished by a combination of a digital signature and certification mechanism.

A digital certificate from a mutually trusted third party verifies the authenticity of the individual's public key. This party is the Certificate Authority (CA), and operates in a similar manner to a notary public in the nonelectronic world. The certificate contains some standard information about the individual and holds that individual's public key. The CA digitally "signs" the individual's certificate, verifying his or her digital identity and the validity of his or her public key.

Digital signatures have legal significance for parties to an electronic transaction. Encrypting creates the signature using the private key of the signatory, information that is verifiable by both parties. The signature provides proof of the individual's identity: only the owner of the private key could have encrypted something that could be decrypted with his or her public key.

In the case of the CA signing a digital certificate, the CA uses its private key to encrypt select information stored in the digital certificate — information such as the person's name, the name of the issuing CA, the serial number and valid dates of the certificate, etc. This information is called the message authentication code (MAC). Both the sender and the receiver of the transmission have access to the certificate; thus, the MAC information is verifiable by both parties.

Anyone can verify a digital certificate by fetching the public key of the CA that signed it. When sending an encrypted document, one exchanges certificates with the other party as a separate step from the actual document exchange, to establish trust and verification.

As an example, consider a two-party exchange of private messages between Jane and Sam, and the mutual verification process. If Jane wants to send an encrypted document to Sam, she first gets Sam's digital certificate, which includes his public key signed by his CA. Jane also gets the CA's public key to verify the CA's signature, and now has confidence that the public key she has does indeed belong to Sam, because the CA's private key was used to sign it. Sam invokes a similar procedure when he receives Jane's certificate.

Of course, most of the work in this process is software controlled, transparent to the user, and, given current technology, performs with nearly imperceptible delay.

Certification Infrastructure

The previous description of a transaction between two parties describes the public key cryptography and certification process. This is a simplified example because even within the same enterprise, security policy might dictate segregating certificate management along departmental or geographic lines to provide a fine-grained level of security control and accountability.

One solution to this problem is to have a single master CA issue all certificates throughout the world. This business model has been attempted; however, the CA quickly becomes a bottleneck for organizations needing fast access to hundreds or thousands of certificates. An important fundamental in the security foundation is the capability to control one's own resources. A critical responsibility such as managing certificates should not be left to third parties.

One solution that some organizations have adopted is to establish a hierarchical certification infrastructure. A single "Top CA" within the organization is identified to certify the lower level user or departmental CAs (UCAs). The Top CA maintains certificate revocation lists (CRLs) for the organization, but would otherwise not be involved in day-to-day certificate management. The UCAs handle this stage in the certification process. Outside the organization, a top-level CA is appointed, the Policy Certificate Authority (PCA), who certifies all Top CAs and manages inter-organization CRLs to provide trust between enterprises. Finally, all PCAs in the world are certified by an Internet PCA Registration Authority, ensuring trust between certification infrastructures.

Implementing the Enterprise Security Framework

Implementing an enterprise information security environment is a major, complex task, one that will be different within each enterprise. The implementation should be done in stages, with the first stage being to establish a set of security regulations and a design for the framework, both of which need to be structured to meet both current and future needs as well as budgetary considerations. Consideration must also be given to the inter-enterprise requirements: who are the vendors, partners, and customers involved in the exchange of electronic data? In what order of priority does one wish to secure these communications?

The following chapter sections provide a reasonably comprehensive description of the tasks generally involved in implementing a secure IT environment for the enterprise.

The Security Audit

The security implementation should begin with a security audit by a qualified firm. The roles of the audit are to:

- Map out the current IT environment.

- Understand all aspects of the security mechanisms currently in place — physical security as well as software and hardware solutions.
- Obtain a detailed and confidential analysis of security breaches that have or may have already occurred.
- Provide an assessment of the current security mechanisms with specific emphasis on deficiencies as compared with other organizations.
- Provide an independent assessment as to the root causes of previous incidents.
- Provide recommendations for improvements to the security infrastructure.

Business Analysis and Development of Security Policy

The next step is to conduct an in-depth security analysis along with a business analysis based on the audit findings. Then a set of security policies to meet the needs of the enterprise can be developed. The security framework will be adapted to adhere to these policies. This process encompasses the following multi-stage process:

1. *Establish the organizational relationship between security personnel and the IT organization*. Is there a separate security organization; and if so, how are its policies implemented in the IT organization? What is the security budget, and how are resources shared?
2. *Define the security and IT distribution models*. Does the headquarters organization set policy and implement at all sites, or do remote sites have authority and accountability for their own IT environments?
3. *Understand the security goals at a business level.* Determine the key resources requiring protection and from whom. Who are the typical users of these resources, and what do they do with them? What auditing mechanisms are in place, and what are the physical isolation versus hardware/software considerations?
4. *Assess the IT-vendor business issues*: dealing with a single vendor versus several, buying product and service from different vendors, experience with training and support, etc.
5. *List the applications, data files, and server and client systems* that need to be enhanced with security.
6. *Plan the current, near-term, and longer-term IT environment*: addressing issues such as major data flows between business components, platform, hardware, network topology, third-party electronic interaction requirements, space planning, and physical security.
7. *Propose a high-level security paradigm* for defining and controlling access to corporate data, for example, access control server with firewall, smart-card tokens versus single-factor authentication, centralized versus peer-to-peer certification, etc.
8. *Develop a high-level set of security policies for the enterprise*, including site security personnel, access control, certification, and the interaction of the security infrastructure with other enterprise resources.
9. *Analyze and document key dependencies* within the security framework and between the framework and the applications.

Project Planning

Once high-level security policies and a framework have been established, the project plan will have a basic structure. The next stage is to break down the framework into tasks that can be sized, cost-justified, and scheduled for delivery and deployment.

There is no single, definable approach to the planning phase — it will consume resources from potentially many different groups. There are various trade-offs that can be made in terms of an implementation model, such as cost based or complexity based. A project manager should be identified at this stage. This individual should have a broad technical background in IT development projects and a fairly deep knowledge of security implementations.

Selecting an Implementation Model

It is difficult to advise on the selection of an implementation model because so much depends on other work going on in the IT organization. For example, if the organization is about to embark on a major software program, implementing a thorough security program would be a prudent approach because all systems may be open for modification and enhancement with security components. Conversely, if resources are already over-allocated, few large security-related programs can be implemented.

A recommended guideline for rolling out a security implementation is to proceed in stages from a localized client/server (group) level, to a site-wide deployment, to the full enterprise, and finally to an inter-enterprise configuration. At each stage, the issues can be tackled in a similar manner. For example, it might be best to start by installing a basic authentication and access control implementation that provides basic security for individual devices and the network perimeter.

The next stage would be an enhanced level of authentication and access control with centralized services at the network level, as well as a cryptographic environment for privacy and integrity. Finally, truly robust security can be provided at the network perimeter and inside the network with access control, strong cryptography, certification, token management, and non-repudiation.

It is good design practice to start the design form with legacy systems because:

- These systems tend to transcend the many organizational changes common to business today.
- They are often at the core of the business.
- Modifying these applications may be sufficiently onerous that it is considered a better strategy to "surround" the system with security, versus adding it in.

There are two basic approaches to the development of a security framework. One approach is to begin with the servers and work outward. This approach has the advantage of integrating security into the enterprise at the primary data source. However, for a decentralized IT organization, a better approach might be to build up the levels of security from the clients inward.

One technique that can be used for the client-inward approach is to incorporate smart-card readers into all client PCs up front and require local authentication via the smart card. This functionality could later be expanded to provide single-sign-on access to the network and other features. The disadvantage of this approach is that the client side is difficult to measure, in terms of numbers, because it is usually a changing number, as clients may be added, removed, or receive software upgrades fairly frequently in some organizations. This approach may not catch strategically important server data, which needs protection.

Skills Assessment

Once the implementation model is chosen, a skills inventory needs to be developed. This inventory of skills will be used to determine the appropriate staff resources available and the training requirements. The use of open, standards-based security tools is essential in minimizing the need for extensive training in a proprietary environment.

It is advisable to prepare a high-level workflow diagram to identify the affected organizations requiring representation on the project teams. All affected organizations should be identified and staffing resources within each organization nominated. If physical equipment isolation requiring space planning is required, for example, building operations may need to become involved.

At this stage, project teams can be formed with representation from IT and other organizations. To ensure that all departments have input to the security framework design, end-user departments should have representatives on project teams.

Sizing and Resource Planning

The next major stage in the design process is to prepare project sizing estimates and a resource plan. This is the point at which the security framework project should dovetail with any other planned IT projects. A complete IT budget and staffing plan review may be necessary. In some cases, project priorities will need to be adjusted. The security implementation sub-tasks should be prioritized in groups, where dependencies were identified in the framework, to ensure that the priorities are consistent.

As for any major IT project, price/performance trade-offs within a sub-task need to be analyzed. In the analysis of business requirements and the development of security policy performed previously, the determination might have been made that the enterprise had numerous physically isolated resources, relative to the threat of attack. In this situation, a hardware/software technology solution might better optimize resources across the enterprise, while still providing more than adequate security.

Local authentication processes can range from simply verifying the user's network address to sophisticated biometrics with varying degrees of robustness and cost.

It is also important to evaluate price-performance trade-offs for hardware/software combinations. It might, for example, be more cost-effective to implement a Windows NT®-based firewall and accept somewhat less performance scaling than to use a more powerful UNIX product. These decisions will be influenced by the technical skill sets available within the IT organization.

Selecting the Technology Vendor

Once high-level security policies and the project plan have been established, it is time to approach the security product vendor community to assess product offerings. A system integrator may also be required to supplement the local IT resources and ensure the proper interface of all components. RFPs and RFIs for security products can be quite extensive and should include the following criteria, which are the most important characteristics required from a security product vendor:

- *Performance, scalability.* How much delay is incurred in implementing security, and how does the solution scale as users and resources are added to the system?
- *Robustness.* How secure is the solution against a complex attack?
- *Completeness.* How broad and deep is the solution, and for what type of environment is the solution best suited?
- *Interoperability.* How well does the solution integrate into the proposed environment?
- *Support, availability.* How available is the solution, and what are the support and maintenance characteristics?

In support of these five basic and fundamental characteristics, the following set of extensive questions on vendor products should form part of the vendor evaluation process, along with any other concerns involving a specific IT environment.

1. Which of the five primary security functions — access control, authentication, privacy, integrity, and non-repudiation — are provided by the products, and how do they work?
2. Describe the types of attacks the products are designed to thwart.
3. What is the level of network granularity (client only, local client/server, site-wide, full enterprise, inter-enterprise) for which the products are best suited?
4. What type, if any, of encryption do the products use?
5. Does the encryption technology ship from the United States? If so, when messages travel between countries, is encryption "weakened," and down to what level?
6. Do the products use certification and signing? Describe the architecture.
7. Who conducted the security audit? Present the results.
8. To what standards do the products conform, and where have proprietary extensions been added?
9. With which third-party security offerings do the products inter-operate "out of the box"?
10. How precisely do the products interface with one's existing security products, such as security gateways and network managers? Where are modifications required?
11. On which of the proposed platforms, applications, and tools will the products work without modification?
12. Does the product function identically on all supported platforms, or will separate support and training be required?
13. What are the availability levels of the products (e.g., routine maintenance required, periodic maintenance required (7×24)?
14. How are the products managed, and can they be easily integrated with the rest of the proposed system and network management infrastructure?
15. Is the product support provided by the vendor, or is it outsourced? Will the vendor support mission-critical environments around the clock?
16. Do the products support cross-departmental, cross-geographical, and potentially inter-enterprise interaction? How exactly? Does the vendor have reference sites available with this functionality running? How easy are the products to use based on references?

17. Does one need to deploy the products all at once, or can they be phased in? That is, do the products run in a hybrid environment, enabling communication, for example, between secure and unsecured users?
18. Provide quantitative information on the scalability of the solution as users and secured resources are added.

Implementation and Testing

The project implementation will always reveal issues not identified in the planning stages. For this reason, it is important to develop a well-thought-out framework for the implementation, and to choose manageable, well-defined tasks for the project plan. As the implementation progresses from design to development, testing, and eventually deployment, it is important that new requirements not be introduced into the process, potentially resulting in major delays. New requirements should be collected for a revision to the project that would go through the same methodology.

When the project has exited the testing phase, to ensure a smooth transition, a localized pilot test that does not interfere with mission-critical systems should be performed. The pilot should match as closely as possible the live configuration in a controlled environment and should last as long as necessary to prove the technology, as well as the processes and practices used in developing the security framework.

Conclusion

The major stages of an IT security implementation — audit, requirements analysis, framework construction, project planning, and implementation — have been described in this chapter, with a focus on some of the approaches that can be used to implement a security framework, as well as some of the key issues to consider.

This chapter on enterprise security provided an overview of the security requirements needed to protect corporate information from unwarranted access, and a detailed process for designing and implementing an enterprisewide security framework. Some of the solutions available to implement this security framework were described, along with recommendations for the appropriate processes and guidelines to follow for a successful, effective implementation.

The security of information in the enterprise must be viewed from five perspectives:

1. Authentication
2. Access control
3. Privacy
4. Integrity
5. Non-repudiation

An effective enterprise security framework will integrate these functions with the existing IT environment, and the final system will have the following characteristics:

- Flexible enough to provide IT management with the capability to control the level of security
- Minimal disruption to users
- Cost-effective to implement
- Usable in evolving enterprise network topologies, spanning organizational and geographic boundaries; the security framework must also provide interoperability with organizations outside the enterprise

Managing Enterprise Security Information

Matunda Nyanchama, Ph.D., CISSP and Anna Wilson, CISSP, CISA

Today's business and computing environments have blurred traditional boundaries between what is considered trusted and untrusted. As a result, organizations are taking measures to protect their information assets. Information from various sources in an organization's network is key to managing security. Such information comes from a number of security devices (intrusion detection systems and firewalls), operating systems, and network devices such as switches and routers.

In general, each of these devices performs a function that contributes to the overall enterprise needs and hence its security posture. Moreover, each of these technologies has a responsibility in the overall security management of the computing environment. Collectively, these devices produce a large amount of information.

The challenge before us is to make sense of all this information and to mange it in a way that is useful in protecting the computing environment, and in a manner that will benefit the entire enterprise. To achieve this, one must first understand the technology one is dealing with, how it collects and interprets information, and at what point one needs to intervene in the overall process. Having this understanding will allow one to set out the best strategy in one's approach to the management of enterprise security information.

This chapter discusses issues pertaining to challenges of managing security information for purposes of improving an organization's security posture through aggregation, analysis, and correlation.

This chapter discusses the sources of information that are useful for security management and the nature of the information they produce. Among technologies discussed are intrusion detection systems (IDSs), firewalls, routers, switches, and operating systems. Also explored are their primary function in security management, the manner in which they collect information, and how this information can be analyzed, collectively, to offer an enterprisewide security view. Ways of collecting this information and how it informs the security management process are also discussed.

Having this appreciation, one can look into the various strategies available in the overall management of this security information. In addition, there is a quick overview of the issues of security management and the challenges for managing this information in a manner that raises security effectiveness. This knowledge is intended to empower security information security practitioners in planning the most effective way in which to blend technology and man, ongoing efforts to keep business environments secure.

The material in this chapter should be read in conjunction with suggested references. In discussing various network and security technologies, the authors do so with a view to understanding the nature of information they produce and how this information can be used to ensure enterprise security. Specific technologies are not discussed in sufficient detail to make this chapter a stand-alone technical reference with respect to the said technologies. However, the chapter does include discussions of the following:

- The need for and sources of enterprise security information, including:
  - — IDSs
  - — Firewalls
  - — System logs
  - — Switches and routers

Some strategies for enterprise security management are discussed; these include approaches to collection and analysis strategies. The section also touches on the challenges of associating vulnerability data to business risk. The final section offers a summary and pointers to future challenges for managing security information.

Sources of Enterprise Security Information

This chapter section focuses on the need for security information, sources of such information, and how this information helps with the management of enterprise security. Understanding the need to collect security information is important because it is this need that determines the nature of desirable information, the means of collection, and the necessary manipulation that helps in security management.

The Need for Security Information

The past decade has seen tremendous growth of issues of information security, including technology, skilled professionals, and security-related information. This growth, spurred by the central role computers and networking continue to play in all aspects of daily endeavors and commerce, has resulted in reaches beyond physical boundaries. Networking has extended this reach into areas outside organizations' and individuals' immediate control. Further, it has contributed to the development of today's commercially available security technologies, in an effort to assert control over one's "territory."

On the other hand, networking has resulted in complex systems composed of differing network devices. The ensuing systems produce information used in the ongoing management of the networks and computing resources. This information must be analyzed to better understand the environment in which it is produced.

On the whole, security information forms a component of the total information produced in entire systems within organizations. Such security information is important for making security-related decisions, without which the situation would be tantamount to getting behind the steering wheel of a car, blindfolded, and hoping for the best. The value of information from security systems and devices is useful for making informed, cost-effective choices about how best to protect and manage computing environments.

Be it an audit log, firewall log, or intrusion information, such information is useful in many different ways. It can be used for performing system audits to determine the nature of activity in the system. It can also be used for the diagnosis required from time to time, especially in cases of a security incident; and is also useful for forensic analysis, which forms a core component of incident resolution. In general, security information is useful to determine an enterprise's security.

Sources of Security Information

To be effective, information security management requires varied pieces of information across an enterprise. This information that originates from various sources contributes to an enterprise's information security jigsaw puzzle. Each piece of information is useful for what it reveals. Aggregation of these information pieces contributes to a better understanding of the overall security posture.

Perhaps the most familiar source of security information is operating system logs. Operating system logs have been a common feature of computers for a long time, even before security administration became entrenched as it is today. During this time, system administrators have used system logs to manage computing environments, specifically pertaining to determining who was doing what, where, and when, in a fairly detailed manner.

With the growth of inter-networking, the need to connect internal networks to other external networks has continued to grow. Invariably, connecting to untrusted networks creates a need to control communication between internal and external networks. This is the role filled by the use of firewalls as they act as gateways between internal and external networks. Firewalls are a common feature in today's networking. And just as operating systems produce logs pertaining to system activity, firewalls track activity at the gateway.

With operating system logs recording activity on systems and the firewalls controlling and logging activity through the gateway, one might assume that a network would be secure against external attacks. Right? Not exactly! This is because those who venture on the dark side are also pretty clever. They have a knack of getting around established defenses and backdoors, exploiting weaknesses in communication protocols, applications, and operating systems.

This creates a need for intrusion monitoring to supplement the firewalls defenses. Intrusion detection systems (IDSs) provide information about flagged events on systems and networks. IDSs track suspicious

network activity, which may indicate attack attempts, probing, or successful intrusion. Information provided by an IDS may reveal missed or unforeseen weaknesses or holes in internal systems and the gateway. This affords the opportunity to harden or close the exposures caused by the security weakness and holes.

Systems, firewalls, and IDSs play different but complementary roles in enforcing security. Each of these is responsible for a specified role in the computing infrastructure. In practice, however, their boundaries may not be as distinct as may be suggested here. And given the different roles they play, there exist differences in the type of information they produce, the way it is collected, and how it is analyzed and interpreted.

Security information also comes from routers and switches in a network. Routers and switches play a critical role in networking and are critical to the availability of infrastructure segments.

When combined, this information from diverse sources provides a holistic picture of enterprise security. The resulting aggregation benefits from the power of correlation and may yield useful patterns and trends in a manner that informs the security management process. For example, such information can improve the management of security incidents and ensure that lessons learned will help improve future management of similar incidents, helping shift the management of incidents from a reactive to proactive mode.

Security information, if used and managed appropriately, can offer the prescription for the total security "health"[1] of our computing environments.

Intrusion Detection Systems (IDSs)

This chapter section focuses on IDSs, what they are, and their role in the management of enterprise security. IDSs can be seen as devices that monitor the pulse of the enterprise health. They depend on anomalies and known attacks to raise alarms about potential attacks and intrusions. They are limited to the extent that they can recognize anomalies or associate an activity to a known attack based on activity signature.

Introduction

IDSs play an important role in the monitoring and enforcement of security in an enterprise. They are usually deployed at vantage points where they detect activity and take action as desired, including logging the associated activity, raising an alarm or a pager, or sending an e-mail message to specified users for attention.

IDSs detect flagged activity that is deemed suspicious for which they generate specified action. Whether monitoring traffic on a network or watching for suspicious changes on a specific host, IDSs form part of the "active security" components in an organization.

IDSs continue to evolve as they face ever-growing security challenges. These challenges include keeping up with hacker exploits that evade IDS detection. IDSs must also contend with denial-of-service attacks intended to bring them down.

In general, intrusion detection technology is relatively young. Although there are minor differences among security professionals as to what constitutes an IDS, there is substantial agreement on the role that IDSs play in enterprise security management. Further, there is concurrence on the need for analysis of IDS information as an aid to security management. In general, IDSs are a major source of information which, when analyzed and acted upon, helps improve enterprise security.

An ideal IDS has several automated components that define its functionality, including:

- Providing information about events on a computer system or network
- Analyzing the information in a manner that aids the security process
- Logging and storing security-sensitive event information for future use, specifically for making improvements
- Acting on that information in a manner that improves security
- Performing all of the above in a flawless and timely manner

The above list is an ultimate IDS dream for all security professionals. Whether such a system exists is a matter for another discussion.

There are two key approaches to IDS monitoring. These include knowledge-based and anomaly detection IDSs. Moreover, there are two key strategies for IDS deployment; that is, on the network or on a host. These are discussed individually, along with an overview of incident response, given the close relationship between IDS and incident response.

Knowledge-Based Intrusion Detection Systems

Misuse detection-based IDSs, also called knowledge-based IDSs, are the most widely used today. Such IDSs contain accumulated knowledge about known attacks and vulnerabilities based on signatures. Using this knowledge base of attack signatures of exploits, the IDS matches patterns of events to the attack signatures. When an attack attempt is detected, the IDS may trigger an alarm, log the event, raise a pager, or send an e-mail message.

Knowledge-based IDSs are easy to implement and manage due to their simplicity. They are very effective at quickly and reliably detecting attacks. With continued tuning and update of signatures, it is possible to lower the false alarm rate. In the process, this enables security professionals to respond to incidents very effectively, regardless of their level of expertise.

There is a downside to misusing detection-based IDSs; they are most effective when the information in their knowledge base remains current. The predefined rules or attack signatures must be continuously updated. Moreover, there is usually a time lag between the time an exploit is publicized and when an associated attack signature is available. This leaves a window of opportunity for a new, undetectable attack. Such IDSs can be seen to be blind to potentially many attacks that they do not "know" about, especially where there is a substantial time lag in the update of the IDS' knowledge base.

Anomaly Detection (Behavior-Based IDS)

Anomaly detection, or behavior-based, IDSs operate on the premise of identifying abnormal or unusual behavior. Anomalies on a host or network stand apart from what is considered normal or legitimate activity. These differences are used to identify what could be an attack.

To determine what an anomaly is, systems develop profiles representing normal user activity on hosts or networks over a period of time. The system collects event data and uses various metrics to determine if an activity being monitored is a deviation from what is considered "normal behavior."

To determine such normal behavior, some, all, or a combination of the following techniques are used:

- Rules
- Statistical measurements
- Thresholds

However, these systems are subject to false alarms because patterns of activity considered to be normal behavior can change and vary dramatically.

The key advantage of behavior-based IDSs is that they are able to detect new attack forms without previous specific knowledge of the attacks. Further, there is the possibility of using the information produced by anomaly detection to define attack patterns for use in knowledge-based IDSs.

Host-Based Intrusion Detection Systems

Host-based IDSs are installed on specific hosts on which they perform monitoring. A host-based IDS can be seen as system specific. It uses the system's audit, system, and application logs for IDS information. Using the system's various logs lends to the quality of the information available to the IDS. Given that it is dealing with a specific operating system, the accuracy of the associated information will be substantially high because the operating system retains a good sense of activity on the host on which it is installed.

A host-based IDS responds when flagged events happen on the host. These events could pertain to file changes, privilege escalation, or any such activity deemed security sensitive. This makes a host-based IDS very effective in detecting integrity attacks. Using an operating system's audit trails, a detected inconsistency in a process could be an indication of a Trojan horse or some other similar attack.

Additional advantages of a host-based system include the ability to detect attacks that go undetected by network-based systems. Depending on where information sources are generated, host-based systems can operate in environments in which network traffic is encrypted. Where switching technology is utilized on a network, host-based systems remain unaffected.

Host-based IDSs suffer some drawbacks. Given that they are usually designed for specific systems and applications, host-based systems may not be very portable. Moreover, an IDS that supports one platform may not support another. In a complex environment in which there are varied systems and applications, there may be a temptation to install a different host-based IDS on each of the systems. This would result in a complex

environment with many different IDSs, which, in turn, presents a challenge in the monitoring and management of all the resulting information from the diverse systems.

Despite these disadvantages, a host-based IDS remains an important tool, as the resources on those hosts are the targets for many attackers — which leads to yet another disadvantage. Suppose a specific host on a network running an IDS is under attack. What will be the first target on that host?

Network-Based Intrusion Detection Systems

A network-based IDS monitors network traffic in the network segment on which it is installed. It functions by analyzing every packet to detect any anomalies or performing pattern matching against captured packets based on known attack signatures. Based on the information in the packet, the IDS attempts to identify anything that may be considered hostile or patterns that match what may have been defined as hostile activity.

Packet analysis presents a challenge in that the information may no longer be as revealing as in the host-based system. Indeed, a substantial degree of inference is required to determine whether observed patterns or detected signatures constitute hostile activity. This is because one can determine the physical source of a packet but one may not know who is behind it.

Network-based IDSs have some key advantages, including their nonintrusive stealth nature. As well, unlike host-based IDSs that may impact hosts on which they reside, network-based IDS performance does not impact systems. As well, network-based IDS packet analysis is beneficial over the host-based system when under some type of fragmentation attack.

One major disadvantage of network-based IDSs is the inability to scale well with respect to network traffic. The ability to inspect every packet under high traffic conditions offers a challenge to IDSs. The result is packet loss. Where such packet loss is substantial, there may be less IDS information to manage but that information may be critical to the desired security.

After examining the pros and cons of the various IDS technologies, one can clearly see that the most effective use of an IDS would be to use some combination of all.

IDS Selection and Deployment

The selection and deployment of an IDS must take a number of factors into consideration, including the:

- Purpose for which it is intended: host- or network-based intrusion detection
- Ability to scale up to high volumes of traffic if it is a network-based IDS
- Scope of attack signatures, where it is knowledge-based, or the ability to perform accurate anomaly detection

Other factors that determine deployment include the volume of information being analyzed, the degree of analysis desired, and the significance of the intrusions or attacks one wants to monitor.

The physical location of an IDS is determined by the type of activity intended to be monitored. Placing a network-based IDS outside the security perimeter (e.g., outside the firewall) will monitor for attacks targeted from outside, as well as attacks launched from inside but targeted outside the perimeter. On the other hand, placing an IDS inside the security perimeter will monitor for successful intrusions. Placing the IDS on either side of the firewall will effectively monitor the firewall rules (policy), because it will offer the difference between activity outside the firewalls and successful intrusions.

In deploying an IDS, one must select the mode of operation, which can be either real-time (in which IDS information is passed in real-time for analysis) or interval-based (also known as batch) mode (in which information is sent in intervals for offline analysis). Real-time analysis implies immediate action from the IDS due to the constant flow of information from its various sources. Interval-based or offline analysis refers to the storage of intrusion-related information for future analysis.

The choice of one of these methods over the other depends on the need for the IDS information. Where immediate action is desirable, real-time mode is used; where analysis can wait, batch-mode collection of information would be advantageous.

Incidence Response

IDSs are useful for detecting suspicious activity. As discussed in the previous chapter section, IDSs log and transmit intrusion-related information. Security management requires that this information be transformed

into suitable format for storage and analysis. Potentially, anything identified by an IDS — whether it is an attack, intrusion, or even a false alarm — represents an incident requiring analysis and action. The materiality of the incident depends on the threat posed by the incident.

In cases where an intrusion is thought to have occurred, the security organization must respond quickly and act urgently to contain the intrusion, limit the damage caused by the intrusion, repair any damage, and restore the system to full function.

Once things have calmed down, it is important to perform a root cause analysis to determine the nature of the attack and then use this information to improve defenses against future attack. Without applying the "lessons learned" into the process of security enforcement, an organization risks future attack and exploitation.

In general, the incident response process should take a system approach based on detection, response, repair, and prevent. The IDS performs detection, raising the alert to an incident. Human intervention must respond to the incident, perform the repair, and ensure that the lessons learned help improve security.

IDSs can be configured to help manage incidents better based on how they are configured to respond to attacks and intrusions. These responses can be passive (e.g., logging) or active (e.g., generating a page to the security administrator).

Active responses involve automated actions based on the type of intrusion detected. In some cases, IDSs can be configured to attempt to stop an attack, for example, through actively killing the offensive packets. It can also involve terminating the attacker's connection by reconfiguring routers and firewalls to block ports, services, or protocols being utilized by the attacker. Further, network traffic can also be blocked based on the source or destination address and, if necessary, all connections through a particular interface.

The least offensive approach for an active response is to raise the attention of a security administrator, who will then review the logged information about the attack. The analysis will show the nature of the attack and the associated response necessary. Based on the outcome of this analysis, the sensitivity of the IDS can be adjusted to reflect the need for response.

This can be accomplished by increasing the sensitivity of the system to collect a broader scope of information, assisting in the diagnosis of whether an attack actually occurred. Collection of this information will also support further investigation into an attack and provide evidence for legal purposes, if necessary.

There are other approaches to responding to perceived attacks, including fighting back. This involves actively attempting to gain information about the attacker or launching an attack against them. Despite being appealing to some, this type of approach should be used only to the extent of gathering information about the attacker. Actively launching an attack against a perceived attack has a number of potential perils. For example, suppose the source IP has been spoofed, and the last hop of the attack has been just a launch pad rather than originating the attack. Moreover, this has legal implications. As such, professionals should be very clear about their legal boundaries and take care not to cross them.

Most of today's commercially available IDSs depend on the passive responses by logging attack information and raising alarms. Invariably, this requires human intervention to respond to the information provided by the IDS. These come in the form of alarms, notifications, and SNMP traps. An alarm or notification is triggered when an attack is detected and can take the form of a pop-up window or an on-screen alert, e-mail notification, or an alert sent to a cellular phone or pager. To some degree, some commercial IDSs give users the options to do "active kills" of suspicious traffic.

To send alarm information across the network, many systems use SNMP traps and messages to send alarms to a network management system. One is beginning to see security-focused management systems coming onto the market that consolidate security events and manage them through a single console. The benefit of such a system is its holistic nature, allowing the entire network infrastructure to play a role in the response to an attack. Many of the recognized network management systems have incorporated security-specific modules into their systems to meet this demand.

Is IDS Technology Sufficient for Security?

Given an understanding of the role of the IDS and the role of incidence response in security management, IDS technology can only go so far; that is, cause alerts, log security-sensitive events, and to a limited degree, perform active kills of offensive traffic. The information generated by IDSs across an enterprise must then be used to make informed decisions intended for security improvements.

Even if we have a state-of-the-art IDS deployed, the analysis of incidents by experts provides critical data for the enhancement of the response and management process. Once an alerted incident has been identified

and determined to be, in fact, a critical incident, the response team will react quickly to ensure the event is contained and the network and systems are protected from any further possible damage. At this point, the role of forensics comes into play. The forensics experts will conduct a detailed analysis to establish the cause and effect of the incident, and the resulting data from this forensic analysis will provide the information necessary to find a solution. Taking this information and organizing it into various categories such as hostile attacks, denial-of-service, or misuse of IT resources, to name a few, allows for statistical reporting to improve the handling and response of future incidents.

Finally, one needs to use this information to address any weaknesses that may have been identified during the analysis. These can range from technical vulnerabilities or limitations on the systems and network, to administrative controls such as policies and procedures. One must effectively inoculate against possible future incidents to prevent them from occurring again. Case in point: how many security professionals have to repeatedly deal with the effects of the same virus being released as a variant, simply because the lessons from a previous infection were not learned? These post-mortem activities will serve to improve one's security posture, contribute to lessons learned, and heighten security awareness.

Other IDS management issues include ensuring that the IDSs are updated and constantly tuned to catch the most recent attacks and also filter false alarms. Like all systems, IDSs require constant maintenance to ensure the usefulness of the information they collect.

Firewalls: Types and Role in Security Enforcement

This chapter section reviews firewalls and their role in protecting information, including the different firewall types and advantages and limitations in security management.

Introduction

A firewall is a device that provides protection between different network zones by regulating access between the zones. Typically, a firewall filters specific services or applications based on specified rules, and provides protection based on this controlled access between network segments.

Firewalls have major advantages, including:

- The ability to consolidate security via a common access point; where there is no firewall, security is solely the function of the specific hosts or network devices. This consolidation allows for centralized access management to protected segments.
- Being a single access point, the firewall provides a point for logging network traffic. Firewall logs are useful in many ways as log reviews can offer major insights into the nature of traffic transiting at the firewall. Such traffic could be intrusion related, and its analysis helps to understand the nature of associated security threats.
- The capability to hide the nature of the internal network behind the firewall, which is a major boon to privacy.
- The ability to offer services behind a firewall without the threat of external exploitation.[2]

While providing a core security function, a firewall cannot guarantee security for the organization. Effective firewall security depends on how it is administered, including associated processes and procedures for its management. Further, there must be trained personnel to ensure proper configuration and administration of the firewall.

Although overall, firewalls help to enhance organization security, they have some disadvantages. These include hampered network access for some services and hosts, and being a potential single point of failure.[3]

There are two major approaches to firewall configuration, namely:

1. Permit all (e.g., packets or services) except those specified as denied
2. Deny all (packets or services) except those specified as allowed

The "permit all" policy negates the desired restrictive need for controlled access. Typically, most firewalls implement the policy of "deny all except those specified as allowed."

Firewall Types

Packet Filters

Packet filtering firewalls function at the IP layer and examine packet types, letting through only those packets allowed by the security policy while dropping everything else. Packet filtering can be filtering based on packet type, source and destination IP address, or source and destination TCP/UDP ports. Typically, packet filtering is implemented with routers.

The major advantage of packet filters is that they provide security at a relatively inexpensive price as well as high-level performance. As well, their use remains transparent to users.

Packet filters have disadvantages, however. These include:

- They are more difficult to configure, and it is more difficult to verify configurations. The high potential for misconfiguration increases the risk of security holes.
- They neither support user-level authentication nor access based on the time of day.
- They have only limited auditing capability and have no ability to hide the private network from the outside world.
- They are susceptible to attacks targeted at protocols higher than the network layer.

Application Gateways

Application gateways function at the application layer and examine traffic in more detail than packet filters. They allow through only those services for which there is a specified proxy. In turn, proxy services are configured to ensure that only trusted services are allowed through the firewall. New services must have their proxies defined before being allowed through.

In general, application gateways are more secure than packet filtering firewalls.

The key advantages of firewalls based on application gateways are:

- They provide effective information hiding because the internal network is not "visible" from the outside. In effect, application gateways have the ability to hide the internal network architecture.
- They allow authentication, logging, and can help centralize internal mail delivery.
- Their auditing capability allows tracking of information such as source and destination addresses, size of information transferred, start and end times, as well as user identification.
- It is also possible to refine the filtering on some commands within a service. For example, the FTP application gateway has the ability to filter **put** and **get** commands.

The downside of application gateways is that the client/server connection is a two-stage process. Their functioning is not transparent to the user. Moreover, because of the extent of traffic inspection employed, application gateways are usually slower than packet filters.

Firewall Management Issues

Good security practices require that firewall activity be logged. If all traffic into and out of the secured network passes through the firewall, log information can offer substantial insight into the nature of traffic, usage patterns, and sources and destinations for different types of network traffic. Analysis of log information can provide valuable statistics — not only for security planning, but also with respect to network usage.

Where desirable, a firewall can provide a degree of intrusion detection functionality. When properly configured with appropriate alarms, the firewall can be a good source of information about whether the firewall and network are being probed or attacked. This plays a complementary role when used in conjunction with an IDS.

Network usage statistics and evidence of probing can be used for several purposes. Of primary importance is the analysis of whether or not the firewall can withstand external attacks, and determining whether or not the controls on the firewall offer robust protection. Network usage statistics are a key input into network requirements studies and risk analysis activities.

More recent techniques for study of attacks and intrusions use "honey pots" for studying traffic patterns, potential attacks, and the nature of these attacks on enterprise. Here, a honey pot with known vulnerabilities is deployed to capture intrusion attempts, their nature, their success, and the source of the attacks. Further

analysis of the honey pot traffic can help determine the attackers motives and the rate of success of specific types of attacks.[4]

Is Firewall Security Sufficient?

There are many organizations that install a firewall, configure it, and move on, feeling confident that their information is secure. In real life, a firewall is like that giant front door through which most intruders are likely to come should they find holes they can exploit. In reality, there are many ways an intruder can evade or exploit the firewall to gain access to the internal network. This includes exploitation of protocol or application-specific weaknesses or circumventing the firewall where there are alternate routes for traffic into and out of the internal network.[5]

In reality, the issues that guarantee maximum security pertain to processes, people, and technology. The technology must be right; there must be trained people to manage the technology; and processes must be in place for managing the security and the people enforcing security.

Key processes include:

- Applying updates or upgrades of the software
- Acquiring and applying the patches
- Properly configuring the firewall to include collection of logs and log information
- Reviewing log information for security-sensitive issues
- Correlating the log information with information from other security devices in the network
- Determining the findings from the security information and acting on the findings
- Repeating the cycle

Operating System Logs

This chapter section reviews system logs, what they are, and why they are required; different means of collecting log information; strategies for managing system logs; and the challenges of managing log information and its impact on system security.

Introduction

Operating system logs are an important and very useful tool in the gathering and analysis of information about systems. They serve to provide valuable detailed information regarding system activity. Logs are divided into several categories responsible for recording information about specific activities, including user, security, and system, and application related events. They can support ongoing operations and provide a trail of the activity on a system, which can then be used to determine if the system has been compromised and, in the event of criminal activity, provide important evidence in a court of law.

Types of Logs, Their Uses, and Their Benefits

The auditing of operating systems logs information about system activity, application activity, and user activity. They may function under different names depending on the operating system but each is responsible for recording activity in its category. A system can log activity in two ways: event oriented or recording every keystroke on the system (keystroke monitoring).

The event-oriented log contains information related to activities of the system, an application, or user, telling us about the event, when it occurred, the user ID associated with the event, what program was used to initiate it, and the end result.

Keystroke monitoring is viewed as a special type of system logging, and there can be legal issues surrounding it that must be understood prior to its use. Using this form of auditing, a user's keystrokes are recorded as they are entered, and sometimes the computer's response to those keystrokes are also recorded. This type of system logging can be very useful for system administrators for the repair of damage that may have been caused by an intruder.

System log information is used for monitoring system performance. Activities such as drivers loading, processes and services starting, and throughput can provide valuable information to the system administrator for fine-tuning the system. In addition, these logs can capture information about access to the system and what programs were invoked.

Events related to user activity establish individual accountability and will record both successful and unsuccessful authentication attempts. These logs will also contain information about commands invoked by a user and what resources, such as files, were accessed. If additional granularity is required, the detailed activity within an application can be recorded, such as what files were read or modified. The application logs can also be used to determine if there are any defects within the application and whether any application-specific security rules were violated.

The benefits of these audit logs are numerous. By recording user-related events, not only does one establish individual accountability but, in addition, users may be less likely to venture into forbidden areas if they are aware their activities are being recorded. The system logs can also work with other security mechanisms such as an access control mechanism or an intrusion detection system to further analyze events. In the event operations cease, the logs are very useful in determining activity leading up to the event and perhaps even revealing the root cause.

Of course, for these logs to be useful, they must be accurate and available, reinforcing the need for appropriate controls to be placed on them. Protection of the integrity of log records is critical to its usefulness, and the disclosure of this information could have a negative impact if vulnerabilities or flaws recorded in the logs are disclosed to the wrong parties. In many situations, the audit or operating system logs may be a target of attack by intruders or insiders.

Challenges in Management and Impact

Without a doubt, the operating system logs are a very important aspect of our systems, but the amount information being collected can be very difficult to manage effectively. The information contained in the logs is virtually useless unless it is reviewed on a regular basis for anomalous activities. This can be an arduous task for a group of individuals, let alone one person. The reviewers must know what they are looking for to appropriately interpret the information and take action. They must be able to spot trends, patterns, and variances that might indicate unusual behavior among the recorded events. When one considers the amount of information recorded in logs each day, and adds the responsibility of managing it in an effective manner to an already busy security professional, the challenge becomes all too apparent. This could easily become a full-time job for one person or a group of individuals.

If the management of this vast amount of information can cause a security professional to reach for pain relief, imagine the impact on a system during collection of this information — not to mention the additional overhead for storage and processing.

Fortunately, there are analysis tools designed to assist in the ongoing management of all this information. Audit reduction tools will reduce the amount of data by removing events that have little consequence on security, such as activities related to normal operations, making the remaining information more meaningful. Trends/variance detection and attack-signature detection tools similar to the functionality associated with intrusion detection systems will extract useful information from all the available raw data.

Conclusion

Operating system logs can provide a wealth of useful information in the ongoing security management of an organization's systems and resources, but not without a price. Managing this information in a meaningful way requires a commitment of time, computing resources, and perseverance, making it an ongoing challenge.

Other: Routers and Switches

Routers and switches play a critical role in enterprise networks. Routers connect different network segments and mediate in routing traffic from one segment to another. They can be considered as "sitting" at critical points of the network.

Routers are the glue that connects the pieces of a network. Even in the simplest networks, this is not a simple task.

Like routers, switches are critical components in networks. Switches sort out traffic intended for one network, while allowing separation of network segments.

Switches and routers continue to evolve into fairly complex devices with substantial computing power. Further, given their criticality in the network function, their impact on security is critical. Routers have evolved into highly specialized computing platforms, with extremely flexible but complex capabilities. Such complexity lends itself to vulnerabilities and attacks.

Issues pertaining to routers and switches deal with:

- *Access:* who has what access to the device
- *Configuration:* what kind of configuration ensures security of the device
- *Performance:* once deployed, how well it performs to meet intended requirements

It is of interest to track information on the above to ensure the "health" of the network devices and their performance. Ensuring device health means that the device is kept functioning based on its intended purposes. Not only must one keep track of changes and performance of the device, but one must also determine whether the changes are authorized and the impact on the security of the device.

Issues of managing routers and switches are similar to those pertaining to network devices such as firewalls and IDSs. Like firewalls and IDSs, switches and routers require due care; that is, logging suspicious activity, generating alarms where necessary, and constant reviewing of logged activity for purposes of improving their protection.

Similar to using firewalls and IDSs, users must ensure that routers and switches are not deployed with default configurations and that there exist processes for updating and patching the devices.

Typically, switches and routers are used in an internal network. For many, this may suggest a lower level of protection than that required for devices on the perimeter. Indeed, there are some who may feel that once the perimeter is secured, the degree of protection on the inside must be lower. This would be a false sense of security, considering that most attacks arise from sources in the internal network. Moreover, in the case of a successful attack, the intruder will have a free reign where there is insufficient protection on internal network devices.

There is more. The distinction between the inside and outside of a network continues to blur. Typically, an enterprise network is composed of intranets, extranets, the internal network, as well as the Internet. It takes the weakest link to break the security chain. And this could be the switch or router through which one links the business partner. As such, as much attention must be paid to managing these devices securely as is required for devices on the perimeter.

Security information from routers and switches should be part of total enterprise security information. This will help define a holistic picture of the enterprise security posture.

Strategies for Managing Enterprise Information

Managing security information presents a number of challenges to enterprise security and risk managers. The challenges include the potentially overwhelming amounts of information generated by a diverse number of network devices, analyzing the information, correlating security events, and relating technical risks to business risk. Moreover, security and risk managers must continuously perform these security-related activities to be aware of the organization's security posture while finding ways to improve this posture.

To have meaningful insight into an enterprise's security posture, information from diverse sources must be aggregated and correlated in a meaningful manner. Subsequent analysis would show underlying patterns, trends, and metrics associated with the information.

Patterns can be indicators of profiles of system usage. These profiles, in turn, may be due to the nature of the project and maintenance process for security in the enterprise. Trends, on the other hand, indicate variation in various security aspects over time. They may be indicators of improvements realized; they may also indicate problem areas that need improvements. Metrics and patterns are also useful for root cause analysis and problem resolution.

The most challenging tasks for security and risk managers include analyzing information collected across an enterprise from diverse network devices — devices that are used for different but complementary security functions. For example, information coming from firewalls, intrusion systems, and syslogs is complementary in nature with respect to security. Defining a suitable association for information from these diverse sources remains a key test.

Aside from dealing with the volumes of data collected, specific analysis techniques are required to ease the analysis process. These techniques can be based on anomalies, correlation, association with known exposures, trends, and user profiles. These techniques act as filters and aggregators for security information, converting massive data elements to useful information for decision-making.

In general, the range of issues is technical, process, people, and business related. They must be viewed with this totality for the information to be meaningful for improving security posture.

The remainder of this chapter section offers an overview of security information management issues and approaches to meeting the challenges of the complexity of managing the security information. While many practices identified in this chapter section are useful in improving an organization's security predisposition, their total application is key to improved enterprise security bearing. Practitioners of information security realize that security is both social and technical. As such, practices and norms in an organization, especially those pertaining to self-improvement, are core to improving the organization's security.

Security Data Collection and Log Management Issues

Collection, storage, and analysis of security-related information across an enterprise are crucial to understanding an organization's security predisposition. Managers must determine ways of managing the potentially huge amounts of information in a manner that makes business sense. Specifically, how does one translate technical vulnerability data to business risk?

There is a potential danger of being overwhelmed by the amount of information generated if proper filtering is not applied to ensure that only critical security-related information gets collected. The choice of filters for security-related information is borne out of experience and depends on the nature of the environment to which the information pertains.

There remains the challenge of collecting information in a manner that retains security-sensitive information and yet eliminates the amount of "noise" in the information collected. As an example, most intrusion detection systems raise a lot of false positives based on the configuration of the IDS sensors. In practice, a lot of information they generate can be classified as "white noise" and is of little value to security management. Security managers are faced with the challenge of designing appropriate filters to enable the filtering of white noise and thus lessen the burden of managing the collected information.

There are other fundamental issues pertaining to collecting security information. These include ensuring sufficient storage space for log information and periodic transmittal of collected information to a central log collection host. In many cases, projects are executed without sufficient planning for collection of log data, a fact that makes it extremely difficult to do root cause analysis when incidents occur.

Other log management issues pertain to the process in place for reviewing log information. In many organizations, information is logged but hardly examined to discern whether any serious security breach might have taken place. Given that security is more than technology, the process of managing security is as important as the technology used and the qualification of the people charged with managing that security. Technically proficient people managing security not only will understand the technology they are managing, but also appreciate security-related issues pertaining to their technology, including the role of the technology in ensuring security in the organization.

Issues of log management and associated technical personnel to execute them must be part of an organization's security management plan arising from an enterprise's security policy.

Data Interchange and Storage

The lack of an industry standard for exchange of security information presents a major problem for management of security information. Although the XML standard promises to close this gap, it has yet to be adopted as widely in industry as desirable. Thus, while users wait for vendors to adopt a standard for exchanging information, they must live with managing security from diverse sources in the different formats presented by vendors.

A security information exchange standard such as XML is one step, however. A long-term challenge is to find a common classification of security information from different products in the same security space. For example, IDSs would classify data the same way so that a security event generated by one IDS would be treated the same way as a similar event generated by an IDS from a different vendor.

Although there is no industry standard for data interchange yet, most products have the ability to store security-related information in a database. Being Open Database Connectivity (ODBC) compliant allows for data interchange between different programs and databases.

Storage issues include the determination of the amount of data collected and the format of storage. Typically, a database schema must be designed that makes sense with respect to the information collected. The schema will determine the nature of the breakdown of security events and their storage.

In designing storage requirements, security managers must incorporate such known concepts as backup and restoration properties. Others include high availability and remote access provision.

Correlation and Analysis

To get an enterprisewide security view, security information must be aggregated across the enterprise. This includes information from a diverse range of devices (intrusion detection systems, firewalls, system hosts, applications, routers, switches, and more) in the enterprise network. The above information, along with vulnerability data, can help discern an organization's security posture.

Log Data Analysis

Ultimately, the analysis of security information is intended to better understand the associated technical risk. Better still, the information would be useful for managing business risk.[6]

The information aggregation principle is based on the fact that the sum of the information from individual parts is less than the information obtained from the whole composed of the parts. Given the number of potential security-related events generated in an enterprise, there is a big challenge to associate, in a meaningful manner, related security-sensitive information or events.

A security event detected by an IDS can be related to a similar event recorded by the firewall or a Web server in an enterprise's DMZ. Indeed, such an event can be associated with specific activity in back-end systems behind the DMZ.

Event correlation has the power to give insight into the nature of a security-related event. One can play out different scenarios of how an event manifests itself once it hits an organization's network.

Take an event that has been detected by an IDS sitting on the DMZ. Now suppose that it was not detected by the firewall. This may be due to the failure to configure the firewall appropriately; and if the event is detected and blocked by the firewall, it is well and good. However, if it is not detected, it may require investigation. And if picked up by the Web server at the DMZ, then there is cause for concern. Correlation also allows for incorporation of the desirable response based on the criticality of the device under attack.[7]

It makes sense to associate security events seen at the firewall with those seen by the firewall and (if necessary) those happening in the DMZ and even the backend applications behind the DMZ. The collective picture gained is powerful and offers a more holistic view of security-related events in an organization.

Event correlation requires an enterprisewide strategy to become meaningful. Exhibit 66.1 depicts one possible way to organize collection and correlation of information. In this example, there are collections agents that can be configured in peer-to-peer or master-slave modes. Peer-to-peer agents have similar control in the communication. The master-slave relationship retains control within the matter.

To be effective and offer a totality of an organization's security posture, the agents must be capable of handling information from a diverse range of sources, including event logs, syslogs, intrusion systems, firewalls, routers, and switches. Special agents can also be deployed for specific network devices (e.g., firewalls) to offer a view of the security configuration of firewalls.[8]

The above example shows a possible scenario in which collection agents are deployed across the enterprise but organized along the way the enterprise is organized. This ensures that business units can collect their information and pass up the chain only specific flagged information, in the form of aggregates, that contributes to the overall picture of enterprise security posture.

There may be other models along which information is organized. For example, collection agents can be deployed as peer-to-peer, master-slave, or a mix of both. Organizations must determine which model best suits them.

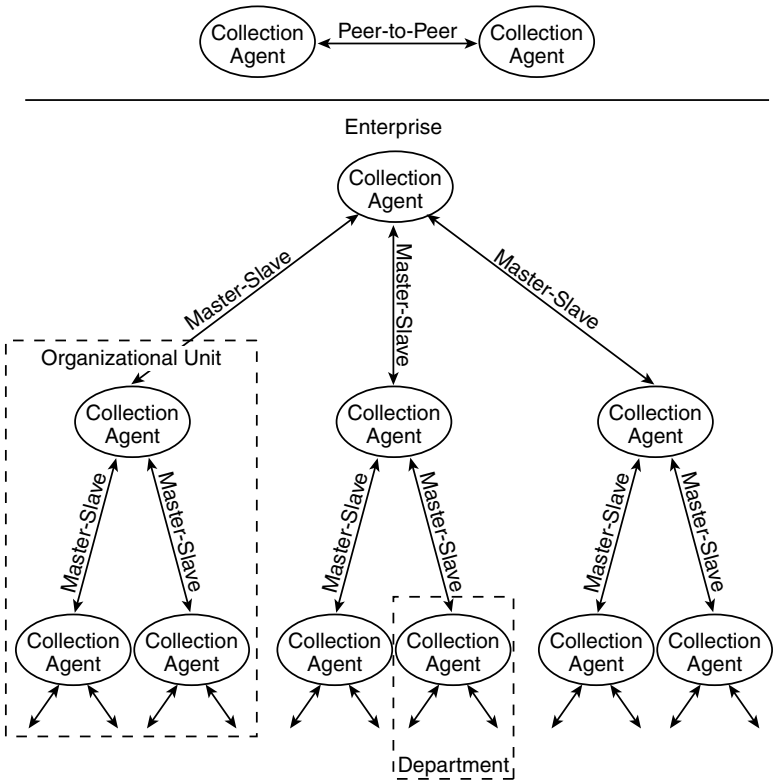

EXHIBIT 66.1 Collection and correlation of information.

Vulnerability Data

Log data analysis and correlation alone is not sufficient to ensure enterprise security posture, although it is important as a component of the "active security" of an organization. Typically, further analysis will include vulnerability data from network assessments.

Vulnerability data usually pertains to scans targeted at discovering such things as the number of ports open, the types of services running, the kind of exposures said services are vulnerable to, and the potential severity of these exposures.

There are few guidelines on the market indicating how vulnerability data should be manipulated. However, creating data mining can give indications on such aspects as the following:

- Risk profiles (e.g., per network, department, etc.) based on the number of vulnerabilities in that network segment
- Metrics about proportions of vulnerabilities regarded as high risk versus those with high risk
- Indication of trends of vulnerability data based on scans taken at different periods of time; interpolation and extrapolation of such trends will offer insight into any improvements in the security posture and whether or not there are improvements

Specific risk profiles will be useful in root cause analysis. It may be that certain vulnerability risk profiles indicate specific weaknesses pertaining to a number of factors such as the process of security planning, design and implementation, as well as the strength of the security process.

For security practitioners, the challenge is to determine the best way to present vulnerability data so as to help improve the way security is managed; specifically, lessons learned from correlation, trends in vulnerability data, and the metrics in performance as well as root cause analysis. And while these insights can be useful in managing security, the ultimate goal would be to associate technical vulnerability information to business risk. The data is not in yet but it is possible that certain vulnerability data profiles suggest specific types of likely business risks. Others, such as Donn Parker,[9] argue that such an approach is not

suitable. Instead, Parker advocates the concept of due care based on the fact that one cannot quantify the cost of avoiding potential security failure.

Summary and Conclusions

In an enterprise, there are diverse sources of security information that comes from devices that perform various network functions. Technologies such as firewalls and IDSs play a key role in enforcing security, while information from routers, switches, and system logs helps in providing a view of an organization's security posture.

Security managers face the challenge of collecting, storing, and analyzing the information in an effective manner that informs and improves the security management process. It must be understood that while security depends a lot on technology, it remains an issue pertaining to people and processes around managing security.

Strategies for the collection of information include the application of filters at strategic locations, complete with filters that pass only that information which must be passed on. This may use intelligent agents that correlate and aggregate information in useful ways to help minimize the amount of information collected centrally.

Security management is also faced with the challenge of creating measures for various aspects of enterprise security. These include metrics such as the percentage of network devices facing particular risks. This requires comparative criteria for measuring technical risk. Further, the said metrics can be used for root cause analysis to both identify and solve problems in a computing environment. Future challenges include being able to associate technical and business risk measures.

There is more. Taking technical risk numbers over time can be used to obtain trends. Such trends would indicate whether there are improvements to the organization's security posture over time.

Security and risk managers, apart from understanding the function of network technologies, face other major challenges. Coming to grips with the reality of the complexity of security management is one step. Defining clear processes and means of managing the information is a step ahead. Yet, using information in a manner that informs the security process and contributes to improvement of the security posture would be a major achievement. Finally, defining metrics and trends useful for managing business risk will be a critical test in the future.

Notes

1. We deliberately use the term "health" because an organization's security posture can be seen in terms of health.
2. This is true for a single access point network. This claim is questionable for networks with multiple access points that blur the concept of what is in and what is out.
3. Most vendors offer high-availability solutions. This, however, is additional cost to network infrastructure. As well, load balancing is a challenge for many firewall vendors.
4. The Honeynet Project (www.honeynet.org) has taken this concept further by creating typical environments for attack and using forensic methodologies to study attacks, their sources, and the motives of attackers.
5. This is the case where users have dialup access to the Internet while logged on to the internal network.
6. Few organizations have been successful in showing the link between technical vulnerability/risk data and associated business risk.
7. Event correlation is dealt with in greater detail in Matunda Nyanchama and Paul Sop's Enterprise Security Management: Managing Complexity, in *Information Systems Security,* January/February 2001.
8. There are products on the market that claim to perform event correlation across different network devices. As of writing this chapter (March 2001), there is no a single product with convincing performance to warrant such a claim.
9. See Risk Reduction Out, Enablement and Due Care In, in *CSI Computer Security Journal*, Vol. XVI, #4, Fall 2000.

Risk Analysis and Assessment

Will Ozier

There are a number of ways to identify, analyze, and assess risk, and there is considerable discussion of "risk" in the media and among information security professionals. But, there is little real understanding of the process and metrics of analyzing and assessing risk. Certainly everyone understands that "taking a risk" means "taking a chance," but a risk or chance of what is often not so clear.

When one passes on a curve or bets on a horse, one is taking a chance of suffering harm/injury or financial loss — undesirable outcomes. We usually give a degree of more or less serious consideration to such an action before taking the chance, so to speak. Perhaps we would even go so far as to calculate the odds (chance) of experiencing the undesirable outcome and, further, take steps to reduce the chance of experiencing the undesirable outcome.

To effectively calculate the chance of experiencing the undesirable outcome, as well as its magnitude, one must be aware of and understand the elements of risk and their relationship to each other. This, in a nutshell, is the process of risk analysis and assessment.

Knowing more about the risk, one is better prepared to decide what to do about it — accept the risk as now assessed (go ahead and pass on the blind curve or make that bet on the horse), or mitigate the risk. To mitigate the risk is to do something to reduce the risk to an acceptable level (wait for a safe opportunity to pass or put the bet money in a savings account with interest).

There is a third choice; to transfer the risk, that is, buy insurance. However prudent good insurance may be, all things considered, having insurance will not prevent the undesirable outcome. Having insurance will only serve to make some compensation — almost always less than complete — for the loss. Further, some risks — betting on a horse — are uninsurable.

The processes of identifying, analyzing and assessing, mitigating, or transferring risk are generally characterized as Risk Management.

There are a few key questions at the core of the risk management process:

1. What could happen (threat event)?
2. If it happened, how bad could it be (threat impact)?
3. How often could it happen (threat frequency, annualized)?
4. How certain are the answers to the first three questions (recognition of uncertainty)?

These questions are answered by analyzing and assessing risk.

Uncertainty is the central issue of risk. Sure, one might pass successfully on the curve or win big at the races, but does the gain warrant taking the risk? Do the few seconds saved with the unsafe pass warrant the possible head-on collision? Are you betting this month's paycheck on a long shot to win? Cost/benefit analysis would most likely indicate that both of these examples are unacceptable risks.

Prudent management, having analyzed and assessed the risks by securing credible answers to these four questions, will almost certainly find there to be some unacceptable risks as a result. Now what? Three questions remain to be answered:

1. What can be done (risk mitigation)?
2. How much will it cost (annualized)?
3. Is it cost effective (cost/benefit analysis)?

Answers to these questions, decisions to budget and execute recommended activities, and the subsequent and ongoing management of all risk mitigation measures — including periodic reassessment — comprise the balance of the Risk Management process.

Managing the risks associated with information in the information technology (IT) environment, information risk management, is an increasingly complex and dynamic task. In the budding Information Age, the technology of information storage, processing, transfer, and access has exploded, leaving efforts to secure that information effectively in a never-ending catch-up mode. For the risks potentially associated with information and information technology to be identified and managed cost-effectively, it is essential that the process of analyzing and assessing risk is well understood by all parties — and executed on a timely basis. This chapter is written with the objective of illuminating the process and the issues of risk analysis and assessment.

Terms and Definitions

To discuss the history and evolution of information risk analysis and assessment, several terms whose meanings are central to this discussion should first be defined.

Annualized Loss Expectancy (ALE)

This discrete value is derived, classically, from the following algorithm (see also the definitions for single loss expectancy [SLE] and annualized rate of occurrence [ARO] below):

$$\begin{matrix}\text{SINGLE LOSS}\\ \text{EXPECTANCY}\end{matrix} \times \begin{matrix}\text{ANNUALIZEDRATE}\\ \text{OFOCCURRENCE}\end{matrix} = \begin{matrix}\text{ANNUALIZED LOSS}\\ \text{EXPECTANCY}\end{matrix}$$

To effectively identify the risks and to plan budgets for information risk management, it is helpful to express loss expectancy in annualized terms. For example, the preceding algorithm will show that the **ALE** for a threat (with an **SLE** of $1,000,000) that is expected to occur only about once in 10,000 years is ($1,000,000 divided by 10,000) only $100.00. When the expected threat frequency (**ARO**) is factored into the equation, the significance of this risk factor is addressed and integrated into the information risk management process. Thus, the risks are more accurately portrayed, and the basis for meaningful cost/benefit analysis of risk reduction measures is established.

Annualized Rate of Occurrence (ARO)

This term characterizes, on an annualized basis, the frequency with which a threat is expected to occur. For example, a threat occurring once in 10 years has an **ARO** of 1/10 or 0.1; a threat occurring 50 times in a given year has an **ARO** of 50.0. The possible range of frequency values is from 0.0 (the threat is not expected to occur) to some whole number whose magnitude depends on the type and population of threat sources. For example, the upper value could exceed 100,000 events per year for minor, frequently experienced threats such as misuse of resources. For an example of how quickly the number of threat events can mount, imagine a small organization — about 100 staff members — having logical access to an information processing system. If each of those 100 persons misused the system only once a month, misuse events would be occurring at the rate of 1200 events per year. It is useful to note here that many confuse **ARO** or frequency with the term and concept of probability (defined below). While the statistical and mathematical significance of these frequency and probability metrics tends to converge at about 1/100 and become essentially indistinguishable below that level of frequency or probability, they become increasingly divergent above 1/100 to the point where probability stops — at 1.0 or certainty — and frequency continues to mount undeterred, by definition.

Exposure Factor (EF)

This factor represents a measure of the magnitude of loss or impact on the value of an asset. It is expressed as a percent, ranging from 0 to 100 percent, of asset value loss arising from a threat event. This factor is used in the calculation of single loss expectancy (**SLE**), which is defined below.

Information Asset

This term, in general, represents the body of information an organization must have to conduct its mission or business. A specific information asset may consist of any subset of the complete body of information, that is, accounts payable, inventory control, payroll, etc. Information is regarded as an intangible asset separate from the media on which it resides. There are several elements of value to be considered: first is the simple cost of replacing the information; second is the cost of replacing supporting software; and third through fifth is a series of values that reflect the costs associated with loss of the information's confidentiality, availability, and integrity. Some consider the supporting hardware and netware to be information assets as well. However, these are distinctly tangible assets. Therefore, using tangibility as the distinguishing characteristic, it is logical to characterize hardware differently than the information itself. Software, on the other hand, is often regarded as information.

These five elements of the value of an information asset often dwarf all other values relevant to an assessment of information-related risk. It should be noted that these elements of value are not necessarily additive for the purpose of assessing risk. In both assessing risk and establishing cost-justification for risk-reducing safeguards, it is useful to be able to isolate the value of safeguard effects among these elements.

Clearly, for an organization to conduct its mission or business, the necessary information must be present where it is supposed to be, when it is supposed to be there, and in the expected form. Further, if desired confidentiality is lost, results could range from no financial loss if confidentiality is not an issue, to loss of market share in the private sector, to compromise of national security in the public sector.

Qualitative/Quantitative

These terms indicate the (oversimplified) binary categorization of risk metrics and information risk management techniques. In reality, there is a spectrum across which these terms apply, virtually always in combination. This spectrum may be described as the degree to which the risk management process is quantified. If all elements — asset value, impact, threat frequency, safeguard effectiveness, safeguard costs, uncertainty, and probability — are quantified, the process can be characterized as fully quantitative.

It is virtually impossible to conduct a purely quantitative risk management project because the quantitative measurements must be applied to the qualitative properties, that is, characterizations of vulnerability, of the target environment. For example, "failure to impose logical access control" is a qualitative statement of vulnerability. However, it is possible to conduct a purely qualitative risk management project. A vulnerability analysis, for example, may identify only the absence of risk-reducing countermeasures, such as logical access controls. Even this simple qualitative process has an implicit quantitative element in its binary — yes/no — method of evaluation. In summary, risk analysis and assessment techniques should be described not as either qualitative or quantitative but in terms of the degree to which such elementary factors as asset value, exposure factor, and threat frequency are assigned quantitative values.

Probability

This term characterizes the chance or likelihood, in a finite sample, that an event will occur or that a specific loss value may be attained should the event occur. For example, the probability of getting a six on a single roll of a die is 1/6, or 0.16667. The possible range of probability values is 0.0 to 1.0. A probability of 1.0 expresses certainty that the subject event will occur within the finite interval. Conversely, a probability of 0.0 expresses certainty that the subject event will not occur within the finite interval.

Risk

The potential for harm or loss, best expressed as the answer to those four questions:

- What could happen? (What is the threat?)
- How bad could it be? (What is the impact or consequence?)
- How often might it happen? (What is the frequency?)
- How certain are the answers to the first three questions? (What is the degree of confidence?)

The key element among these is the issue of uncertainty captured in the fourth question. If there is no uncertainty, there is no "risk," per se.

Risk Analysis

This term represents the process of analyzing a target environment and the relationships of its risk-related attributes. The analysis should identify threat vulnerabilities, associate these vulnerabilities with affected assets, identify the potential for and nature of an undesirable result, and identify and evaluate risk-reducing countermeasures.

Risk Assessment

This term represents the assignment of value to assets, threat frequency (annualized), consequence (i.e., exposure factors), and other elements of chance. The reported results of risk analysis can be said to provide an assessment or measurement of risk, regardless of the degree to which quantitative techniques are applied. For consistency in this chapter, the term "risk assessment" hereafter is used to characterize both the process and the results of analyzing and assessing risk.

Risk Management

This term characterizes the overall process. The first phase, risk assessment, includes identification of the assets at risk and their value, risks that threaten a loss of that value, risk-reducing measures, and the budgetary impact of implementing decisions related to the acceptance, mitigation, or transfer of risk. The second phase of risk management includes the process of assigning priority to, budgeting, implementing, and maintaining appropriate risk-reducing measures. Risk management is a continuous process.

Safeguard

This term represents a risk-reducing measure that acts to detect, prevent, or minimize loss associated with the occurrence of a specified threat or category of threats. Safeguards are also often described as controls or countermeasures.

Safeguard Effectiveness

This term represents the degree, expressed as a percent, from 0 to 100 percent, to which a safeguard may be characterized as effectively mitigating a vulnerability (defined below) and reducing associated loss risks.

Single Loss Expectancy or Exposure (SLE)

This value is classically derived from the following algorithm to determine the monetary loss (impact) for each occurrence of a threatened event:

$$\text{ASSET VALUE} \times \text{EXPOSURE FACTOR} = \text{SINGLE LOSS EXPECTANCY}$$

The **SLE** is usually an end result of a business impact analysis (BIA). A BIA typically stops short of evaluating the related threats' **ARO** or their significance. The **SLE** represents only one element of risk, the expected impact, monetary or otherwise, of a specific threat event. Because the BIA usually characterizes the massive losses resulting from a catastrophic event, however improbable, it is often employed as a scare tactic to get management attention — and loosen budgetary constraints — often unreasonably.

Threat

This term defines an event (e.g., a tornado, theft, or computer virus infection), the occurrence of which could have an undesirable impact.

Uncertainty

This term characterizes the degree, expressed as a percent, from 0.0 to 100 percent, to which there is less than complete confidence in the value of any element of the risk assessment. Uncertainty is typically measured inversely with respect to confidence; that is, if confidence is low, uncertainty is high.

Vulnerability

This term characterizes the absence or weakness of a risk-reducing safeguard. It is a condition that has the potential to allow a threat to occur with greater frequency, greater impact, or both. For example, not having a fire suppression system could allow an otherwise minor, easily quenched fire to become a catastrophic fire. The expected frequency (**ARO**) and the exposure factor (**EF**) for major and catastrophic fire are both increased as a consequence of not having a fire suppression system.

Central Tasks of Information Risk Management

The following sections describe the tasks central to the comprehensive information risk management process. These tasks provide concerned management with credible decision support information regarding the identification and valuation of assets potentially at risk, an assessment of risk, and cost-justified recommendations for risk reduction. Thus, the execution of well-informed management decisions whether to accept, mitigate, or transfer risk cost-effectively is supported. The degree of quantitative orientation determines how the results are characterized, and, to some extent, how they are used. Each of these tasks is discussed below.

Establish Information Risk Management (IRM) Policy

A sound IRM program is founded on a well-thought-out IRM policy infrastructure that effectively addresses all elements of information security. Generally Accepted Information Security Principles (GASSP), currently being developed, based on an Authoritative Foundation of supporting documents and guidelines, will be helpful in executing this task.

IRM policy should begin with a high-level policy statement and supporting objectives, scope, constraints, responsibilities, and approach. This high-level policy statement should drive subordinate policy, from logical access control to facilities security to contingency planning.

Finally, IRM policy should be communicated effectively — and enforced — to all parties. Note that this is important for both internal control and external control — EDI, the Web, and the Internet — for secure interface with the rest of the world.

Establish and Fund an IRM Team

Much of the IRM functionality should already be in place — logical access control, contingency planning, etc. However, it is likely that the central task of IRM, risk assessment, has not been built into the established approach to IRM or has, at best, been given only marginal support.

At the most senior management level possible, the tasks and responsibilities of IRM should be coordinated and IRM-related budgets cost-justified based on a sound integration and implementation of the risk assessment process. At the outset, the IRM team may be drawn from existing IRM-related staff. The person charged with responsibility for executing risk assessment tasks should be an experienced IT generalist with a sound understanding of the broad issues of information security and the ability to "sell" these concepts to management. This person will need the incidental support of one who can assist at key points of the risk assessment task, that is, scribing a Modified Delphi information valuation (see below for details).

In the first year of an IRM program, the lead person could be expected to devote 50 to 75 percent of his or her time to the process of establishing and executing the balance of the IRM tasks, the first of which follows immediately below. Funds should be allocated (1) according to the above minimum staffing, and (2) to acquire, and be trained in the use of, a suitable automated risk assessment tool — $25 to 35K.

Establish IRM Methodology and Tools

There are two fundamental applications of risk assessment to be addressed: (1) determining the current status of information security in the target environment(s) and ensuring that associated risk is managed (accepted, mitigated, or transferred) according to policy, and (2) assessing risk strategically. Strategic assessment assures that the risks associated with alternative strategies are effectively considered before funds are expended on a specific change in the IT environment, a change that could have been shown to be "too risky." Strategic assessment allows management to effectively consider the risks associated with various strategic alternatives in its decision-making process and weigh those risks against the benefits and opportunities associated with each alternative business or technical strategy.

With the availability of proven automated risk assessment tools, the methodology is, to a large extent, determined by the approach and procedures associated with the tool of choice. An array of such tools is listed at the end of this chapter. Increasingly, management is looking for quantitative results that support a credible cost/benefit analysis and budgetary planning.

Identify and Measure Risk

Once the IRM policy, team, and risk assessment methodology and tools are established and acquired, the first risk assessment will be executed. This first risk assessment should be scoped as broadly as possible, so that (1) management is provided with a good sense of the current status of information security, and (2) management has a sound basis for establishing initial risk acceptance criteria and risk mitigation priorities.

Project Sizing

This task includes the identification of background, scope, constraints, objectives, responsibilities, approach, and management support. Clear project sizing statements are essential to a well-defined and well-executed risk assessment project. It should also be noted that a clear articulation of project constraints (what is not included in the project) is very important to the success of a risk assessment.

Threat Analysis

This task includes the identification of threats that may adversely impact the target environment. This task is important to the success of the entire IRM program and should be addressed, at least initially, by risk assessment experts to ensure that all relevant risks are adequately considered. One without risk management and assessment experience may fail to consider a threat, whether of natural causes or the result of human behavior, that stands to cause substantial harm or loss to the organization. Some risk assessment tools, such as BDSS™, help to preclude this problem by assuring that all threats are addressed as a function of expert system knowledge bases.

Asset Identification and Valuation

This task includes the identification of assets, both tangible and intangible, their replacement costs, and the further valuing of information asset availability, integrity, and confidentiality. These values may be expressed in monetary (for quantitative) or nonmonetary (for qualitative) terms. This task is analogous to a BIA in that it identifies the assets at risk and their value.

Vulnerability Analysis

This task includes the qualitative identification of vulnerabilities that could increase the frequency or impact of threat event(s) affecting the target environment.

Risk Evaluation

This task includes the evaluation of all collected information regarding threats, vulnerabilities, assets, and asset values in order to measure the associated chance of loss and the expected magnitude of loss for each of an array of threats that could occur. Results are usually expressed in monetary terms on an annualized basis (ALE) or graphically as a probabilistic "risk curve" for a quantitative risk assessment. For a qualitative risk assessment, results are usually expressed through a matrix of qualitative metrics such as ordinal ranking (low, medium, high or 1, 2, 3).

Interim Reports and Recommendations

These key reports are often issued during this process to document significant activity, decisions, and agreements related to the project:

- *Project sizing*. This report presents the results of the project sizing task. The report is issued to senior management for their review and concurrence. This report, when accepted, assures that all parties understand and concur in the nature of the project before it is launched.
- *Asset identification and valuation*. This report may detail (or summarize) the results of the asset valuation task, as desired. It is issued to management for their review and concurrence. Such review helps prevent conflict about value later in the process. This report often provides management with their first insight into the value of the availability, confidentiality, or integrity of their information assets.
- *Risk evaluation*. This report presents management with a documented assessment of risk in the current environment. Management may choose to accept that level of risk (a legitimate management decision) with no further action or to proceed with risk mitigation analysis.

Establish Risk Acceptance Criteria

With the results of the first risk assessment — through the risk evaluation task and associated reports (see below) — management, with the interpretive help from the IRM leader, should establish the maximum acceptable financial risk. For example, "Do not accept more than a 1 in 100 chance of losing $1,000,000," in a given year. And, with that, and possibly additional risk acceptance criteria, such as "Do not accept an ALE greater than $500,000," proceed with the task of risk mitigation.

Mitigate Risk

The first step in this task is to complete the risk assessment with the risk mitigation, costing, and cost/benefit analysis. This task provides management with the decision support information necessary to plan for, budget, and execute actual risk mitigation measures. In other words, fix the financially unacceptable vulnerabilities. The following risk assessment tasks are discussed in further detail under the section "Tasks of Risk Assessment" later in this chapter.

Safeguard Selection and Risk Mitigation Analysis

This task includes the identification of risk-reducing safeguards that mitigate vulnerabilities and the degree to which selected safeguards can be expected to reduce threat frequency or impact. In other words, this task comprises the evaluation of risk regarding assets and threats before and after selected safeguards are applied.

Cost/Benefit Analysis

This task includes the valuation of the degree of risk mitigation that is expected to be achieved by implementing the selected risk-mitigating safeguards. The gross benefit less the annualized cost for safeguards selected to achieve a reduced level of risk, yields the net benefit. Tools such as present value and return on investment are often applied to further analyze safeguard cost-effectiveness.

Final Report

This report includes the interim reports' results as well as details and recommendations from the safeguard selection and risk mitigation analysis, and supporting cost/benefit analysis tasks. This report, with approved recommendations, provides responsible management with a sound basis for subsequent risk management action and administration.

Monitor Information Risk Management Performance

Having established the IRM program, and gone this far — recommended risk mitigation measures have been acquired/developed and implemented — it is time to begin and maintain a process of monitoring IRM performance. This can be done by periodically reassessing risks to ensure that there is sustained adherence to good control or that failure to do so is revealed, consequences considered, and improvement, as appropriate, duly implemented.

Strategic risk assessment plays a significant role in the risk mitigation process by helping to avoid uninformed risk acceptance and having, later, to retrofit (typically much more costly than built-in security or avoided risk) necessary information security measures.

There are numerous variations on this risk management process, based on the degree to which the technique applied is quantitative and how thoroughly all steps are executed. For example, the asset identification and valuation analysis could be performed independently. This task is often characterized as a business impact analysis. The vulnerability analysis could also be executed independently.

It is commonly but incorrectly assumed that information risk management is concerned only with catastrophic threats, that it is useful only to support contingency planning and related activities. A well-conceived and well-executed risk assessment can, and should, be used effectively to identify and quantify the consequences of a wide array of threats that can and do occur, often with significant frequency, as a result of ineffectively implemented or nonexistent IT management, administrative, and operational controls.

A well-run information risk management program — an integrated risk management program — can help management to significantly improve the cost-effective performance of its information technology environment, whether it is mainframe, client/server, Internet, or any combination, and to ensure cost-effective compliance with applicable regulatory requirements.

The integrated risk management concept recognizes that many often uncoordinated units within an organization play an active role in managing the risks associated with the failure to assure the confidentiality, availability, and integrity of information. The following quote from FIPSPUB-73, published June 30, 1980, is a powerful reminder that information security was long ago recognized as a central, not marginal issue:

> "Security concerns should be an integral part of the entire planning, development, and operation of a computer application. Much of what needs to be done to improve security is not clearly separable from what is needed to improve the usefulness, reliability, effectiveness, and efficiency of the computer application."

Resistance and Benefits

"Why should I bother with doing risk assessment?" "I already know what the risks are!" "I've got enough to worry about already!" "It hasn't happened yet...." Sound familiar? Most resistance to risk assessment boils down to one of three conditions:

1. Ignorance
2. Arrogance
3. Fear

Management is often ignorant, except in the most superficial context, of the risk assessment process, the real nature of the risks, and the benefits of risk assessment. Risk assessment is not yet a broadly accepted element of the management toolkit, yet virtually every "Big 5" consultancy, and other major providers of information security services, offer risk assessment in some form.

Arrogance of the bottom line often drives an organization's attitude about information security, and therefore about risk assessment. "Damn the torpedoes, full speed ahead!" becomes the marching order. If it can not readily be shown to improve profitability, do not do it. It is commendable that IT has become so reliable that management could maintain that attitude for more than a few giddy seconds. Despite the fact that a well-secured IT environment is also a well-controlled, efficient IT environment, management often has difficulty seeing how sound information security can and does affect the bottom line in a positive way.

This arrogance is often described euphemistically as an "entrepreneurial culture."

Finally, there is the fear factor — fear of discovering that the environment is not as well-managed as it could be — and having to take responsibility for that; fear of discovering, and having to address, risks not already known; and fear of being shown to be ignorant or arrogant.

While good information security may seem expensive, inadequate information security will be not just expensive, but, sooner or later, catastrophic.

Risk assessment, while still a young science, with a certain amount of craft involved, has proven itself to be very useful in helping management understand and cost-effectively address the risks to their information and IT environments.

Finally, with regard to resistance, when risk assessment had to be done manually, or could be done only qualitatively, the fact that the process could take many months to execute (and that it was not amenable to revision or "what-if" assessment) was a credible obstacle to its successful use. But that is no longer the case.

Some specific benefits are described below:

- Risk assessment helps management understand:
  1. What is at risk
  2. The value at risk — as associated with the identity of information assets and with the confidentiality, availability, and integrity of information assets
  3. The kinds of threats that could occur and their financial consequences annualized
  4. Risk mitigation analysis; what can be done to reduce risk to an acceptable level
  5. Risk mitigation costs (annualized) and associated cost/benefit analysis; whether suggested risk mitigation activity is cost-effective
- Risk assessment enables a strategic approach to information risk management. In other words, possible changes being considered for the IT environment can be assessed to identify the least-risk alternative before funds are committed to any alternative. This information complements the standard business case for change and may produce critical decision support information that could otherwise be overlooked.

- "What-if" analysis is supported. This is a variation on the strategic approach to information risk management. Alternative approaches can be considered and their associated level of risk compared in a matter of minutes.
- Information security professionals can present their recommendations with credible statistical and financial support.
- Management can make well-informed information risk management decisions.
- Management can justify, with credible quantitative tools, information security budgets/expenditures that are based on a reasonably objective risk assessment.
- Good information security, supported by quantitative risk assessment, will ensure an efficient, cost-effective IT environment.
- Management can avoid spending that is based solely on a perception of risk.
- An information risk management program based on the sound application of quantitative risk assessment can be expected to reduce liability exposure and insurance costs.

Qualitative versus Quantitative Approaches

Background

As characterized briefly above, there are two fundamentally different metric schemes applied to the measurement of risk elements: qualitative and quantitative. The earliest efforts to develop an information risk assessment methodology were reflected originally in the National Bureau of Standards (now the National Institute of Standards and Technology [NIST]) FIPSPUB-31, Automated Data Processing Physical Security and Risk Management, published in 1974. That idea was subsequently articulated in detail with the publication of FIPSPUB-65, Guidelines for Automated Data Processing Risk Assessment, published in August of 1979. This methodology provided the underpinnings for OMB A-71, a federal requirement for conducting "quantitative risk assessment" in the federal government's information processing environments.

Early efforts to conduct quantitative risk assessments ran into considerable difficulty. First, because no initiative was executed to establish and maintain an independently verifiable and reliable set of risk metrics and statistics, everyone came up with their own approach; second, the process, while simple in concept, was complex in execution; third, large amounts of data were collected that required substantial and complex mapping, pairing, and calculation to build representative risk models; and fourth, with no software and desktop computers, the work was done manually — a very tedious and time-consuming process. Results varied significantly.

As a consequence, while some developers launched and continued efforts to develop credible and efficient automated quantitative risk assessment tools, others developed more expedient qualitative approaches that did not require independently objective metrics — and OMB A-130, an update to OMB A-71, was released, lifting the "quantitative" requirement for risk assessment in the federal government.

These qualitative approaches enabled a much more subjective approach to the valuation of information assets and the scaling of risk. In Exhibit 67.1, for example, the value of the availability of information and the associated risk were described as "low," "medium," or "high" in the opinion of knowledgeable management, as gained through interviews or questionnaires.

Often, when this approach is taken, a strategy is defined wherein the highest risk exposures (darkest shaded areas) require prompt attention, the moderate risk exposures (lightly shaded areas) require plans for corrective attention, and the lowest risk exposures (unshaded areas) can be accepted.

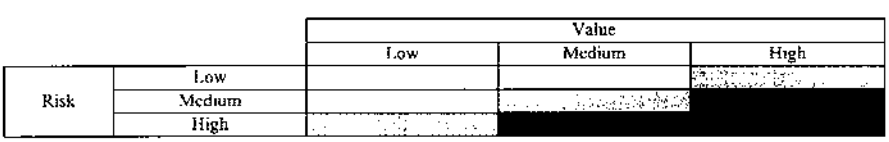

EXHIBIT 67.1 Value of the availability of information and the associated risk.

Elements of Risk Metrics

There are six primitive elements of risk modeling to which some form of metric can be applied:

1. Asset Value
2. Threat Frequency
3. Threat Exposure Factor
4. Safeguard Effectiveness
5. Safeguard Cost
6. Uncertainty

To the extent that each of these elements is quantified in independently objective metrics such as the monetary replacement value for Asset Value or the Annualized Rate of Occurrence for Threat Frequency, the risk assessment is increasingly quantitative. If all six elements are quantified with independently objective metrics, the risk assessment is fully quantified, and the full range of statistical analyses is supported.

Exhibit 67.2 relates both the quantitative and qualitative metrics for these six elements.

Note: The baseline approach makes no effort to scale risk or to value information assets. Rather, the baseline approach seeks to identify in-place safeguards, compare those with what industry peers are doing to secure their information, then enhance security wherever it falls short of industry peer security. A further word of caution is appropriate here. The baseline approach is founded on an interpretation of "due care" that is at odds with the well-established legal definition of due care. Organizations relying solely on the baseline approach could find themselves at a liability risk with an inadequate legal defense should a threat event cause a loss that could have been prevented by available technology or practice that was not implemented because the baseline approach was used.

The classic quantitative algorithm, as presented in FIPSPUB-65, that laid the foundation for information security risk assessment is simple:

$$\text{Annualized Loss Expectancy} = (\text{Asset Value} \times \text{Exposure Factor} = \text{Single Loss Exposure}) (\text{Annualized R of O})$$

For example, let's look at the risk of fire. Assume the asset value is \$1M, the Exposure Factor is 50%, and the annualized rate of occurrence is 1/10 (once in ten years). Plugging these values into the algorithm yields the following:

$$(\$1M \times 50\% = \$500K) \times 1/10 = \$50K$$

Using conventional cost/benefit assessment, the \$50K ALE represents the cost/benefit break-even point for risk mitigation measures. In other words, the organization could justify spending up to \$50K per year to prevent the occurrence or reduce the impact of a fire.

It is true that the classic FIPSPUB-65 quantitative risk assessment took the first steps toward establishing a quantitative approach. However, in the effort to simplify fundamental statistical analysis processes so that everyone could readily understand, the algorithms developed went too far. The consequence was results that had little credibility for several reasons, three of which follow:

1. The classic algorithm addresses all but two of the elements, recommended safeguard effectiveness and uncertainty. Both of these must be addressed in some way, and uncertainty, the key risk factor, must be addressed explicitly.
2. The algorithm cannot distinguish effectively between low frequency/high-impact threats (such as "fire") and high-frequency/low impact threats (such as "misuse of resources"). Therefore, associated risks can be significantly misrepresented.
3. Each element is addressed as a discrete value, which, when considered with the failure to address uncertainty explicitly, makes it difficult to actually model risk and illustrate probabilistically the range of potential undesirable outcomes.

Yes, this primitive algorithm did have shortcomings, but advances in quantitative risk assessment technology and methodology to explicitly address uncertainty and support technically correct risk modeling have largely done away with those problems.

	Quantitative Metrics				Qualitative Metrics			
Risk Element	Monetary Value	Percent Factors (%)	Annualized Rate of Occurrence	Bounded Distribution (Range)	Low, Medium & High	Ordinal Ranking	Vital, Critical, Important, etc.	Baseline
Asset Value	x			x	x	x	x	
Threat Frequency (Annualized)			x	x	x	x		
Threat Exposure Factor		x		x	x	x		
Recommended Safeguard Effectiveness		x		x	x	x		
Safeguard Cost (Annualized)	x			x	x	x		
Uncertainty (Confidence Factor)		x		x	x	x		

EXHIBIT 67.2 Quantitative and qualitative metrics for the six elements.

Pros and Cons of Qualitative and Quantitative Approaches

In this brief analysis, the features of specific tools and approaches will not be discussed. Rather, the pros and cons associated in general with qualitative and quantitative methodologies will be addressed.

Qualitative — Pros

- Calculations, if any, are simple and readily understood and executed.
- It is usually not necessary to determine the monetary value of information (its availability, confidentiality, and integrity).
- It is not necessary to determine quantitative threat frequency and impact data.
- It is not necessary to estimate the cost of recommended risk mitigation measures and calculate cost/benefit.
- A general indication of significant areas of risk that should be addressed is provided.

Qualitative — Cons

- The risk assessment and results are essentially subjective in both process and metrics. The use of independently objective metrics is eschewed.
- No effort is made to develop an objective monetary basis for the value of targeted information assets. Hence, the perception of value may not realistically reflect actual value at risk.
- No basis is provided for cost/benefit analysis of risk mitigation measures, only subjective indication of a problem.
- It is not possible to track risk management performance objectively when all measures are subjective.

Quantitative — Pros

- The assessment and results are based substantially on independently objective processes and metrics. Thus, meaningful statistical analysis is supported.
- The value of information (availability, confidentiality, and integrity), as expressed in monetary terms with supporting rationale, is better understood. Thus, the basis for expected loss is better understood.
- A credible basis for cost/benefit assessment of risk mitigation measures is provided. Thus, information security budget decision-making is supported.
- Risk management performance can be tracked and evaluated.
- Risk assessment results are derived and expressed in management's language, monetary value, percentages, and probability annualized. Thus, risk is better understood.

Quantitative — Cons

- Calculations are complex. If they are not understood or effectively explained, management may mistrust the results of "black-box" calculations.
- It is not practical to attempt to execute a quantitative risk assessment without using a recognized automated tool and associated knowledge bases. A manual effort, even with the support of spreadsheet and generic statistical software, can easily take ten to twenty times the work effort required with the support of a good automated risk assessment tool.
- A substantial amount of information about the target information and its IT environment must be gathered.
- As of this writing, there is not yet a standard, independently developed and maintained threat population and threat frequency knowledge base. Thus, users must rely on the credibility of the vendors who develop and support extant automated tools or do threat research on their own.

Business Impact Analysis versus Risk Assessment

There is still confusion as to the difference between a Business Impact Analysis (BIA) and risk assessment. It is not unusual to hear the terms used interchangeably, but that is not correct. A BIA, at the minimum, is the equivalent of one task of a risk assessment — asset valuation, a determination of the value of the target body of information and its supporting IT resources. At the most, the BIA will develop the equivalent of a Single

Loss Exposure, with supporting details, of course, usually based on a worst case scenario. The results are most often used to convince management that they should fund development and maintenance of a contingency plan.

Information security is much more than contingency planning. A BIA often requires 75 to 100 percent or more of the work effort (and associated cost) of a risk assessment, while providing only a small fraction of the useful information provided by a risk assessment. A BIA includes little if any vulnerability assessment, and no sound basis for cost/benefit analysis.

Target Audience Concerns

Risk assessment continues to be viewed with skepticism by many in the ranks of management. Yet those for whom a well-executed risk assessment has been done have found the results to be among the most useful analyses ever executed for them.

To cite a few examples:

- In one case, involving an organization with multiple large IT facilities — one of which was particularly vulnerable — a well-executed risk assessment promptly secured the attention of the Executive Committee, which had resisted all previous initiatives to address the issue. Why? Because IT management could not previously supply justifying numbers to support its case. With the risk assessment in hand, IT management got the green light to consolidate IT activities from the highly vulnerable site to another facility with much better security. This was accomplished despite strong union and staff resistance. The move was executed by this highly regulated and bureaucratic organization within three months of the quantitative risk assessment's completion! The quantitative risk assessment provided what was needed, credible facts and numbers of their own.
- In another case, a financial services organization found, as a result of a quantitative risk assessment, that it was carrying four to five times the amount of insurance warranted by its level of exposure. It reduced coverage by half, still retaining a significant cushion, and has since saved hundreds of thousands of dollars in premiums.
- In yet another case, management of a relatively young but rapidly growing organization had maintained a rather "entrepreneurial" attitude toward IT in general, until presented with the results of a risk assessment that gave them a realistic sense of the risks inherent to that posture. Substantial policy changes were made on the spot, and information security began receiving real consideration, not just lip service.
- Finally, a large energy industry organization was considering relocating its IT function from its original facility to a bunkered, tornado-proof facility across town that was being abandoned by a major insurance company. The energy company believed that it could reduce its IT-related risk substantially. The total cost of the move would have run into the millions of dollars. Upon executing a strategic risk assessment for the alternatives, it was found that the old facility was sound, and relocating would not significantly reduce the organizations risk. In fact, it was found that the biggest risks were being taken in its failure to maintain good management practices.

Some specific areas of concern are addressed below.

Diversion of Resources

That organizational staff will have to spend some time providing information for the risk assessment is often a major concern. Regardless of the nature of the assessment, there are two key areas of information gathering that will require staff time and participation beyond that of the person(s) responsible for executing the risk assessment:

1. Valuing the intangible information asset's confidentiality, integrity, and availability
2. Conducting the vulnerability analysis

These tasks will require input from two entirely different sets of people in most cases.

Valuing the Intangible Information Asset

There are a number of approaches to this task, and the amount of time it takes to execute will depend on the approach as well as whether it is qualitative or quantitative. As a general rule of thumb, however, one could expect all but the most cursory qualitative approach to require one to four hours of continuous time from two to five key knowledgeable staff for each intangible information asset valued.

Experience has shown that the Modified Delphi approach is the most efficient, useful, and credible. For detailed guidance, refer to the "Guideline for Information Valuation" (GIV) published by the Information System Security Association (ISSA). This approach will require (typically) the participation of three to five staff members knowledgeable in various aspects of the target information asset. A Modified Delphi meeting routinely lasts four hours; so, for each target information asset, key staff time of 12 to 16 hours will be expended in addition to about 20 to 36 hours total for a meeting facilitator (four hours) and a scribe (16 to 32 hours).

Providing this information has proven to be a valuable exercise for the source participants, and the organization, by giving them significant insight into the real value of the target body of information and the consequences of losing its confidentiality, availability, or integrity. Still, this information alone should not be used to support risk mitigation cost/benefit analysis.

While this "Diversion of Resources" may be viewed initially by management with some trepidation, the results have invariably been judged more than adequately valuable to justify the effort.

Conducting the Vulnerability Analysis

This task, which consists of identifying vulnerabilities, can and should take no more than five workdays (about 40 hours) of one-on-one meetings with staff responsible for managing or administering the controls and associated policy (e.g., logical access controls, contingency planning, change control, etc.). The individual meetings — actually guided interviews, ideally held in the interviewees' workspace — should take no more than a couple of hours. Often, these interviews take as little as five minutes. Collectively, however, the interviewees' total diversion could add up to as much as 40 hours. The interviewer will, of course, spend matching time, hour for hour. This one-on-one approach minimizes disruption while maximizing the integrity of the vulnerability analysis by assuring a consistent level-setting with each interviewee.

Credibility of the Numbers

Twenty years ago, the task of coming up with "credible" numbers for information asset valuation, threat frequency and impact distributions, and other related risk factors was daunting. Since then, the GIV was published, and significant progress has been made by some automated tools' handling of the numbers and their associated knowledge bases — the knowledge bases that were developed on the basis of significant research to establish credible numbers. And, credible results are provided if proven algorithms with which to calculate illustrative risk models are used.

However, manual approaches or automated tools that require the users to develop the necessary quantitative data are susceptible to a much greater degree of subjectivity and poorly informed assumptions.

In the past couple of years, there have been some exploratory efforts to establish a Threat Research Center tasked with researching and establishing:

1. A standard information security threat population
2. Associated threat frequency data
3. Associated threat scenario and impact data

and maintaining that information while assuring sanitized source channels that protect the providers of impact and scenario information from disclosure. As recognition of the need for strong information security and associated risk assessment continues to increase, the pressure to launch this function will eventually be successful.

Subjectivity

The ideal in any analysis or assessment is complete objectivity. Just as there is a complete spectrum from qualitative to quantitative, there is a spectrum from subjective to increasingly objective. As more of the elements of risk are expressed in independently objective terms, the degree of subjectivity is reduced accordingly, and the results have demonstrable credibility.

Conversely, to the extent a methodology depends on opinion, point of view, bias, or ignorance (subjectivity), the results will be of increasingly questionable utility. Management is loath to make budgetary decisions based on risk metrics that express value and risk in terms such as low, medium, and high.

There will always be some degree of subjectivity in assessing risks. However, to the extent that subjectivity is minimized by the use of independently objective metrics, and the biases of tool developers, analysts, and knowledgeable participants are screened, reasonably objective, credible risk modeling is achievable.

Utility of Results

Ultimately, each of the above factors (diversion of resources, credibility of the numbers, subjectivity, and, in addition, timeliness) plays a role in establishing the utility of the results. Utility is often a matter of perception. If management feels that the execution of a risk assessment is diverting resources from its primary mission inappropriately, if the numbers are not credible, if the level of subjectivity exceeds an often intangible cultural threshold for the organization, or if the project simply takes so long that the results are no longer timely, then the attention — and trust — of management will be lost or reduced along with the utility of the results.

A risk assessment executed with the support of contemporary automated tools can be completed in a matter of weeks, not months. Developers of the best automated tools have done significant research into the qualitative elements of good control, and their qualitative vulnerability assessment knowledge bases reflect that fact. The same is true with regard to their quantitative elements. Finally, in building these tools to support quantitative risk assessment, successful efforts have been made to minimize the work necessary to execute a quantitative risk assessment.

The bottom line is that it makes very little sense to execute a risk assessment manually or build one's own automated tool except in the most extraordinary circumstances. A risk assessment project that requires many work-months to complete manually (with virtually no practical "what-if" capability) can, with sound automated tools, be done in a matter of days, or weeks at worst, with credible, useful results.

Tasks of Risk Assessment

In this section, we will explore the classic tasks of risk assessment and key issues associated with each task, regardless of the specific approach to be employed. The focus is, in general, primarily on quantitative methodologies. However, wherever possible, related issues in qualitative methodologies are also discussed.

Project Sizing

In virtually all project methodologies, there are a number of elements to be addressed to ensure that all participants, and the target audience, understand and are in agreement about the project. These elements include:

- Background
- Purpose
- Scope
- Constraints
- Objective
- Responsibilities
- Approach

In most cases, it would not be necessary to discuss these individually, as most are well-understood elements of project methodology in general. In fact, they are mentioned here for the exclusive purpose of pointing out the importance of (1) ensuring that there is agreement between the target audience and those responsible for executing the risk assessment, and (2) describing the constraints on a risk assessment project. While a description of the scope, *what is included*, of a risk assessment project is important, it is equally important to describe specifically, in appropriate terms, *what is not included*. Typically, a risk assessment focuses on a subset of the organization's information assets and control functions. If what is not to be included is not identified, confusion and misunderstanding about the risk assessment's ramifications may result.

Again, the most important point about the project sizing task is to ensure that the project is clearly defined and that a clear understanding of the project by all parties is achieved.

Threat Analysis

In manual approaches and some automated tools, the analyst must determine what threats to consider in a particular risk assessment. Because there is not, at present, a standard threat population and readily available threat statistics, this task can require a considerable research effort. Of even greater concern is the possibility that a significant local threat could be overlooked and associated risks inadvertently accepted. Worse, it is possible that a significant threat is intentionally disregarded.

The best automated tools currently available include a well-researched threat population and associated statistics. Using one of these tools virtually assures that no relevant threat is overlooked, and associated risks are accepted as a consequence.

If, however, a determination has been made not to use one of these leading automated tools and instead to do the threat analysis independently, there are good sources for a number of threats, particularly for all natural disasters, fire, and crime (oddly enough, not so much for computer crime), even falling aircraft. Also, the console log is an excellent source for in-house experience of system development, maintenance, operations, and other events that can be converted into useful threat event statistics with a little tedious review. Finally, in-house physical and logical access logs (assuming such are maintained) can be a good source of related threat event data.

However, gathering this information independently, even for the experienced risk analyst, is no trivial task. Weeks, if not months, of research and calculation will be required, and, without validation, results may be less than credible.

For those determined to proceed independently, the following list of sources, in addition to in-house sources previously mentioned, will be useful:

- Fire — National Fire Protection Association (NFPA)
- Flood, all categories — National Oceanic and Atmospheric Administration (NOAA) and local Flood Control Districts
- Tornado — NOAA
- Hurricane — NOAA and local Flood Control Districts
- Windstorms — NOAA
- Snow — NOAA
- Icing — NOAA
- Earthquakes — U.S. Geological Survey (USGS) and local university geology departments
- Sinkholes — USGS and local university geology departments
- Crime — FBI and local law enforcement statistics, and your own in-house crime experience, if any
- Hardware failures — vendor statistics and in-house records

Until an independent Threats Research Center is established, it will be necessary to rely on automated risk assessment tools, or vendors, or your own research for a good threat population and associated statistics.

Asset Identification and Valuation

While all assets may be valued qualitatively, such an approach is useless if there is a need to make well-founded budgetary decisions. Therefore, this discussion of asset identification and valuation will assume a need for the application of monetary valuation.

There are two general categories of assets relevant to the assessment of risk in the IT environment:

1. Tangible assets
2. Intangible assets

Tangible Assets

The tangible assets include the IT facilities, hardware, media, supplies, documentation, and IT staff budgets that support the storage, processing, and delivery of information to the user community. The value of these assets is readily determined, typically, in terms of the cost of replacing them. If any of these are leased, of course, the replacement cost may be nil, depending on the terms of the lease.

Sources for establishing these values are readily found in the associated asset management groups, that is, facilities management for replacement value of the facilities, hardware management for the replacement value for the hardware — from CPUs to controllers, routers and cabling, annual IT staff budgets for IT staff, etc.

Intangible Assets

The intangible assets, which might be better characterized as information assets, are comprised of two basic categories:

1. Replacement costs for data and software
2. The value of the confidentiality, integrity, and availability of information

Replacement Costs

Developing replacement costs for data is not usually a complicated task unless source documents do not exist or are not backed up reliably at a secure off-site location. The bottom line is that "x" amount of data represents "y" keystrokes — a time-consuming but readily measurable manual key entry process.

Conceivably, source documents can now be electronically "scanned" to recover lost, electronically stored data. Clearly, scanning is a more efficient process, but it is still time-consuming. However, if neither source documents nor off-site backups exist, actual replacement may become virtually impossible, and the organization faces the question of whether such a condition can be tolerated. If, in the course of the assessment, this condition is found, the real issue is that the information is no longer available, and a determination must be made as to whether such a condition can be overcome without bankrupting the private-sector organization or irrevocably compromising a government mission.

Value of Confidentiality, Integrity, and Availability

In recent years, a better understanding of the values of confidentiality, integrity, and availability and how to establish these values on a monetary basis with reasonable credibility has been achieved. That understanding is best reflected in the ISSA-published GIV referenced above. These values often represent the most significant "at-risk" asset in IT environments. When an organization is deprived of one or more of these with regard to its business or mission information, depending on the nature of that business or mission, there is a very real chance that unacceptable loss will be incurred within a relatively short time.

For example, it is well-accepted that a bank that loses access to its business information (loss of availability) for more than a few days is very likely to go bankrupt.

A brief explanation of each of these three critical values for information is presented below.

1. *Confidentiality.* Confidentiality is lost or compromised when information is disclosed to parties other than those authorized to have access to the information. In the complex world of IT today, there are many ways for a person to access information without proper authorization if appropriate controls are not in place. Without appropriate controls, that access or theft of information could be accomplished without a trace. Of course, it still remains possible to simply pick up and walk away with confidential documents carelessly left lying about or displayed on an unattended, unsecured PC.
2. *Integrity.* Integrity is the condition that information in or produced by the IT environment accurately reflects the source or process it represents. Integrity can be compromised in many ways, from data entry errors to software errors to intentional modification. Integrity may be thoroughly compromised, for example, by simply contaminating the account numbers of a bank's demand deposit records. Because the account numbers are a primary reference for all associated data, the information is effectively no longer available. There has been a great deal of discussion about the nature of integrity. Technically, if a single character is wrong in a file with millions of records, the file's integrity has been compromised.

   Realistically, however, some expected degree of integrity must be established. In an address file, 99 percent accuracy (only one out of 100 is wrong) may be acceptable. However, in the same file, if each record of 100 characters had only one character wrong — in the account number — the records would meet the poorly articulated 99 percent accuracy standard, but be completely compromised. In other words, the loss of integrity can have consequences that range from trivial to catastrophic. Of course, in a bank with one million clients, 99 percent accuracy means at best that the records of 10,000 clients are in error. In a hospital, even one such error could lead to loss of life!
3. *Availability.* Availability, the condition that electronically stored information is where it needs to be, when it needs to be there, and in the form necessary, is closely related to the availability of the information processing technology. Whether because the process is unavailable, or the information itself is somehow unavailable, makes no difference to the organization dependent on the information to conduct its business or mission. The value of the information's availability is reflected in the costs incurred, over time, by the organization, because the information was not available, regardless of cause. A useful tool (from the Modified Delphi method) for capturing the value of availability, and articulating uncertainty, is illustrated in Exhibit 67.3. This chart represents the cumulative cost, over time, of the best-case and worst-case scenarios, with confidence factors, for the loss of availability of a specific information asset.

INTERVAL	LOS	HI$	CF %	INTERVAL	LOS	HI$	CF %
0-1 HR				4 DAYS			
2 HR				8 DAYS			
4 HR				16 DAYS			
8 HR				1 MONTH			
16 HR				2 MONTHS			
1 DAY				3 MONTHS			
2 DAY				6 MONTHS			

EXHIBIT 67.3 Capturing the value of availability (Modified Delphi method).

Vulnerability Analysis

This task consists of the identification of vulnerabilities that would allow threats to occur with greater frequency, greater impact, or both. For maximum utility, this task is best conducted as a series of one-on-one interviews with individual staff members responsible for developing or implementing organizational policy through the management and administration of controls. To maximize consistency and thoroughness, and to minimize subjectivity, the vulnerability analysis should be conducted by an interviewer who guides each interviewee through a well-researched series of questions designed to ferret out all potentially significant vulnerabilities.

It should be noted that establishment and global acceptance of Generally Accepted System Security Principles (GASSP), as recommended in the National Research Council report "Computers at Risk" (December 1990), the National Information Infrastructure Task Force (NIITF) findings, the Presidential National Security and Telecommunications Advisory Council (NSTAC) report (December 1996), and the President's Commission on Critical Infrastructure Protection (PCCIP) report (October 1997), all of which were populated with a strong private sector representation, will go far in establishing a globally accepted knowledge base for this task. The "Treadwell Commission" report published by the American Institute of Certified Public Accountants (AICPA) Committee of Sponsoring Organizations (COSO) in 1994, "Internal Control, Integrated Framework" now specifically requires that auditors verify that subject organizations assess and manage the risks associated with IT and other significant organizational resources. The guiding model characterized in the requirement represents quantitative risk assessment. Failure to have effectively implemented such a risk management mechanism now results in a derogatory audit finding.

Threat/Vulnerability/Asset Mapping

Without connecting — mapping — threats to vulnerabilities and vulnerabilities to assets and establishing a consistent way of measuring the consequences of their interrelationships, it becomes nearly impossible to establish the ramifications of vulnerabilities in a useful manner. Of course, intuition and common sense are useful, but how does one measure the risk and support good budgetary management and cost/benefit analysis when the rationale is so abstract?

For example, it is only good common sense to have logical access control, but how does one justify the expense? I am reminded of a major bank whose management, in a cost-cutting frenzy, came very close to terminating its entire logical access control program! With risk assessment, one can show the expected risk and annualized asset loss/probability coordinates that reflect the ramifications of a wide array of vulnerabilities. Exhibit 67.4 carries the illustration further with two basic vulnerabilities.

Applying some simple logic at this point will give the reader some insight into the relationships between vulnerabilities, threats, and potentially affected assets.

No Logical Access Control

Not having logical access control means that anyone can sign on the system, get to any information they wish, and do anything they wish with the information. Most tangible assets are not at risk. However, if IT staff productivity is regarded as an asset, as reflected by their annual budget, that asset could suffer a loss (of productivity) while the staff strives to reconstruct or replace damaged software or data. Also, if confidentiality is compromised by the disclosure of sensitive information (competitive strategies or client information), substantial competitive advantage and associated revenues could be lost, or liability suits for disclosure of private information could be very costly. Both could cause company goodwill to suffer a loss.

VULNERABILITY	MAPPED THREAT(S)	AFFECTED ASSETS (At minimum)[a]
No Logical Access Control	Sabotage of Software	Software Goodwill
	Sabotage of Data/Information	Information Integrity Goodwill
	Theft of Software	Software Goodwill
	Theft of Data/Information	Information Confidentiality Goodwill
	Destruction of Software	Software Goodwill
	Destruction of Data/Information	Information Availability Goodwill
No Contingency Plan	Fire Hurricane Earthquake Flood Terrorist Attack	Facilities Hardware Media and Supplies IT Staff Budgets Software Information Availability Goodwill
	Toxic Contamination[b]	IT Staff Budgets Software Information Availability Goodwill

[a] In each case it is assumed that the indicated vulnerability is the only vulnerability; thus, any impact on other information assets is expected to be insignificant. Otherwise, without current backups, for example, virtually every threat on this chart could have a significant impact on information availability.

[b] Tangible assets are not shown as being impacted by a toxic contamination, aside from the IT staff budgets, because it is assumed that the toxic contamination can be cleaned up and the facilities and equipment restored to productive use.

EXHIBIT 67.4 Two basic vulnerabilities.

Because the only indicated vulnerability is not having logical access, it is reasonable to assume monetary loss resulting from damage to the integrity of the information or the temporary loss of availability of the information is limited to the time and resources needed to recover with well-secured, off-site backups. Therefore, it is reasonable to conclude, all other safeguards being effectively in place, that the greatest exposure resulting from not having logical access control is the damage that may result from a loss of confidentiality for a single event. But without logical access control, there could be many such events!

What if there was another vulnerability? What if the information was not being backed up effectively? What if there were no usable backups? The loss of availability — for a single event — could become overwhelmingly expensive, forcing the organization into bankruptcy or compromising a government mission.

No Contingency Plan

Not having an effective contingency plan means that the response to any natural or man-made disaster will be without prior planning or arrangements. Thus, the expense associated with the event is not assuredly contained to a previously established maximum acceptable loss. The event may very well bankrupt the organization or compromise a government mission. This is without considering the losses associated with the tangible assets! Studies have found that organizations hit by a disaster and not having a good contingency plan are likely (4 out of 5) to be out of business within two years of the disaster event.

What if there were no usable backups — another vulnerability? The consequences of the loss of information availability would almost certainly be made much worse, and recovery, if possible, would be much more costly. The probability of being forced into bankruptcy is much higher.

By mapping vulnerabilities to threats to assets, we can see the interplay among them and understand a fundamental concept of risk assessment:

Vulnerabilities allow threats to occur with greater frequency or greater impact. Intuitively, it can be seen that the more vulnerabilities there are, the greater is the risk of loss.

Risk Metrics/Modeling

There are a number of ways to portray risk: some qualitative, some quantitative, and some more effective than others.

In general, the objective of risk modeling is to convey to decision makers a credible, usable portrayal of the risks associated with the IT environment, answering (again) these questions:

- What could happen? (threat event)
- How bad would it be? (impact)
- How often might it occur? (frequency)
- How certain are the answers to the first three questions? (uncertainty)

With such risk modeling, decision-makers are on their way to making well-informed decisions — either to accept, mitigate, or transfer associated risk.

The following brief discussion of the two general categories of approach to these questions, qualitative and quantitative, will give the reader a degree of insight into the ramifications of using one or the other approach:

Qualitative

The definitive characteristic of the qualitative approach is the use of metrics that are subjective, such as ordinal ranking — low, medium, high, etc. (see Exhibit 67.5). In other words, independently objective values such as objectively established monetary value, and recorded history of threat event occurrence (frequency) are not used.

Quantitative

The definitive characteristic of quantitative approaches is the use of independently objective metrics and significant consideration given to minimizing the subjectivity that is inherent in any risk assessment. Exhibit 67.6 was produced from a leading automated tool, BDSS™, and illustrates quantitative risk modeling.

The graph shown in Exhibit 67.6 reflects the integrated "all threats" risk that is generated to illustrate the results of risk evaluation in BDSS™ before any risk mitigation. The combined value of the tangible and intangible assets at risk is represented on the "Y" axis, and the probability of financial loss is represented on the "X" axis. Thus, reading this graphic model, there is a 1/10 chance of losing about $0.5M over a one-year period.

The graph shown in Exhibit 67.7 reflects the same environment after risk mitigation and associated cost/benefit analysis. The original risk curve (Exhibit 67.6) is shown in Exhibit 67.7 with the reduced risk curve and associated average annual cost of all recommended safeguards superimposed on it, so the reader can see the risk before risk mitigation, the expected reduction in risk, and the cost to achieve it. In Exhibit 67.7, the risk at 1/10 and 1/100 chance of loss is now minimal, and the risk at 1/1000 chance of loss has been reduced from about $2.0M to about $0.3M. The suggested safeguards are thus shown to be well justified.

Management Involvement and Guidance

Organizational culture plays a key role in determining, first, whether to assess risk, and second, whether to use qualitative or quantitative approaches. Many firms' management organizations see themselves as "entrepreneurial" and have an aggressive bottom-line culture. Their basic attitude is to minimize all costs, take the chance that nothing horrendous happens, and assume they can deal with it if it does happen.

		Value		
		Low	Medium	High
Risk	Low			
	Medium			
	High			

EXHIBIT 67.5 Value of the availability of information and the associated risk.

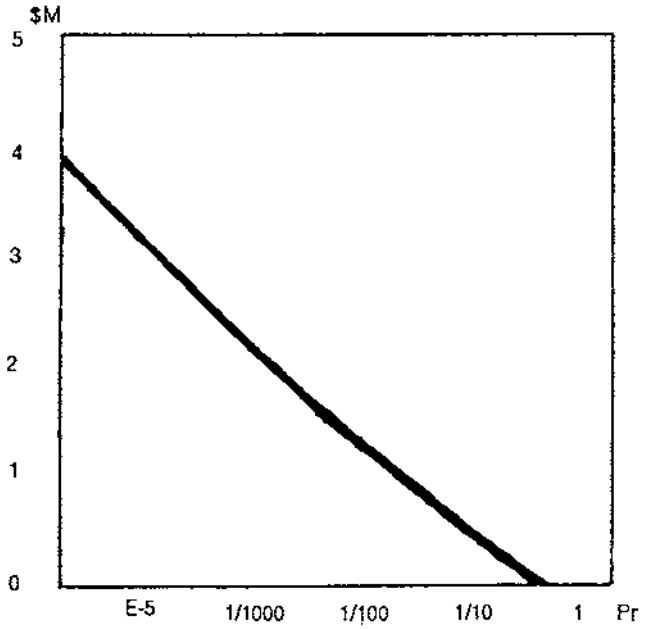

EXHIBIT 67.6 Results of risk evaluation in BDSS™ before any risk mitigation.

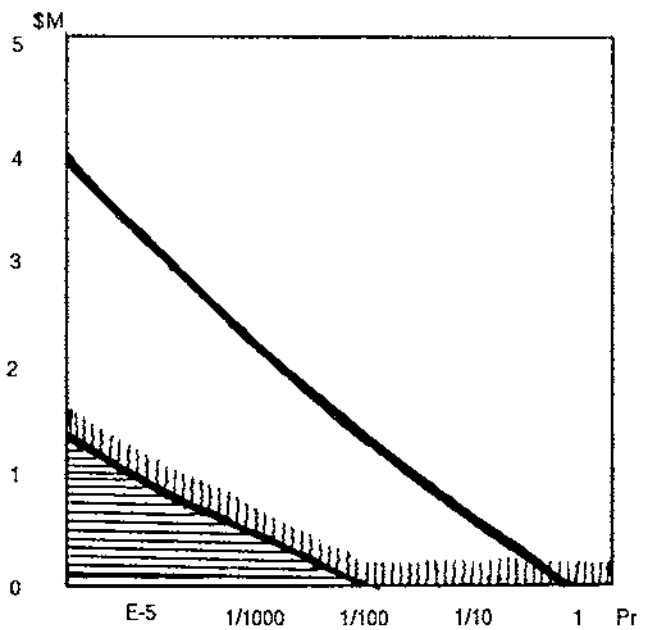

EXHIBIT 67.7 Results of risk evaluation after risk mitigation and associated cost/benefit analysis.

Other firms, particularly larger, more mature organizations, will be more interested in a replicable process that puts results in management language such as monetary terms, cost/benefit assessment, and expected loss. Terms that are understood by business management will facilitate the creation of effective communication channels and support sound budgetary planning for information risk management.

It is very useful to understand the organizational culture when attempting to plan for a risk assessment and get necessary management support. While a quantitative approach will provide, generally speaking, much more useful information, the culture may not be ready to assess risk in significant depth.

In any case, with the involvement, support, and guidance of management, more utility will be gained from the risk assessment, regardless of its qualitative or quantitative nature. And, as management gains understanding of the concepts and issues of risk assessment and begins to realize the value to be gained, reservations about quantitative approaches will diminish, and it will increasingly look toward those quantitative approaches to provide more credible, defensible budgetary support.

Risk Mitigation Analysis

With the completion of the risk modeling and associated report on the observed status of information security and related issues, management will almost certainly find some areas of risk that it is unwilling to accept and for which it wishes to see a proposed risk mitigation analysis. In other words, management will want answers to the last three questions for those unacceptable risks:

1. What can be done?
2. How much will it cost?
3. Is it cost effective?

There are three steps in this process:

1. Safeguard analysis and expected risk mitigation
2. Safeguard costing
3. Safeguard cost/benefit analysis

Safeguard Analysis and Expected Risk Mitigation

With guidance from the results of the risk evaluation, including modeling and associated data collection tasks, and reflecting management concerns, the analyst will seek to identify and apply safeguards that could be expected to mitigate the vulnerabilities of greatest concern to management. Management will, of course, be most concerned about those vulnerabilities that could allow the greatest loss expectancies for one or more threats, or those subject to regulatory or contractual compliance. The analyst, to do this step manually, must first select appropriate safeguards for each targeted vulnerability; second, map or confirm mapping, safeguard/vulnerability pairs to all related threats; and third, determine, for each threat, the extent of asset risk mitigation to be achieved by applying the safeguard. In other words, for each affected threat, determine whether the selected safeguard(s) will reduce threat frequency, reduce threat exposure factors, or both, and to what degree.

Done manually, this step will consume many days or weeks of tedious work effort. Any "what-if" assessment will be very time-consuming as well. When this step is executed with the support of a knowledge-based expert automated tool, however, only a few hours to a couple of days are expended, at most.

Safeguard Costing

To perform a useful cost/benefit analysis, estimated costs for all suggested safeguards must be developed. While these cost estimates should be reasonably accurate, it is not necessary that they be precise. However, if one is to err at this point, it is better to overstate costs. Then, as bids or detailed cost proposals come in, it is more likely that cost/benefit analysis results, as shown below, will not overstate the benefit.

There are two basic categories of costing for safeguards:

1. Cost per square foot, installed
2. Time and materials

In both cases, the expected life and annual maintenance costs must be included to get the average annual cost over the life of the safeguard. An example of each is provided in Exhibits 67.8 and Exhibit 67.9.

These average annual costs represent the break-even point for safeguard cost/benefit assessment for each safeguard. In these examples, discrete, single-point values have been used to simplify the illustration. At least one of the leading automated risk assessment tools, BDSS™, allows the analyst to input bounded distributions with associated confidence factors to articulate explicitly the uncertainty of the values for these preliminary cost estimates. These bounded distributions with confidence factors facilitate the best use of optimal probabilistic analysis algorithms.

EXHIBIT 67.8 Cost per Square Foot, Installed, for a Robust New IT Facility

Cost per square foot	$165.00	
Total Square feet	50,000	
Total		$8,250,000
Safeguard Life expectancy	10 years	
Annualized cost (8,250,000/10)		$825,000
Annual Maintenance	$250,000	
Average Annual Cost		$1,075,000

Safeguard Cost/Benefit Analysis

The risk assessment is now almost complete, though this final set of calculations is, once again, not trivial. In previous steps, the expected value of risk mitigation — the annualized loss expectancy (ALE) before safeguards are applied, less the ALE after safeguards are applied, less the average annual costs of the applied safeguards — is conservatively represented individually, safeguard by safeguard, and collectively. The collective safeguard cost/benefit is represented first, threat by threat with applicable selected safeguards; and, second, showing the overall integrated risk for all threats with all selected safeguards applied. This may be illustrated as follows:

$$\text{Safeguard } 1 \rightarrow \text{Vulnerability } 1 \rightarrow n \rightarrow \text{Threat } 1 \rightarrow n$$

One safeguard may mitigate one or more vulnerabilities to one or more threats. A generalization of each of the three levels of calculation is represented below.

For the Single Safeguard

A single safeguard may act to mitigate risk for a number of threats. For example, a contingency plan will contain the loss for disasters by facilitating a timely recovery. The necessary calculation includes the integration of all affected threats' risk models *before* the safeguard is applied, less their integration *after* the safeguard is applied to define the gross risk reduction benefit. Finally, subtract the safeguard's average annual cost to derive the net annual benefit.

$$[(\text{RB(T)1 RA(T)1}) - (\text{RB(T)n RA(T)n}) = \text{GRRB}] \text{ — SGAAC} = \text{NRRB}$$

where:

RB(T) = the risk model for threats1-n *before* the safeguard is applied
RA(T) = the risk model for threats1-n *after* the safeguard is applied
GRRB = Gross Risk Reduction Benefit
NRRB = Net Risk Reduction Benefit
SGAAC = Safeguard Average Annual Cost

This information is useful in determining whether individual safeguards are cost effective. If the net risk reduction (mitigation) benefit is negative, the benefit is negative (i.e., not cost effective).

For the Single Threat

Any number of safeguards may act to mitigate risk for any number of threats. It is useful to determine, for each threat, how much the risk for that threat was mitigated by the collective population of safeguards selected that act to mitigate the risk for the threat. Recognize at the same time that one or more of these safeguards can also act to mitigate the risk for one or more other threats.

$$[(\text{AALEB} - \text{AALEA} = \text{GRRB}) - \text{SGAACSG1–n}] = \text{NRRB}$$

Cost per labor hour	$65.00	
Labor hours	480	
Implementation cost, labor		$31,200
Purchase/materials for an automated DRP tool	$29,000	
Total acquisition and implementation cost		$70,200
Safeguard life expectancy	8 years	
Annualized acquisition and implementation cost ($70,200/8)		$8,775
Annual maintenance:	$4,350	
DRP license maintenance	$32,500	
DRP staff, .5 work year (65,000 x .5)		$36,850
Average Annual Cost		$45,625

EXHIBIT 67.9 Time and materials for acquiring and implementing a disaster recovery plan (DRP).

where:

AALEB = Average Annual Loss Expectancy *before* safeguards

AALEA = Average Annual Loss Expectancy *after* safeguards

In this case, NRRB refers to the combined benefit of the collective population of safeguards selected for a specific threat. This process should be executed for each threat addressed. Still, these two processes alone should not be regarded as definitive decision support information. There remains the very real condition that the collective population of safeguards could mitigate risk very effectively for one major threat while having only a minor risk mitigating effect for a number of other threats relative to their collective SGAAC.

In other words, if looked at out of context, the selected safeguards could appear, for those marginally affected risks, to be cost prohibitive — their costs may exceed their benefit for those threats. Therefore, the next process is essential to an objective assessment of the selected safeguards overall benefits.

For All Threats

The integration of all individual threat risk models for *before* selected safeguards are applied and for *after* selected safeguards are applied shows the gross risk reduction benefit for the collective population of selected safeguards as a whole. Subtract the average annual cost of the selected safeguards, and the net risk reduction benefit as a whole is established.

This calculation will generate a single risk model that accurately represents the combined effect of all selected safeguards in mitigating risk for the array of affected threats. In other words, an executive summary of the expected results of proposed risk-mitigating measures is generated.

Final Recommendations

After the risk assessment is complete, final recommendations should be prepared on two levels: (1) a categorical set of recommendations in an executive summary, and (2) detailed recommendations in the body of the risk assessment report. The executive summary recommendations are supported by the integrated risk model reflecting all threats risks before and after selected safeguards are applied, the average annual cost of the selected safeguards, and their expected risk mitigation benefit.

The detailed recommendations should include a description of each selected safeguard and its supporting cost benefit analysis. Detailed recommendations may also include an implementation plan. However, in most cases, implementation plans are not developed as part of the risk assessment report. Implementation plans are typically developed upon executive endorsement of specific recommendations.

Automated Tools

The following products represent a broad spectrum of automated risk assessment tools ranging from the comprehensive, knowledge based expert system BDSS™, to RiskCalc, a simple risk assessment shell with provision for user-generated algorithms and a framework for data collection and mapping.

- ARES: Air Force Communications and Computer Security Management Office, Kelly AFB, TX
- @RISK: Palisade Corp, Newfield, NY
- Bayesian Decision Support System (BDSS™), OPA, Inc.: The Integrated Risk Management Group, Petaluma, CA
- Control Matrix Methodology for Microcomputers: Jerry FitzGerald & Associates, Redwood City, CA
- COSSAC: Computer Protection Systems Inc., Plymouth, MI
- CRITI-CALC: International Security Technology, Reston, VA
- CRAMM: Executive Resources Association, Arlington, VA
- GRA/SYS: Nander Brown & Co., Reston, VA
- IST/RAMP: International Security Technology, Reston, VA
- JANBER: Eagon. McAllister Associates Inc., Lexington Park, MD
- LAVA: Los Alamos National Laboratory, Los Alamos, NM
- LRAM: Livermore National Laboratory, Livermore, CA

- MARION: Coopers & Lybrand (UK-based), London, England
- Micro Secure Self Assessment: Boden Associates, East Williston, NY
- Predictor: Concorde Group International, Westport, CT
- PRISM: Palisade Corp., Newfield, NY
- QuikRisk: Basic Data Systems, Rockville, MD
- RA/SYS: Nander Brown & Co., Reston, VA
- RANK-IT: Jerry FitzGerald & Associates, Redwood City, CA
- RISKCALC: Hoffman Business Associates Inc., Bethesda, MD
- RISKPAC: Profile Assessment Corp., Ridgefield, CT
- RISKWATCH: Expert Systems Software Inc., Long Beach, CA
- The Buddy System Risk Assessment and Management System for Microcomputers: Countermeasures, Inc., Hollywood, MD

Summary

While the dialogue on risk assessment continues, management increasingly is finding utility in the technology of risk assessment. Readers should, if possible, given the culture of their organization, make every effort to assess the risks in the subject IT environments using automated, quantitatively oriented tools. If there is strong resistance to using quantitative tools, then proceed with an initial approach using a qualitative tool. But do start the risk assessment process!

Work on automated tools continues to improve the utility and credibility. More and more of the "Big Accounting Firms" and other major consultancies, including those in the insurance industry, are offering risk assessment services using, or planning to use, quantitative tools. Managing risk is the central issue of information security. Risk assessment with automated tools provides organizational management with sound insight into their risks and how best to manage them and reduce liability cost effectively.

MANAGING RISK IN AN INTRANET ENVIRONMENT

Ralph L. Kliem

INSIDE

Types of Risks, Risk Management Concepts, Identifying Risks, Analyzing Risks, Controlling Risks

INTRODUCTION

The rush to adopt intranet technology keeps growing daily. It is not hard to understand the enthusiastic embrace of this new technology. It is, quite frankly, quite inviting. It provides many advantages, especially when compared with the rigid, complex technology of the past. It builds on the existing client/server or distributed systems environment. It provides a convenient means to access and distribute information throughout an enterprise. Users find it easy to enter and navigate. It encourages a truly open computing environment. It enables easier distribution of applications. The advantages go on and on. It seems something akin to a perpetual motion machine. It is just too good to be true.

All these advantages can prove beguiling; many companies are finding that the intranet is too good to be true. As they embrace this technology, many companies are finding that they have more of a perpetual problem machine than one of perpetual motion. This is especially the case when they fail to prepare themselves in advance for the new technology. What is happening, of course, is that many companies are finding that they must deal with issues pertaining to organizational structuring, internal and external access to data, copyright protection, data ownership and maintenance, configuration of hardware and software, traffic management, and many others.

PAYOFF IDEA

Intranets are flexible systems that can have enterprisewide reach. Because of their scale and accessibility, intranets pose risks beyond the prominent one of security. Performance, integration, scalability, and planning are also risks that systems development managers must face when dealing with intranets. This article shows how to identify, analyze, and control risk in an intranet environment.

GROWING RISK

Many intranets are like some mystic poltergeist, lacking any structure, purpose, or boundary. Yet, the posi-

Auerbach Publications

tive and negative benefits of going the intranet route remain untested despite the history of its sister technology, the Internet.

As the intranet becomes more pervasive and complex, the opportunities for vulnerabilities increase. With these vulnerabilities comes risk. Many companies have implemented intranets, for example, without any thought about standards or policies on access, content, or use. Their oversight or deliberate neglect appears acceptable to them, reflecting a willingness to face the consequences if something goes awry.

Part of the problem is that many industries across the United States are willing to accept a certain level of risk as a tradeoff for realizing short- and long-term gains in productivity. Another contributor to the problem is that risk is often narrowly construed as being only security. In reality, a security risk — albeit important — is just one of the many types of risks facing an intranet. Many corporations find themselves facing a host of unanticipated risks related to transaction security, network capacity, configuration control, directory services, maintenance skills availability, upgrades to hardware, and backup procedures. Other intranet-related risks include performance, integration, scalability, and planning.

The risks tend to multiply as the size of, complexity of, and level of reliance on the intranet grows. Once an intranet gains momentum within an organization, it is very difficult to avoid fighting fires. The only mechanism to deal with such an environment is to perform risk management as early as possible, preferably before the intranet is up and running.

RISK MANAGEMENT CONCEPTS

Before discussing the specific types of risks facing an intranet, however, it is important to understand some general concepts about risk management. Risk is the occurrence of an event that has consequences. A vulnerability, or exposure, is a weakness that enables a risk to have an impact. The idea is to institute controls that will prevent, detect, or correct impacts from risks.

Risk management is the entire process of managing risk. It consists of three closely related actions:

- Risk identification
- Risk analysis
- Risk control

Risk identification is identifying the risks confronting a system. Risk analysis is analyzing data collected using a particular technique. Risk control is identifying and verifying the existence of measures to lessen or avoid the impact of a risk. Risk control may involve avoiding, accepting, adopting, or transferring risk. The measures in place to prevent, detect, or correct are called controls.

Risk management for an intranet offers several advantages. It identifies the most likely and most important risks facing an intranet. It enables taking a proactive approach when managing the intranet, such as identifying assets that need augmentation or improvement. It provides an opportunity to define exactly what constitutes an intranet within a company. It enables building an infrastructure to support the overall business objectives that the intranet is to help achieve. It identifies where to focus energies. Finally, it provides the material to develop contingency plans to respond appropriately to certain risks, if and when they do arise.

Of course, it makes sense to do risk assessment as early as possible. It enables identifying control weaknesses before an intranet is implemented and, therefore, institutionalizes them. It allows incorporating better controls when it is cheaper to make the appropriate changes rather than when the intranet is up and running. Finally, it gives everyone a sense of confidence early on that they are using a secure, reliable, well-managed system.

RISK IDENTIFICATION

For an intranet, the risks are innumerable, especially since the technology is new and has been adopted rapidly. Its growth has been so dramatic that a complete listing would be akin to trying to calculate the end of infinity. It impacts both functions and processes within an organization to such an extent that listing all the risks would prove futile. It is possible, however, to categorize the risks according to some arbitrary but generic criteria. Intranet risks can fall into four basic categories: personnel, operational, economic, and technological.

Personnel risks deal with the human side of an intranet. Some examples are:

- Inadequate training of users
- Lack of available skills for intranet development and maintenance
- Lack of available skills for intranet publishing and design
- Lack of available skills for systems administration
- Poor role definition for data content, usage, and maintenance
- Unclear responsibilities for dealing with traffic flow problems

Operational risks deal with business processes. A process transcends a functional entity (e.g., department) within an organization, receives input, and transforms it into output. Some examples are:

- Inadequate capability to find data
- Inadequate presentation of data
- Lack of backup and recovery procedures
- Not adequately controlling access to sensitive data
- Poor directory services

- Poor integration with legacy systems
- Poor online service support
- Poorly maintained links
- Transferring sensitive data over a network with poor security
- Uncontrolled access to unauthorized sites
- Unexpected rise in network traffic

Economic risks relate to the costs of an intranet — from development to ongoing operation. Some examples are excessive or out-of-the-ordinary costs related to:

- Internet service provider services
- Hardware upgrades
- Software upgrades
- Integration of components (e.g., desktops, server applications)
- Integration of applications with legacy systems and databases
- Labor for developing and maintaining the infrastructure (e.g., administering the site)

Technological risks deal with the hardware, software, and other media that form an intranet. Some examples are:

- Immaturity of the technology being employed
- Inadequate communications hardware and software
- Inadequate system hardware and software
- Insufficient availability of network bandwidth
- Poor availability of development and publishing tools
- Poor configuration control of clients
- Poor integration of components (e.g., local area networks, server applications)
- Poor retrieval tools and services
- Slow connection
- Unreliable server hardware and software

It would be a mistake, however, to think that these four categories are mutually exclusive.

Deciding what risks fall within each category is often a judgment call and is mainly academic. The key is to use the categories to identify the risks, determine their relative importance to one another, and recognize the controls that do or should exist.

RISK ANALYSIS

After identifying the risks, the next action is to determine their relative importance to one another and their probability of occurrence. The rank-

EXHIBIT 1 — An Ordered Listing of Intranet Risks

Risk	Probability of Occurrence	Impact
Lack of available skills for system administration	High	Major
Uncontrollable access to unauthorized sites	High	Minor
Poor integration of components (e.g., local area networks, applications)	Low	Minor
Unexpected network utilization costs	High	Major

ing of importance depends largely on the purpose management has established for the intranet. In other words, what business value is the intranet supposed to provide? In what ways is the intranet supposed to serve the interests of its users?

There are multiple approaches to analyzing risk. Basically, the approaches fall into three categories:

- Quantitative
- Qualitative
- A combination of both

Qualitative risk analysis relies on mathematical calculations to determine a risk's relative importance to another and its probability of occurrence. The Monte Carlo simulation technique falls within this category.

Qualitative risk analysis relies less on mathematical calculations and more on judgmental considerations to determine a risk's relative importance to another and probability of occurrence. Heuristics, or rules of thumb, fall within this category.

A combination of the two, of course, uses both mathematical and qualitative considerations to determine a risk's relative importance to another and its probability of occurrence. The precedence diagramming method, which uses an ordinal approach to determine priorities according to some criterion, falls within this category. Regardless of the approach, a resulting rank order listing of risks is shown in Exhibit 1.

RISK CONTROL

With the analysis complete, the next action is to identify controls that should exist to prevent, detect, or correct the impact of risks. Risk control involves a painstaking effort to understand the environment where the intranet finds itself. It means looking at a host of factors, such as:

- Applications at the client and server levels
- Architectural design of the network
- Availability of expertise
- Content and structure in databases (e.g., images, text)

- Current network capacity
- Degree of integration among system components
- Firewall protection
- Hardware components
- Importance of copyright issues
- Level of anticipated network traffic in the future
- Level of financial resources available for ongoing maintenance
- Level of security requirements
- Number of mission-critical systems depending on the intranet
- Sensitivity of data being accessed and transported
- Software components

After identifying the controls that should be in place, the next action is to verify whether they are actually in place to prevent, detect, or correct. Preventive controls mitigate or stop an event that exploits the vulnerabilities of a system. Detective controls disclose the occurrence of an event that exploited a vulnerability. Corrective controls counteract the effects of an event and preclude similar exploitation in the future.

To determine the types of controls that are in place requires painstaking "leg work," often achieved through interviews, literature reviews, and a thorough knowledge of the major components of the intranet. The result is the identification of what controls do exist and which ones are lacking or need improvement.

There are many preventive, detective, and corrective controls to apply in an intranet environment. These include:

- Adequate backup and recovery to safeguard data
- Adequate, relevant, and timely training for users and developers
- Changing passwords
- Documented and followed policies and procedures
- Metrics to ensure goals and objectives are being achieved
- Monitoring of network utilization regarding traffic flow and data content
- Monitoring system performance
- Restricting user access to specific server applications and databases
- Restricting user privileges
- Security for sensitive data and transactions
- Segregation of duties, such as reviews and approvals
- Setting up a firewall
- Tracking of hardware and software
- Tracking user access
- Upgrading hardware and software

Armed with a good idea of the type and nature of the risks confronting an intranet, the next step is to make improvements. This involves

EXHIBIT 2 — Intranet Risks and Their Controls

Risk	Control
Lack of available skills for system administration	• Cross-training • Outsourcing
Uncontrolled access to sensitive databases	• Restrictive access policies • Firewall
Poor integration of components (e.g., local area networks, server applications)	• Client and server configuration guidelines and standards
Unexpected network utilization costs	• Periodic network capacity planning • Limiting nonessential access during high peak periods

strengthening or adding controls. It means deciding whether to accept, avoid, adopt, or transfer risk. To accept a risk means letting it occur and taking no action. An example is not doing anything about external breach to the intranet. To avoid a risk means taking action to not confront a risk. An example is continuing to expand bandwidth without considering the causes (such as surfing). Adopting means living with a risk and dealing with it by working "around it." An example is waiting until a later time to access the network when usage is less. Transfer means shifting a risk over to someone else or some other organization. An example is having the user assume responsibility for accessing and displaying proprietary data. Exhibit 2 presents some examples of controls that may be taken for selected types of risks in an intranet environment.

CONCLUSION

The advantages of performing risk management for an intranet are quite obvious. Yet, the lure of the technology is so inviting that even the thought of doing any risk assessment appears more like an administrative burden. The decision to manage risk depends on the answers to two key questions: Do the advantages of not bothering to identify, analyze, and control risks exceed not doing it? Are you willing to accept the consequences if a vulnerability is taken advantage of, either deliberately or by accident? In the end, the decision to manage risk is, ironically, one of risk.

Security Assessment

Sudhanshu Kairab, CISSP, CISA

During the past decade, businesses have become increasingly dependent on technology. IT environments have evolved from mainframes running selected applications and independent desktop computers to complex client/server networks running a multitude of operating systems with connectivity to business partners and consumers. Technology trends indicate that IT environments will continue to become more complicated and connected.

With this trend in technology, why is security important? With advances in technology, security has become a central part of strategies to deploy and maintain technology. For companies pursuing E-commerce initiatives, security is a key consideration in developing the strategy. In the business-to-consumer markets, customers cite security as the main reason for buying or not buying online. In addition, most of the critical data resides on various systems within the IT environment of most companies. Loss or corruption of data can have devastating effects on a company, ranging from regulatory penalties stemming from laws such as HIPAA (Health Insurance Portability and Accountability Act) to loss of customer confidence.

In evaluating security in a company, it is important to keep in mind that managing security is a process much like any other process in a company. Like any other business process, security has certain technologies that support it. In the same way that an ERP (enterprise resources planning) package supports various supply-chain business processes such as procurement, manufacturing, etc., technologies such as firewalls, intrusion detection systems, etc. support the security process. However, unlike some other business processes, security is something that touches virtually every part of the business, from human resources and finance to core operations. Consequently, security must be looked at as a business process and not a set of tools. The best security technology will not yield a secure environment if it is without sound processes and properly defined business requirements. One of the issues in companies today is that, as they have raced to address the numerous security concerns, security processes and technology have not always been implemented with the full understanding of the business and, as a result, have not always been aligned with the needs of the business.

When securing a company's environment, management must consider several things. In deciding what security measures are appropriate, some considerations include:

- What needs to be protected?
- How valuable is it?
- How much does downtime cost a company?
- Are there regulatory concerns (e.g., HIPAA, GLBA [Gramm–Leach–Bliley Act])?
- What is the potential damage to the company's reputation if there is a security breach?
- What is the probability that a breach can occur?

Depending on the answers to these and other questions, a company can decide which security processes make good business sense for them. The security posture must balance:

- The security needs of the business
- The operational concerns of the business
- The financial constraints of the business

The answers to the questions stated earlier can be ascertained by performing a security assessment. An independent third-party security assessment can help a company define what its security needs are and provide a framework for enhancing and developing its information security program. Like an audit, it is important for an assessment to be independent so that results are not (or do not have the appearance of being) biased in any way. An independent security assessment using an internal auditor or a third-party consultant can facilitate open and honest discussion that will provide meaningful information.

If hiring a third-party consultant to perform an assessment, it is important to properly evaluate its qualifications and set up the engagement carefully. The results of the security assessment will serve as the guidance for short- and long-term security initiatives; therefore, it is imperative to perform the appropriate due-diligence evaluation of any consulting firm considered. In evaluating a third-party consultant, some attributes that management should review include:

- *Client references.* Determine where the client has previously performed security assessments.
- *Sample deliverables.* Obtain a sense of the type of report that will be provided. Clients sometimes receive boilerplate documents or voluminous reports from security software packages that are difficult to decipher, not always accurate, and fail to adequately define the risks.
- *Qualifications of the consultants.* Determine if the consultants have technical or industry certifications (e.g., CISSP, CISA, MCSE, etc.) and what type of experience they have.
- *Methodology and tools.* Determine if the consultants have a formal methodology for performing the assessment and what tools are used to do some of the technical pieces of the assessment.

Because the security assessment will provide a roadmap for the information security program, it is critical that a quality assessment be performed. Once the selection of who is to do the security assessment is finalized, management should define or put parameters around the engagement. Some things to consider include:

- *Scope.* The scope of the assessment must be very clear, that is, network, servers, specific departments or business units, etc.
- *Timing.* One risk with assessments is that they can drag on. The people who will offer input should be identified as soon as possible, and a single point of contact should be appointed to work with the consultants or auditors performing the assessment to ensure that the work is completed on time.
- *Documentation.* The results of the assessment should be presented in a clear and concise fashion so management understands the risks and recommendations.

Standards

The actual security assessment must measure the security posture of a company against standards. Security standards range from ones that address high-level operational processes to more technical and sometimes technology-specific standards. Some examples include:

- *ISO 17799: Information Security Best Practices.* This standard was developed by a consortium of companies and describes best practices for information security in the areas listed below. This standard is very process driven and is technology independent.
  - — Security policy
  - — Organizational security
  - — Asset classification and control
  - — Personnel security
  - — Physical and environmental security
  - — Communications and operations management
  - — Access control
  - — Systems development and maintenance
  - — Business continuity management
  - — Compliance
- *Common Criteria* (http://www.commoncriteria.org). "Represents the outcome of a series of efforts to develop criteria for evaluation of IT security products that are broadly useful within the international community."[1] The Common Criteria are broken down into the three parts listed below:

  - — *Part 1:* Introduction and general model: defines general concepts and principles of IT security evaluation and presents a general model for evaluation
  - — *Part 2:* Security functional requirements
  - — *Part 3:* Security assurance requirements
- *SANS/FBI Top 20 Vulnerabilities* (http://www.sans.org/top20.htm). This is an updated list of the 20 most significant Internet security vulnerabilities broken down into three categories: general, UNIX related, and NT related.
- *Technology-specific standards.* For instance, best practices for locking down Microsoft products can be found on the Microsoft Web site.

When performing an assessment, parts or all of the standards listed above or other known standards can be used. In addition, the consultant or auditor should leverage past experience and his or her knowledge of the company.

Understanding the Business

To perform an effective security assessment, one must have a thorough understanding of the business environment. Some of the components of the business environment that should be understood include:

- What are the inherent risks for the industry in which the company operates?
- What is the long- and short-term strategy for the company?
  - — What are the current business requirements, and how will this change during the short term and the long term?
- What is the organizational structure, and how are security responsibilities handled?
- What are the critical business processes that support the core operations?
- What technology is in place?

To answer these and other questions, the appropriate individuals, including business process owners, technology owners, and executives, should be interviewed.

Inherent Risks

As part of obtaining a detailed understanding of the company, an understanding of the inherent risks in the business is required. Inherent risks are those risks that exist in the business without considering any controls. These risks are a result of the nature of the business and the environment in which it operates. Inherent risks can be related to a particular industry or to general business practices, and can range from regulatory concerns as a result of inadequate protection of data to risks associated with disgruntled employees within an information technology (IT) department. These risks can be ascertained by understanding the industry and the particular company. Executives are often a good source of this type of information.

Business Strategy

Understanding the business strategy can help identify what is important to a company. This will ultimately be a factor in the risk assessment and the associated recommendations. To determine what is important to a company, it is important to understand the long- and short-term strategies. To take this one step further, how will IT support the long- and short-term business strategies? What will change in the IT environment once the strategies are implemented? The business strategy gives an indication of where the company is heading and what is or is not important. For example, if a company is planning on consolidating business units, the security assessment might focus on integration issues related to consolidation, which would be valuable input in developing a consolidation strategy.

One example of a prevalent business strategy for companies of all sizes is facilitating employee telecommuting. In today's environment, employees are increasingly accessing corporate networks from hotels or their homes during business hours as well as off-hours. Executives as well as lower-level personnel have become dependent on the ability to access company resources at any time. From a security assessment perspective, the

key objective is to determine if the infrastructure supporting remote access is secure and reliable. Some questions that an assessment might address in evaluating a remote access strategy include:

- How will remote users access the corporate network (e.g., dial in, VPN, etc.)?
- What network resources do remote users require (e.g., e-mail, shared files, certain applications)?
  - Based on what users must access, what kind of bandwidth is required?
- What is the tolerable downtime for remote access?

Each of the questions above has technology and process implications that need to be considered as part of the security assessment.

In addition to the business strategies, it is also helpful to understand security concerns at the executive level. Executives offer the "big-picture" view of the business, which others in the business sometimes do not. This high-level view can help prioritize the findings of a security assessment according to what is important to senior management. Interfacing with executives also provides an opportunity to make them more aware of security exposures that may potentially exist.

Organizational Structure

For an information security program to be effective, the organization structure must adequately support it. Where the responsibility for information security resides in an organization is often an indication of how seriously management views information security. In many companies today, information security is the responsibility of a CISO (chief information security officer) who might to report to either the CIO (chief information officer) or the CEO (chief executive officer). The CISO position has risen in prominence since the September 11 attacks. According to a survey done in January 2002 by Booz Allen Hamilton, "firms with more than $1 billion in annual revenues … 54 percent of the 72 chief executive officers it surveyed have a chief security officer in place. Ninety percent have been in that position for more than two years."[2] In other companies, either middle- or lower-level management within an IT organization handles security.

Having a CISO can be an indication that management has a high level of awareness of information security issues. Conversely, information security responsibility at a lower level might mean a low level of awareness of information security. While this is not always true, a security assessment must ascertain management and company attitude regarding the importance of information security. Any recommendations that would be made in the context of a security assessment must consider the organizational impact and, more importantly, whether the current setup of the organization is conducive to implementing the recommendations of the security assessment in the first place.

Another aspect of where information security resides in an organization is whether roles and responsibilities are clearly defined. As stated earlier, information security is a combination of process and technology. Roles and responsibilities must be defined such that there is a process owner for the key information security-related processes. In evaluating any part of an information security program, one of the first questions to ask is: "Who is responsible for performing the process?" Oftentimes, a security assessment may reveal that, while the process is very clearly defined and adequately addresses the business risk, no one owns it. In this case, there is no assurance that the process is being done. A common example of this is the process of ensuring that terminated employees are adequately processed. When employees are terminated, some things that are typically done include:

- Payroll is stopped.
- All user access is eliminated.
- All assets (i.e., computers, ID badges, etc.) are returned.
- Common IDs and passwords that the employee was using are changed.

Each of the steps above requires coordination among various departments, depending on the size and structure of a given company. Ensuring that terminated employees are processed correctly might mean coordination among departments such as human resources, IT, finance, and others. To ensure the steps outlined above are completed, a company might have a form or checklist to help facilitate communication among the relevant departments and to have a record that the process has been completed. However, without someone in the company owning the responsibility of ensuring that the items on the checklist are completed, there is no assurance that a terminated employee is adequately processed. It might be the case that each department

thought someone else was responsible for it. Too often, in the case of terminated employees, processing is incomplete because of a lack of ownership of the process, which presents significant risk for any company.

Once there are clear roles and responsibilities for security-related processes, the next step is to determine how the company ensures compliance. Compliance with security processes can be checked using two methods.

First, management controls can be built into the processes to ensure compliance. Building on the example of terminated employees, one of the significant elements in the processing is to ensure that the relevant user IDs are removed. If the user IDs of the terminated employees are, by mistake, not removed, it can be still be caught during periodic reviews of user IDs. This periodic review is a management control to ensure that only valid user IDs are active, while also providing a measure of security compliance.

The second method of checking compliance is an audit. Many internal audit departments include information security as part of their scope as it grows in importance. The role of internal audit in an information security program is twofold. First, audits check compliance with key security processes. Internal audits focus on different processes and related controls on a rotation basis over a period of time based on risk. The auditors gain an understanding of the processes and associated risks and ensure that internal controls are in place to reasonably mitigate the risks. Essentially, internal audit is in a position to do a continuous security assessment. Second, internal audits provide a company with an independent evaluation of the business processes, associated risks, and security policies. Because of their experience with and knowledge of the business and technology, internal auditors can evaluate and advise on security processes and related internal controls.

While there are many internal audit departments that do not have an adequate level of focus on information security, its inclusion within the scope of internal audit activities is an important indication about the level of importance placed on it. Internal audit is in a unique position to raise the level of awareness of information security because of its independence and access to senior management and the audit committee of the board of directors.

Business Processes

In conjunction with understanding the organization, the core business processes must be understood when performing a security assessment. The core business processes are those that support the main operations of a company. For example, the supply-chain management process is a core process for a manufacturing company. In this case, the security related to the systems supporting supply-chain management would warrant a close examination.

A good example of where core business processes have resulted in increased security exposures is business-to-business (B2B) relationships. One common use of a B2B relationship is where business partners manage supply-chain activities using various software packages. In such a relationship, business partners might have access to each other's manufacturing and inventory information. Some controls for potential security exposures as a result of such an arrangement include ensuring that:

- Business partners have access based on a need-to-know basis
- Communication of information between business partners is secure
- B2B connection is reliable.

These security exposure controls have information security implications and should be addressed in an information security program. For example, ensuring that business partners have access on a need-to-know basis might be accomplished using the access control features of the software as well as strict user ID administration procedures. The reliability of the B2B connection might be accomplished with a combination of hardware and software measures as well as SLAs (service level agreements) establishing acceptable downtime requirements.

In addition to the core business processes listed above, security assessments must consider other business processes in place to support the operations of a company, including:

- Backup and recovery
- Information classification
- Information retention
- Physical security
- User ID administration

- Personnel security
- Business continuity and disaster recovery
- Incident handling
- Software development
- Change management
- Noncompliance

The processes listed above are the more traditional security-related processes that are common across most companies. In some cases, these processes might be discussed in conjunction with the core business processes, depending on the environment. In evaluating these processes, guidelines such as the ISO 17799 and the Common Criteria can be used as benchmarks.

It is important to remember that understanding any of the business processes means understanding the manual processes as well as the technology used to support them. Business process owners and technology owners should be interviewed to determine exactly how the process is performed. Sometimes, a walk-through is helpful in gaining this understanding.

Technology Environment

As stated in the previous section, the technology supporting business processes is an important part of the security assessment. The technology environment ranges from industry-specific applications, to network operating systems, to security software such as firewalls and intrusion detection systems. Some of the more common areas to focus on in a security assessment include:

- Critical applications
- Local area network
- Wide area network
- Server operating systems
- Firewalls
- Intrusion detection systems
- Anti-virus protection
- Patch levels

When considering the technology environment, it is important to not only identify the components but also to determine how they are used. For example, firewalls are typically installed to filter traffic going in and out of a network. In a security assessment, one must understand what the firewall is protecting and if the rule base is configured around business requirements. Understanding whether the technology environment is set up in alignment with business requirements will enable a more thoughtful security assessment.

Risk Assessment

Once there is a good understanding of the business, its critical processes, and the technology supporting the business, the actual risk assessment can be done — that is, what is the risk as a result of the security exposures? While gaining an understanding of the business and the risk assessment are listed as separate steps, it is important to note that both of these steps will tend to happen simultaneously in the context of an audit; and this process will be iterative to some extent. Due to the nature of how information is obtained and the dynamic nature of a security assessment, the approach to performing the assessment must be flexible.

The assessment of risk takes the understanding of the critical processes and technology one step further. The critical business processes and the associated security exposures must be evaluated to determine what the risk is to the company. Some questions to think about when determining risk include:

- What is the impact to the business if the business process cannot be performed?
- What is the monetary impact?
  - Cost to restore information
  - Regulatory penalties

- What is the impact to the reputation of the company?
- What is the likelihood of an incident due to the security exposure?
- Are there any mitigating controls that reduce the risk?

It is critical to involve business process and technology owners when determining risks. Depending on how the assessment is performed, some of the questions will come up or be answered as the initial information is gathered. In addition, other more detailed questions will come up that will provide the necessary information to properly assess the risk.

In addition to evaluating the business processes, the risk assessment should also be done relative to security exposures in the technology environment. Some areas on which to focus here include:

- Perimeter security (firewalls, intrusion detection, etc.)
- Servers
- Individual PCs
- Anti-virus software
- Remote access

Security issues relating to the specific technologies listed above may come up during the discussions about the critical business processes. For example, locking down servers may arise because it is likely that there are servers that support some of the critical business processes.

Once all the security risks have been determined, the consultant or auditor must identify what measures are in place to mitigate the risks. Some of the measures to look for include:

- Information security policies
- Technical controls (e.g., servers secured according to best-practice standards)
- Business process controls (e.g., review of logs and management reports)

The controls may be identified while the process is reviewed and the risk is determined. Again, a security assessment is an iterative process in which information may not be uncovered in a structured manner. It is important to differentiate and organize the information so that risk is assessed properly.

The combination of security exposures and controls (or lack thereof) to mitigate the associated risks should then be used to develop the gap analysis and recommendations. The gap analysis is essentially a detailed list of security exposures, along with controls to mitigate the associated risks. Those areas where there are inadequate controls or no controls to mitigate the security exposure are the gaps, which potentially require remediation of some kind.

The final step in the gap analysis is to develop recommendations to close the gaps. Recommendations could range from writing a security policy to changing the technical architecture to altering how the current business process is performed. It is very important that the recommendations consider the business needs of the organization. Before a recommendation is made, a cost/benefit analysis should be done to ensure that it makes business sense. It is possible that, based on the cost/benefit analysis and operational or financial constraints, the organization might find it reasonable to accept certain security risks. Because the recommendations must be sold to management, they must make sense from a business perspective.

The gap analysis should be presented in an organized format that management can use to understand the risks and implement the recommendations. An effective way to present the gap analysis is with a risk matrix with the following columns represented:

- Finding
- Risk
- Controls in place
- Recommendation

This format provides a simple and concise presentation of the security exposures, controls, and recommendations. The presentation of the gap analysis is very important because management will use it to understand the security exposures and associated risks. In addition, the gap analysis can be used to prioritize short- and long-term security initiatives.

Conclusion

For many companies, the security assessment is the first step in developing an effective information security program because many organizations do not know where they are from a security perspective. An independent security assessment and the resulting gap analysis can help determine what the security exposures are, as well as provide recommendations for additional security measures that should be in implemented. The gap analysis can also help management prioritize the tasks in the event that all the recommendations could not be immediately implemented.

The gap analysis reflects the security position at a given time, and the recommendations reflect current and future business requirements to the extent they are known. As business requirements and technologies change, security exposures will invariably change. To maintain a sound information security program, the cycle of assessments, gap analysis, and implementation of recommendations should be done on a continuous basis to effectively manage security risk.

Evaluating the Security Posture of an Information Technology Environment: The Challenges of Balancing Risk, Cost, and Frequency of Evaluating Safeguards

Brian R. Schultz, CISSP, CISA

The elements that could affect the integrity, availability, and confidentiality of the data contained within an information technology (IT) system must be assessed periodically to ensure that the proper safeguards have been implemented to adequately protect the resources of an organization. More specifically, the security that protects the data contained within the IT systems should be evaluated regularly. Without the assurance that the data contained within the system has integrity and is therefore accurate, the system is useless to serve the stakeholders who rely on the accuracy of such data.

Historically, safeguards over a system have been evaluated as a function of compliance with laws, regulations, or guidelines that are driven by an external entity. External auditors such as financial statement auditors might assess security over a system to understand the extent of security controls implemented and whether these controls are adequate to allow them to rely on the data processed by the systems. Potential partners for a merger might assess the security of an organization's systems to determine the effectiveness of security measures and to gain a better understanding of the systems' condition and value. See Exhibit 21-1 for a list of common IT evaluation methodologies.

Exhibit 21-1. Common IT evaluation types.

Type of Evaluation: Financial Statement Audit

Stakeholders: All professionals who work for the organization or who own a company that undergoes an annual financial statement audit.

Description: Financial statement auditors review the financial data of an organization to determine whether the financial data is accurately reported. As a component of performing the financial statement audit, they also review the controls (safeguards) used to protect the integrity of the data. Financial statement auditors are not concerned with the confidentiality or availability of data as long as it has no impact on the integrity of the data. This work will be conducted in accordance with American Institute of Certified Public Accountants (AICPA) standards for public organizations and in accordance with the Federal Information System Control Audit Methodology (FISCAM) for all U.S. federal agency financial statement audits.

Type of Evaluation: Due Diligence Audit before the Purchase of a Company

Stakeholders: Potential buyers of a company.

Description: Evaluation of the safeguards implemented and the condition of an IT system prior to the purchase of a company.

Type of Evaluation: SAS 70 Audit

Stakeholders: The users of a system that is being processed by a facility run by another organization.

Description: The evaluation of data centers that process (host) applications or complete systems for several organizations. The data center will frequently obtain the services of a third-party organization to perform an IT audit over the data center. The report, commonly referred to as an SAS 70 Report, provides an independent opinion of the safeguards implemented at the shared data center. The SAS 70 Report is generally shared with each of the subscribing organizations that uses the services of the data center. Because the SAS 70 audit and associated report are produced by a third-party independent organization, most subscribing organizations of the data center readily accept the results to be sufficient, eliminating the need to initiate their own audits of the data center.

Type of Evaluation: Federal Financial Institutions Examination Council (FFIEC) Information Systems Examination

Stakeholders: All professionals in the financial industry and their customers.

Description: Evaluation of the safeguards affecting the integrity, reliability, and accuracy of data and the quality of the management information systems supporting management decisions.

Type of Evaluation: Health Insurance Portability Accountability Act (HIPAA) Compliance Audit

Stakeholders: All professionals in health care and patients.

Description: Evaluation of an organization's compliance with HIPAA specifically in the area of security and privacy of healthcare data and data transmissions.

Exhibit 21-1. Common IT evaluation types (Continued).

Type of Evaluation: U.S. Federal Government Information Systems Reform Act (GISRA) Review

Stakeholders: All U.S. federal government personnel and American citizens.

Description: Evaluation of safeguards of federal IT systems with a final summary report of each agency's security posture provided to the Office of Management and Budget.

Type of Evaluation: U.S. Federal Government Risk Assessment in compliance with Office of Management and Budget Circular A-130

Stakeholders: All federal government personnel and those who use the data contained within those systems.

Description: Evaluation of U.S. government major applications and general support systems every three years to certify and accredit that the system is properly secured to operate and process data.

Evaluations of IT environments generally are not performed proactively by the IT department of an organization. This is primarily due to a performance-focused culture within the ranks of the chief information officers and other executives of organizations who have been driven to achieve performance over the necessity of security. As more organizations experience performance issues as a result of lack of effective security, there will be more proactive efforts to integrate security into the development of IT infrastructures and the applications that reside within them. In the long run, incorporating security from the beginning is significantly more effective and results in a lower cost over the life cycle of a system.

Internal risk assessments should be completed by the information security officer or an internal audit department on an annual basis and more often if the frequency of hardware and software changes so necessitates. In the case of a major launch of a new application or major platform, a pre-implementation (before placing into production) review should be performed. If an organization does not have the capacity or expertise to perform its own internal risk assessment or pre-implementation evaluation, a qualified consultant should be hired to perform the risk assessment. The use of a contractor offers many advantages:

- Independent evaluators have a fresh approach and will not rely on previously formed assumptions.
- Independent evaluators are not restricted by internal politics.
- Systems personnel are generally more forthright with an outside consultant than with internal personnel.
- Outside consultants have been exposed to an array of systems of other organizations and can offer a wider perspective on how the security posture of the system compares with systems of other organizations.

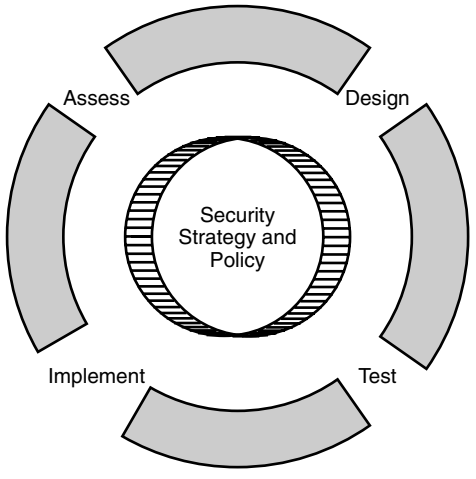

Exhibit 21-2. Security life-cycle model.

- Outside consultants might have broader technology experience based on their exposure to multiple technologies and therefore are likely to be in a position to offer recommendations for improving security.

When preparing for an evaluation of the security posture of an IT system, the security life-cycle model should be addressed to examine the organization's security strategy, policies, procedures, architecture, infrastructure design, testing methodologies, implementation plans, and prior assessment findings.

SECURITY LIFE-CYCLE MODEL

The *security life-cycle model* contains all of the elements of security for a particular component of security of an information technology as seen in Exhibit 21-2. Security elements tend to work in cycles. Ideally, the *security strategy and policy* are determined with a great deal of thought and vision followed by the sequential phases of *design*, *test*, *implement* and, finally, *assess*.

The *design phase* is when the risk analyst examines the design of safeguards and the chosen methods of implementation. In the second phase, the *test phase*, the risk assessment examines the testing procedures and processes that are used before placing safeguards into production. In the following phase, the *implementation phase*, the risk assessment analyzes the effectiveness of the technical safeguards settings contained within the operating system, multilevel security, database management system, application-level security, public key infrastructure, intrusion detection system, firewalls, and routers. These safeguards are evaluated using

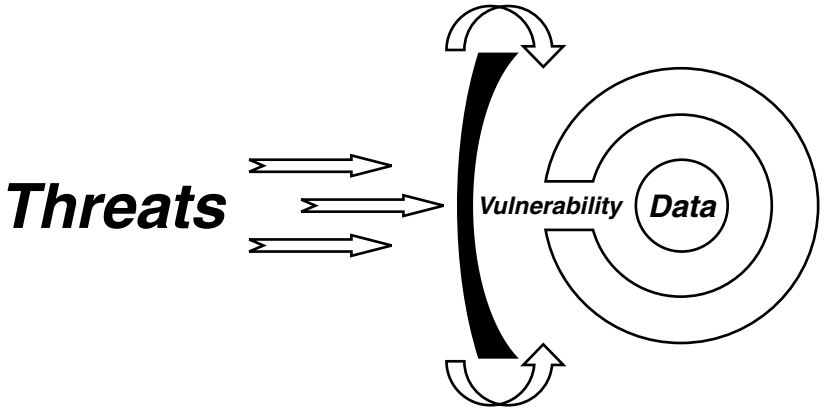

Exhibit 21-3. Elements of an organization's security posture.

technical vulnerability tools as well as a manual review of security settings provided on printed reports.

Assessing security is the last phase of the security life-cycle model, and it is in this phase that the actions taken during the previous phases of the security life-cycle model are assessed. The *assess* phase is the feedback mechanism that provides the organization with the condition of the security posture of an IT environment. The risk assessment first focuses on the security strategy and policy component of the model. The security strategy and policy component is the core of the model, and many information security professionals would argue that this is the most important element of a successful security program. The success or failure of an organization's security hinges on a well-formulated, risk-based security strategy and policy. When used in the appropriate context, the security life-cycle model is an effective tool to use as a framework in the evaluation of IT security risks.

ELEMENTS OF RISK ASSESSMENT METHODOLOGIES

A risk assessment is an active process that is used to evaluate the security of an IT environment. Contained within each security assessment methodology are the elements that permit the identification and categorization of the components of the security posture of a given IT environment. These identified elements provide the language necessary to identify, communicate, and report the results of a risk assessment. These elements are comprised of threats, vulnerabilities, safeguards, countermeasures, and residual risk analysis. As seen in Exhibit 21-3, each of these elements is dynamic and, in combination, constitutes the security posture of the IT environment.

THREATS

A threat is a force that could affect an organization or an element of an organization. Threats can be either external or internal to an organization and, by themselves, are not harmful. However, they have the potential to be harmful. Threats are also defined as either man-made — those that mankind generates — or natural — those that naturally occur. For a threat to affect an organization, it must exploit an existing vulnerability. Every organization is vulnerable to threats. The number, frequency, severity, type, and likelihood of each threat are dependent on the environment of the IT system. Threats can be ranked on a relative scale of low, medium, and high, based on the potential risk to an asset or group of assets.

- *Low* indicates a relatively low probability that this threat would have significant effect.
- *Medium* indicates a moderate probability that this threat would have significant effect if not mitigated by an appropriate safeguard.
- *High* indicates a relatively high probability that the threat could have significant effect if not mitigated by an appropriate safeguard or series of safeguards.

VULNERABILITY

Vulnerability is a weakness or condition of an organization that could permit a threat to take advantage of the weakness to affect its performance. The absence of a firewall to protect an organization's network from external attacks is an example of vulnerability in the protection of the network from potential external attacks. All organizations have and will continue to have vulnerabilities. However, each organization should identify the potential threats that could exploit vulnerabilities and properly safeguard against threats that could have a dramatic effect on performance.

SAFEGUARDS

Safeguards, also called controls, are measures that are designed to prevent, detect, protect, or sometimes react to reduce the likelihood — or to completely mitigate the possibility — of a threat to exploit an organization's vulnerabilities. Safeguards can perform several of these functions at the same time, or they may only perform one of these functions. A firewall that is installed and configured properly is an example of a safeguard to prevent external attacks to the organization's network. Ideally, a "defense-in-depth" approach should be deployed to implement multiple layers of safeguards to establish the appropriate level of protection for the given environment. The layering of protection provides several obstacles for an attacker, thereby consuming the attacker's resources of time, money, and risk in continuing the attack. For instance, a medical research firm should safeguard its product research from theft by implementing a firewall on its

network to prevent someone from obtaining unauthorized access to the network. In addition, the firm might also implement a network intrusion detection system to create an effective defense-in-depth approach to external network safeguards.

A countermeasure is a type of safeguard that is triggered by an attack and is reactive in nature. Its primary goal is to defend by launching an offensive action. Countermeasures should be deployed with caution because they could have a profound effect on numerous systems if activated by an attack.

RESIDUAL RISK ANALYSIS

As a risk assessment is completed, a list of all of the identified vulnerabilities should be documented and a residual risk analysis performed. Through this process, each individual vulnerability is examined along with the existing safeguards (if any), and the residual risk is then determined. The final step is the development of recommendations to strengthen existing safeguards or recommendations to implement new safeguards to mitigate the identified residual risk.

RISK ASSESSMENT METHODOLOGIES

Several risk assessment methodologies are available to the information security professional to evaluate the security posture of an IT environment. The selection of a methodology is based on a combination of factors, including the purpose of the risk assessment, available budget, and the required frequency.

The primary consideration in selecting a risk assessment methodology, however, is the need of the organization for performing the risk assessment. The depth of the risk assessment required is driven by the level of risk attributed to the continued and accurate performance of the organization's systems. An organization that could be put out of business by a systems outage for a few days would hold a much higher level of risk than an organization that could survive weeks or months without their system. For example, an online discount stockbroker would be out of business without the ability to execute timely stock transactions, whereas a construction company might be able to continue operations for several weeks without access to its systems without significant impact.

An organization's risk management approach should also be considered before selecting a risk assessment methodology. Some organizations are proactive in their approach to addressing risk and have a well-established risk management program. Before proceeding in the selection of a risk assessment methodology, it would be helpful to determine if the organization has such a program and the extent of its depth and breadth. In the case

of a highly developed risk assessment methodology, several layers of safeguards are deployed and require a much different risk assessment approach than if the risk management program were not developed and few safeguards had been designed and deployed. Gaining an understanding of the design of the risk management program, or lack thereof, will enable the information security professional conducting the risk assessment to quickly identify the layers of controls that should be considered when scoping the risk assessment.

The risk assessment methodologies available to the information security professional are general and not platform specific. There are several methodologies available, and the inexperienced information security professional and those not familiar with the risk assessment process will quickly become frustrated with the vast array of methodologies and opinions with regard to how to conduct an IT risk assessment. It is the author's opinion that all IT risk assessment methodologies should be based on the platform level. This is the only real way to thoroughly address the risk of a given IT environment. Some of the highest risks associated within an IT environment are technology specific; therefore, each risk assessment should include a technical-level evaluation. However, the lack of technology-specific vulnerability and safeguard information makes the task of a technically driven risk assessment a challenge to the information security professional. Hardware and software changes frequently open up new vulnerabilities with each new version. In an ideal world, a centralized depository of vulnerabilities and associated safeguards would be available to the security professional. In the meantime, the information security professional must rely on decentralized sources of information regarding technical vulnerabilities and associated safeguards. Although the task is daunting, the information security professional can be quite effective in obtaining the primary goal, which is to reduce risk to the greatest extent possible. This might be accomplished by prioritizing risk mitigation efforts on the vulnerabilities that represent the highest risk and diligently eliminating lower-risk vulnerabilities until the risk has been reduced to an acceptable level.

Several varieties of risk assessments are available to the information security professional, each one carrying unique qualities, timing, and cost. In addition, risk assessments can be scoped to fit an organization's needs to address risk and to the budget available to address risk. The lexicon and standards of risk assessments vary greatly. While this provides for a great deal of flexibility, it also adds a lot of frustration when trying to scope an evaluation and determine the associated cost. Listed below are several of the most common types of risk assessments.

QUALITATIVE RISK ASSESSMENT

A qualitative risk assessment is subjective, based on best practices and the experience of the professional performing it. Generally, the findings of a qualitative risk assessment will result in a list of vulnerabilities with a relative ranking of risk (low, medium, or high). Some standards exist for some specific industries, as listed in Exhibit 21-1; however, qualitative risk assessments tend to be open and flexible, providing the evaluator a great deal of latitude in determining the scope of the evaluation. Given that each IT environment potentially represents a unique combination of threats, vulnerabilities, and safeguards, the flexibility is helpful in obtaining quick, cost-effective, and meaningful results. Due to this flexibility, the scope and cost of the qualitative risk assessment can vary greatly. Therefore, evaluators have the ability to scope evaluations to fit an available budget.

QUANTITATIVE RISK ASSESSMENT

A quantitative risk assessment follows many of the same methodologies of a qualitative risk assessment, with the added task of determining the cost associated with the occurrence of a given vulnerability or group of vulnerabilities. These costs are calculated by determining asset value, threat frequency, threat exposure factors, safeguard effectiveness, safeguard cost, and uncertainty calculations. This is a highly effective methodology in communicating risk to an audience that appreciates interpreting risk based on cost. For example, if an information systems security officer of a large oil company wanted to increase the information security budget of the department, presentation of the proposed budget to the board of directors for approval is required. The best way for this professional to effectively communicate the need for additional funding to improve safeguards and the associated increase in the budget is to report the cost of the risk in familiar terms with which the board members are comfortable. In this particular case, the members of the board are very familiar with financial terms. Thus, the expression of risk in terms of financial cost provides a compelling case for action. For such an audience, a budget increase is much more likely to be approved if the presenter indicates that the cost of not increasing the budget has a high likelihood of resulting in a "two billion dollar loss of revenue" rather than "the risk represents a high operational cost." Although the risk represented is the same, the ability to communicate risk in financial terms is very compelling.

A quantitative risk assessment approach requires a professional or team of professionals who are exceptional in their professions to obtain meaningful and accurate results. They must be well seasoned in performing qualitative and quantitative risk assessments, as the old GI-GO (garbage-in, garbage-out) rule applies. If the persons performing the quantitative risk assessment do not properly estimate the cost of an asset and frequency of

loss expectancy, the risk assessment will yield meaningless results. In addition to requiring a more capable professional, a quantitative risk assessment approach necessitates the use of a risk assessment tool such as RiskWatch or CORA (Cost of Risk Analysis). The requirement for the advanced skills of a quantitative risk assessment professional and the use of a quantitative risk assessment tool significantly increases the cost above that of a qualitative risk assessment. For many organizations, a qualitative risk assessment would be more than adequate to identify risk for appropriate mitigation.

As a word of caution when using a quantitative approach, much like the use of statistics in politics to influence an audience's opinion, the cost information that results from a quantitative risk assessment could be manipulated to lead an audience to a variety of conclusions.

INFORMATION TECHNOLOGY AUDIT

IT audits are primarily performed by external entities and internal audit departments with the charge to determine the effectiveness of the security posture over an IT environment and, in the case of a financial statement audit, to determine the reliability (integrity) of the data contained within the system. They essentially focus on the adequacy of and compliance with existing policies, procedures, technical baseline controls, and guidelines. Therefore, the primary purpose of an IT audit is to report the condition of the system and not to improve security. However, IT auditors are usually more than willing to share their findings and recommendations with the IT department. In addition, IT auditors are required to document their work in sufficient detail as to permit another competent IT auditor to perform the exact same audit procedure (test) and come to the same conclusion. This level of documentation is time-consuming and therefore usually has an effect on the depth and breadth of the evaluation. Thus, IT audits may not be as technically deep in scope as a non-audit type of evaluation.

TECHNICAL VULNERABILITY ASSESSMENT

A technical vulnerability assessment is a type of risk assessment that is focused primarily on the technical safeguards at the platform and network levels and does not include an assessment of physical, environmental, configuration management, and management safeguards.

NETWORK TECHNICAL VULNERABILITY ASSESSMENT

The safeguards employed at the network level support all systems contained within its environment. Sometimes these collective systems are referred to as a general support system. Most networks are connected to the Internet, which requires protection from exterior threats. Accordingly, a network technical vulnerability assessment should include an evaluation of the

Exhibit 21-4. Automated technical vulnerability assessment tools.

Nessus. This is a free system security scanning software that provides the ability to remotely evaluate security within a given network and determine the vulnerabilities that an attacker might use.

ISS Internet Scanner. A security scanner that provides comprehensive network vulnerability assessment for measuring online security risks, it performs scheduled and selective probes of communication services, operating systems, applications, and routers to uncover and report systems vulnerabilities.

Shadow Security Scanner. This tool identifies known and unknown vulnerabilities, suggests fixes to identified vulnerabilities, and reports possible security holes within a network's Internet, intranet, and extranet environments. It employs a unique artificial intelligence engine that allows the product to think like a hacker or network security analyst attempting to penetrate your network.

NMAP. NMAP (Network Mapper) is an open-source utility for network exploration or security auditing. It rapidly scans large networks using raw IP packets in unique ways to determine what hosts are available on the network, what services (ports) they are offering, what operating system (and OS version) they are running, and what type of packet filters or firewalls are in use. NMAP is free software available under the terms of the GNU GPL.

Snort. This packet-sniffing utility monitors displays and logs network traffic.

L0ftCrack. This utility can crack captured password files through comparisons of passwords to dictionaries of words. If the users devised unique passwords, the utility uses brute-force guessing to reveal the passwords of the users.

safeguards implemented to protect the network and its infrastructure. This would include the routers, load balancers, firewalls, virtual private networks, public key infrastructure, single sign-on solutions, network-based operating systems (e.g., Windows 2000), and network protocols (e.g., TCP/IP). Several automated tools can be used to assist the vulnerability assessment team. See Exhibit 21-4 for a list of some of the more common tools used.

PLATFORM TECHNICAL VULNERABILITY ASSESSMENT

The safeguards employed at the platform level support the integrity, availability, and confidentiality of the data contained within the platform. A platform is defined as a combination of hardware, operating system software, communications software, security software, and the database management system and application security that support a set of data (see Exhibit 21-5 for an example of a mainframe platform diagram). The combination of these distinctly separate platform components contains a unique set of risks, necessitating that each platform be evaluated based on its unique combination. Unless the evaluator is able to examine the safeguards at the platform level, the integrity of the data cannot be properly and completely assessed and, therefore, is not reliable. Several automated tools can be used by the vulnerability assessment team.

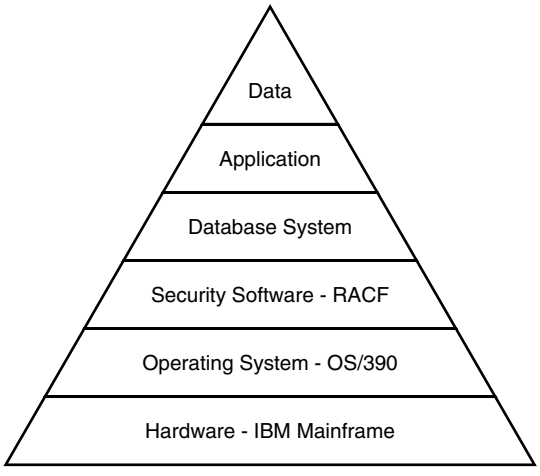

Exhibit 21-5. Mainframe platform diagram.

PENETRATION TESTING

A penetration test, also known as a pen test, is a type of risk assessment; but its purpose is quite different. A pen test is designed to test the security of a system after an organization has implemented all designed safeguards, performed a risk assessment, implemented all recommended improvements, and implemented all new recommended safeguards. It is the final test to determine if enough layered safeguards have been sufficiently implemented to prevent a successful attack against the system. This form of ethical hacking attempts to find vulnerabilities that have been overlooked in prior risk assessments. Frequently, a successful penetration is accomplished as a result of the penetration team, otherwise known as a tiger team, discovering multiple vulnerabilities that by themselves are not considered high risk but, when combined, create a backdoor permitting the penetration team to successfully exploit the low-risk vulnerabilities. There are several potential components to a pen test that, based on the organization's needs, can be selected for use:

- *External penetration testing* is performed from outside of the organization's network, usually from the Internet. The organization can either provide the pen team with the organization's range of IP addresses or ask the evaluators to perform a blind test. Blind tests are more expensive because it will take the penetration team time to discover the IP addresses of the organization. While it might seem to be a more effective test to have the team perform a blind test, it is inevitable that the team will find the IP addresses; therefore, it may be considered a waste of time and funds.

- *Internal penetration testing* is performed within the internal network of the organization. The penetration team attempts to gain access to sensitive unauthorized areas of the system. The internal penetration test is a valuable test, especially in light of the fact that an estimated 80 percent of incidents of unauthorized access are committed by employees.
- *Social engineering* can be used by the pen testers to discover vital information from the organization's personnel that might be helpful in launching an attack. For instance, a pen tester might drive up to the building of the organization, write down the name on an empty reserved parking space, and then call the help desk impersonating the absent employee to report that they had forgotten their password. The pen tester would then request that his password be reset so that he can get back into the system. Unless the help desk personnel have a way (employee number, etc.) to verify his identity, they will reset the password, giving the attacker the opportunity to make a new password for the absent employee and gain unauthorized access to the network.
- *War dialing tools* can be used to automatically dial every combination of phone numbers for a given phone number exchange in an attempt to identify a phone line that has a modem connected. Once a phone line with an active modem has been discovered, the penetration team will attempt to gain access to the system.
- *Dumpster diving* is the practice of searching through trash cans and recycling bins in an attempt to obtain information that will allow the penetration team to gain access to the system.

Penetration testing is the most exciting of all of the risk assessments because it is an all-out attempt to gain access to the system. It is the only risk assessment methodology that proves the existence of a vulnerability or series of vulnerabilities. The excitement of penetration testing is also sometimes perpetuated by those who perform them. Some pen testers, also known as ethical hackers or "white hats," are retired hackers who at one time were "black hats."

Some organizations might be tempted to skip the detailed risk assessment and risk remediation plan and go straight to a penetration test. While pen testing is an enthralling process, the results will be meaningless if the organization does not do its homework before the penetration test. In all likelihood, a good penetration team will gain access to an organization's systems if it has not gone through the rigors of the risk assessment and improvement of safeguards.

EVALUATING IDENTIFIED VULNERABILITIES

After the vulnerabilities have been identified through a risk assessment, a vulnerability analysis should be performed to rank each vulnerability according to its risk level:

- *Low.* The risk of this vulnerability is not considered significant; however, when combined with several other low-risk vulnerabilities, the aggregate might be considered either a medium or high risk. Recommended safeguards need to be reviewed to determine if they are practical or cost-effective relative to the risk of the vulnerability.
- *Medium.* This risk is potentially significant. If the vulnerability could be exploited more readily in combination with another vulnerability, then this risk could be ranked higher. Corrective action of a medium risk level should be taken within a short period of time after careful consideration of the cost-effectiveness of implementing the recommended safeguard.
- *High.* The risk of this vulnerability is significant and, if exploited, could have profound effects on the viability of the organization. Immediate corrective action should be taken to mitigate the risk.

ANALYZING PAIRED VULNERABILITIES

In addition to ranking individual vulnerabilities, an analysis of all of the vulnerabilities should be performed to determine if any of the combinations of vulnerabilities, when considered together, represent a higher level of risk. These potentially higher-risk combinations should be documented and action taken to mitigate the risk. This is particularly important when considering the low-risk items because the combination of these lower-risk items could create the backdoor that permits an attacker to gain access to the system. To determine the relative nominal risk level of the identified vulnerabilities, the information security professional should identify potential layers of safeguards that mitigate a risk and then determine the residual risk. A residual risk mitigation plan should then be developed to reduce the residual risk to an acceptable level.

CONCLUSION

Unfortunately, security assessments are usually the last action that the IT department initiates as part of its security program. Other priorities such as application development, infrastructure building, or computer operations typically take precedence. Many organizations typically do not take security past the initial implementation because of a rush-to-build functionality of the systems — until an IT auditor or a hacker forces them to take security seriously. The "pressures to process" sometimes force organizations to ignore prudent security design and security assessment, leaving security as an afterthought. In these circumstances, security is not considered a critical element in serving the users; thus, many times security is left behind. The reality is that information contained within a system cannot be relied upon as having integrity unless security has been assessed and adequate protection of the data has been provided for the entire time the data has resided on the system.

Evaluating the security posture of an IT environment is a challenge that involves balancing the risk, frequency of evaluation, and cost. Security that is designed, tested, and implemented based on a strong security strategy and policy will be highly effective and in the long run cost-effective. Unfortunately, there are no clear-cut answers regarding how often a given IT environment should be evaluated. The answer may be found by defining how long the organization may viably operate without the systems. Such an answer will define the level of risk the organization is willing, or is not willing, to accept. A security posture that is built with the knowledge of this threshold of risk can lead to a system of safeguards that is both risk-based and cost-effective.

ABOUT THE AUTHOR

Brian Schultz, CISSP, CISA, is chairman of the board of INTEGRITY, a nonprofit organization dedicated to assisting the federal government with implementation of information security solutions. An expert in the field of information security assessment, Mr. Schultz has, throughout his career, assessed the security of numerous private and public organizations. He is a founding member of the Northern Virginia chapter of the Information Systems Security Association (ISSA).

Cyber-Risk Management: Technical and Insurance Controls for Enterprise-Level Security

Carol A. Siegel, Ty R. Sagalow, and Paul Serritella

Traditional approaches to security architecture and design have attempted to achieve the goal of the elimination of risk factors — the complete prevention of system compromise through technical and procedural means. Insurance-based solutions to risk long ago admitted that a complete elimination of risk is impossible and, instead, have focused more on reducing the impact of harm through financial avenues — providing policies that indemnify the policyholder in the event of harm.

It is becoming increasingly clear that early models of computer security, which focused exclusively on the risk-elimination model, are not sufficient in the increasingly complex world of the Internet. There is simply no magic bullet for computer security; no amount of time or money can create a perfectly hardened system. However, insurance cannot stand alone as a risk mitigation tool — the front line of defense must always be a complete information security program and the implementation of security tools and products. It is only through leveraging both approaches in a complementary fashion that an organization can reach the greatest degree of risk reduction and control. Thus, today, the optimal model requires a program of understanding, mitigating, and transferring risk through the use of integrating technology, processes, and insurance — that is, a risk management approach.

The risk management approach starts with a complete understanding of the risk factors facing an organization. Risk assessments allow for security teams to design appropriate control systems and leverage the necessary technical tools; they also are required for insurance companies to properly draft and price policies for the remediation of harm. Complete risk assessments must take into account not only the known risks to a system but also the possible exploits that might develop in the future. The completeness of cyber risk management and assessment is the backbone of any secure computing environment.

After a risk assessment and mitigation effort has been completed, insurance needs to be procured from a specialized insurance carrier of top financial strength and global reach. The purpose of the insurance is threefold: (1) assistance in the evaluation of the risk through products and services available from the insurer, (2) transfer of the financial costs of a successful computer attack or threat to the carrier, and (3) the provision of important post-incident support funds to reduce the potential reputation damage after an attack.

The Risk Management Approach

As depicted in Exhibit 69.1, risk management requires a continuous cycle of assessment, mitigation, insurance, detection, and remediation.

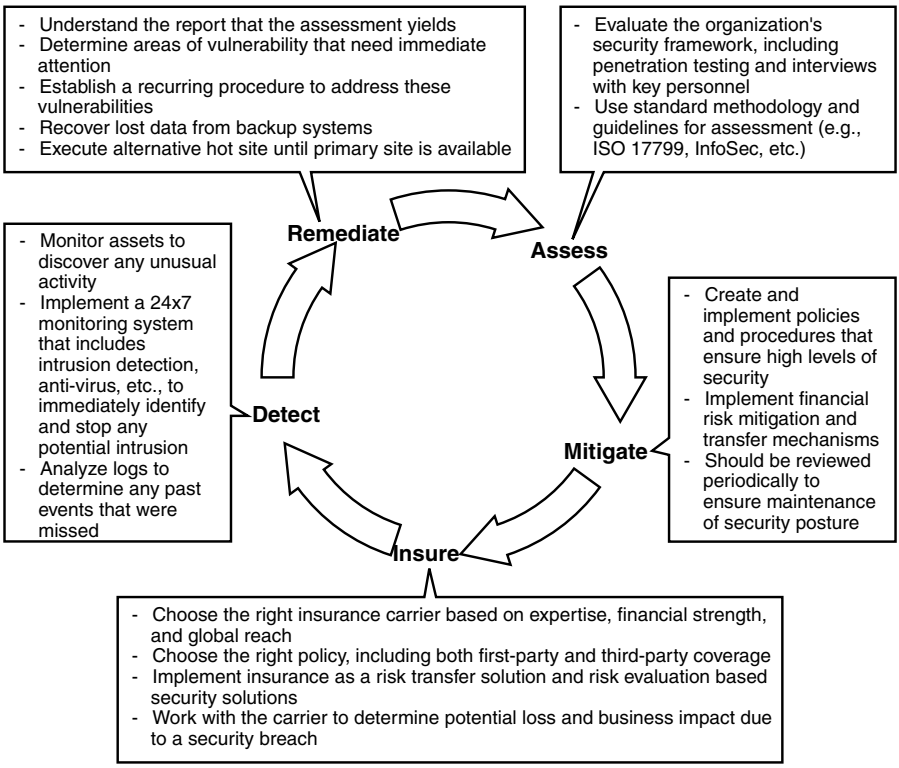

EXHIBIT 69.1 Risk management cycle.

Assess

An assessment means conducting a comprehensive evaluation of the security in an organization. It usually covers diverse aspects, ranging from physical security to network vulnerabilities. Assessments should include penetration testing of key enterprise systems and interviews with security and IT management staff. Because there are many different assessment formats, an enterprise should use a method that conforms to a recognized standard (e.g., ISO 17799, InfoSec — Exhibit 69.2). Regardless of the model used, however, the assessment should evaluate people, processes, technology, and financial management. The completed assessment should then be used to determine what technology and processes should be employed to mitigate the risks exposed by the assessment.

An assessment should be done periodically to determine new vulnerabilities and to develop a baseline for future analysis to create consistency and objectivity.

Mitigate

Mitigation is the series of actions taken to reduce risk, minimize chances of an incident occurring, or limit the impact of any breach that does occur. Mitigation includes creating and implementing policies that ensure high levels of security. Security policies, once created, require procedures that ensure compliance. Mitigation also includes determining and using the right set of technologies to address the threats that the organization faces and implementing financial risk mitigation and transfer mechanisms.

Insure

Insurance is a key risk transfer mechanism that allows organizations to be protected financially in the event of loss or damage. A quality insurance program can also provide superior loss prevention and analysis recommendations, often providing premium discounts for the purchase of certain security products and services from

EXHIBIT 69.2 The 11 Domains of Risk Assessment

Security Policy: During the assessment, the existence and quality of the organization's security policy are evaluated. Security policies should establish guidelines, standards, and procedures to be followed by the entire organization. These need to be updated frequently.

Organizational Security: One of the key areas that any assessment looks at is the organizational aspect of security. This means ensuring that adequate staff has been assigned to security functions, that there are hierarchies in place for security-related issues, and that people with the right skill sets and job responsibilities are in place.

Asset Classification and Control: Any business will be impacted if the software and hardware assets it has are compromised. In evaluating the security of the organization, the existence of an inventory management system and risk classification system have to be verified.

Personnel Security: The hiring process of the organization needs to be evaluated to ensure that adequate background checks and legal safeguards are in place. Also, employee awareness of security and usage policies should be determined.

Physical and Environmental Security: Ease of access to the physical premises needs to be tested, making sure that adequate controls are in place to allow access only to authorized personnel. Also, the availability of redundant power supplies and other essential services has to be ensured.

Communication and Operations Management: Operational procedures need to be verified to ensure that information processing occurs in a safe and protected manner. These should cover standard operating procedures for routine tasks as well as procedures for change control for software, hardware, and communication assets.

Access Control: This domain demands that access to systems and data be determined by a set of criteria based on business requirement, job responsibility, and time period. Access control needs to be constantly verified to ensure that it is available only on a need-to-know basis with strong justification.

Systems Development and Maintenance: If a company is involved in development activity, assess whether security is a key consideration at all stages of the development life cycle.

Business Continuity Management: Determining the existence of a business continuity plan that minimizes or eliminates the impact of business interruption is a part of the assessment.

Compliance: The assessment has to determine if the organization is in compliance with all regulatory, contractual, and legal requirements.

Financial Considerations: The assessment should include a review to determine if adequate safeguards have to be implemented to ensure that any security breach results in minimal financial impact. This is implemented through risk transfer mechanisms — primarily insurance that covers the specific needs of the organization.

companies known to the insurer that dovetail into a company's own risk assessment program. Initially, determining potential loss and business impact due to a security breach allows organizations to choose the right policy for their specific needs. The insurance component then complements the technical solutions, policies, and procedures. A vital step is choosing the right insurance carrier by seeking companies with specific underwriting and claims units with expertise in the area of information security, top financial ratings, and global reach. The right carrier should offer a suite of policies from which companies can choose to provide adequate coverage.

Detect

Detection implies constant monitoring of assets to discover any unusual activity. Usually this is done by implementing a 24/7 monitoring system that includes intrusion detection to immediately identify and stop any potential intrusion. Additionally, anti-virus solutions allow companies to detect new viruses or worms as they appear. Detection also includes analyzing logs to determine any past events that were missed and specification of actions to prevent future misses. Part of detection is the appointment of a team in charge of incident response.

Remediate

Remediation is the tactical response to vulnerabilities that assessments discover. This involves understanding the report that the assessment yields and prioritizing the areas of vulnerability that need immediate attention.

The right tactic and solution for the most efficient closing of these holes must be chosen and implemented. Remediation should follow an established recurring procedure to address these vulnerabilities periodically.

In the cycle above, most of the phases focus on the assessment and implementation of technical controls. However, no amount of time or money spent on technology will eliminate risk. Therefore, insurance plays a key role in any risk management strategy. When properly placed, the insurance policy will transfer the financial risk of unavoidable security exposures from the balance sheet of the company to that of the insurer. As part of this basic control, companies need to have methods of detection (such as intrusion detection systems, or IDS) in place to catch the cyber-attack when it takes place. Post incident, the insurer will then remediate any damage done, including finance and reputation impacts. The remediation function includes recovery of data, insurance recoveries, and potential claims against third parties. Finally, the whole process starts again with an assessment of the company's vulnerabilities, including an understanding of a previously unknown threat.

Types of Security Risks

The CSI 2001 Computer Crime and Security Survey[2] confirms that the threat from computer crime and other information security breaches continues unabated and that the financial toll is mounting. According to the survey, 85 percent of respondents had detected computer security breaches within the past 12 months; and the total amount of financial loss reported by those who could quantify the loss amounted to $377,828,700 — that is, over $2 million per event.

One logical method for categorizing financial loss is to separate loss into three general areas of risk:

1. *First-party financial risk:* direct financial loss not arising from a third- party claim (called first-party security risks).
2. *Third-party financial risk:* a company's legal liabilities to others (called third-party security risks).
3. *Reputation risk:* the less quantifiable damages such as those arising from a loss of reputation and brand identity. These risks, in turn, arise from the particular cyber-activities. Cyber-activities can include a Web site presence, e-mail, Internet professional services such as Web design or hosting, network data storage, and E-commerce (i.e., purchase or sale of goods and services over the Internet).

First-party security risks include financial loss arising from damage, destruction, or corruption of a company's information assets — that is, data. Information assets — whether in the form of customer lists and privacy information, business strategies, competitor information, product formulas, or other trade secrets vital to the success of a business — are the real assets of the 21st century. Their proper protection and quantification are key to a successful company. Malicious code transmissions and computer viruses — whether launched by a disgruntled employee, overzealous competitor, cyber-criminal, or prankster — can result in enormous costs of recollection and recovery.

A second type of first-party security risk is the risk of revenue loss arising from a successful denial-of-service (DoS) attack. According to the Yankee Group, in February 2000 a distributed DoS attack was launched against some of the most sophisticated Web sites, including Yahoo, Buy.com, CNN, and others, resulting in $1.2 billion in lost revenue and related damages. Finally, first-party security risk can arise from the theft of trade secrets.

Third-party security risk can manifest itself in a number of different types of legal liability claims against a company, its directors, officers, or employees. Examples of these risks can arise from the company's presence on the Web, its rendering of professional services, the transmission of malicious code or a DoS attack (whether or not intentional), and theft of the company's customer information.

The very content of a company's Web site can result in allegations of copyright and trademark infringement, libel, or invasion of privacy claims. The claims need not even arise from the visual part of a Web page but can, and often do, arise out of the content of a site's metatags — the invisible part of a Web page used by search engines.

If a company renders Internet-related professional services to others, this too can be a source of liability. Customers or others who allege that such services, such as Web design or hosting, were rendered in a negligent manner or in violation of a contractual agreement may find relief in the court system.

Third-party claims can directly arise from a failure of security. A company that negligently or through the actions of a disgruntled employee transmits a computer virus to its customers or other e-mail recipients may be open to allegations of negligent security practices. The accidental transmission of a DoS attack can pose similar legal liabilities. In addition, if a company has made itself legally obligated to keep its Web site open on a 24/7 basis to its customers, a DoS attack shutting down the Web site could result in claims by its customers.

EXHIBIT 69.3 First- and Third-Party Risks

Activity	First-Party Risk	Third-Party Risk
Web site presence	Damage or theft of data (assumes database is connected to network) via hacking	Allegations of trademark, copyright, libel, invasion of privacy, and other Web content liabilities
E-mail	Damage or theft of data (assumes database is connected to network) via computer virus; shutdown of network via DoS attack	Transmission of malicious code (e.g., NIMDA) or DoS due to negligent network security; DoS customer claims if site is shut down due to DoS attack
E-commerce	Loss of revenue due to successful DoS attack	Customer suits
Internet professional services		Customer suits alleging negligent performance of professional services
Any		Claims against directors and officers for mismanagement

A wise legal department will make sure that the company's customer agreements specifically permit the company to shut down its Web site for any reason at any time without incurring legal liability.

Other potential third-party claims can arise from the theft of customer information such as credit card information, financial information, health information, or other personal data. For example, theft of credit card information could result in a variety of potential lawsuits, whether from the card-issuing companies that then must undergo the expense of reissuing, the cardholders themselves, or even the Web merchants who later become the victims of the fraudulent use of the stolen credit cards. As discussed later, certain industries such as financial institutions and healthcare companies have specific regulatory obligations to guard their customer data.

Directors and officers (D&Os) face unique, and potentially personal, liabilities arising out of their fiduciary duties. In addition to case law or common-law obligations, D&Os can have obligations under various statutory laws such as the Securities Act of 1933 and the Securities & Exchange Act of 1934. Certain industries may also have specific statutory obligations such as those imposed on financial institutions under the Gramm–Leach–Bliley Act (GLBA), discussed in detail later.

Perhaps the most difficult and yet one of the most important risks to understand is the intangible risk of damage to the company's reputation. Will customers give a company their credit card numbers once they read in the paper that a company's database of credit card numbers was violated by hackers? Will top employees remain at a company so damaged? And what will be the reaction of the company's shareholders? Again, the best way to analyze reputation risk is to attempt to quantify it. What is the expected loss of future business revenue? What is the expected loss of market capitalization? Can shareholder class or derivative actions be foreseen? And, if so, what can the expected financial cost of those actions be in terms of legal fees and potential settlement amounts?

The risks just discussed are summarized in Exhibit 69.3.

Threats

The risks defined above do not exist in a vacuum. They are the product of specific threats, operating in an environment featuring specific vulnerabilities that allow those threats to proceed uninhibited. Threats may be any person or object, from a disgruntled employee to an act of nature, that may lead to damage or value loss for an enterprise. While insurance may be used to minimize the costs of a destructive event, it is not a substitute for controls on the threats themselves.

Threats may arise from external or internal entities and may be the product of intentional or unintentional action. External entities comprise the well-known sources — hackers, virus writers — as well as less obvious ones such as government regulators or law enforcement entities. Attackers may attempt to penetrate IT systems through various means, including exploits at the system, server, or application layers. Whether the intent is to interrupt business operations, or to directly acquire confidential data or access to trusted systems, the cost in system downtime, lost revenue, and system repair and redesign can be crippling to any enterprise. The collapse

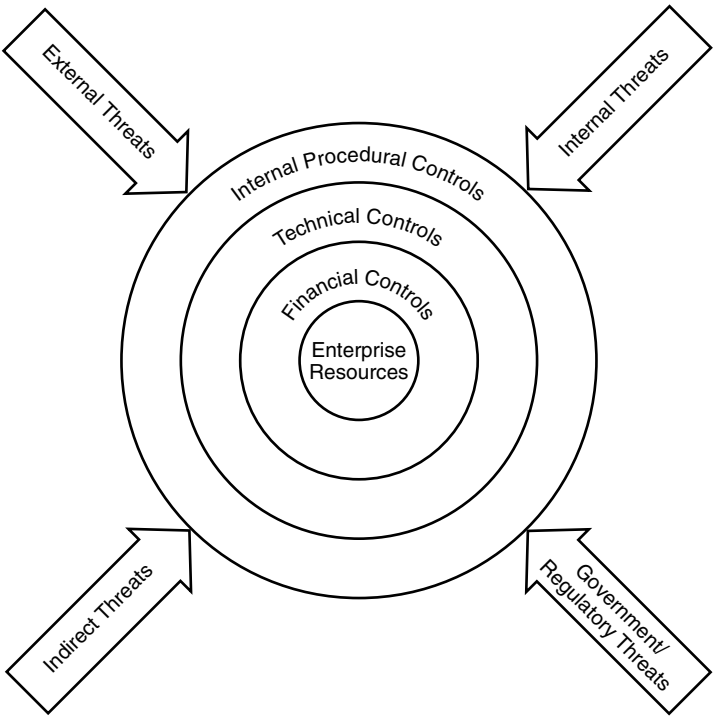

EXHIBIT 69.4 Enterprise resource threats.

of the British Internet service provider (ISP) Cloud-Nine in January 2002, due to irreparable damage caused by distributed DoS attacks launched against its infrastructure, is only a recent example of the enterprise costs of cyber-attacks.[3]

Viruses and other malicious code frequently use the same exploits as human attackers to gain access to systems. However, as viruses can replicate and spread themselves without human intervention, they have the potential to cause widespread damage across an internal network or the Internet as a whole.

Risks may arise from non-human factors as well. For example, system outages through failures at the ISP level, power outages, or natural disasters may create the same loss of service and revenue as attackers conducting DoS attacks. Therefore, technical controls should be put in place to minimize those risks. These risks are diagrammed in Exhibit 69.4.

Threats that originate from within an organization can be particularly difficult to track. This may entail threats from disgruntled employees (or ex-employees), or mistakes made by well-meaning employees as well. Many standard technical controls — firewalls, anti-virus software, or intrusion detection — assume that the internal users are working actively to support the security infrastructure. However, such controls are hardly sufficient against insiders working actively to subvert a system. Other types of risks — for example, first-party risks of intellectual property violations — may be created by internal entities without their knowledge. Exhibit 69.5 describes various threats by type.

As noted, threats are comprised of motive, access, and opportunity — outsiders must have a desire to cause damage as well as a means of affecting the target system. While an organization's exposure to risk can never be completely eliminated, all steps should be taken to minimize exposure and limit the scope of damage. Such vulnerabilities may take a number of forms.

Technical vulnerabilities include exploits against systems at the operating system, network, or application level. Given the complexity and scope of many commercial applications, vulnerabilities within code become increasingly difficult to detect and eradicate during the testing and quality assurance (QA) processes. Examples range from the original Internet Worm to recently documented vulnerabilities in commercial instant messaging clients and Web servers. Such weaknesses are an increasing risk in today's highly interconnected environments.

EXHIBIT 69.5 Threat Matrix

	Threat	Description	Security Risk	Controls
External	System penetration (external source)	Attempts by external parties to penetrate corporate resources to modify or delete data or application systems	Moderate	Strong authentication; strong access control; ongoing system support and tracking
	Regulatory action	Regulatory action or investigation based on corporate noncompliance with privacy and security guidelines	Low to moderate	Data protection; risk assessment and management programs; user training; contractual controls
	Virus penetration	Malicious code designed to self-replicate	Moderate	Technological: anti-virus controls
	Power loss or connectivity loss	Loss of Internet connectivity, power, cooling system; may result in large-scale system outages	Low	Redundant power and connectivity; contractual controls with ISP/hosting facilities
Internal	Intellectual property violation	Illicit use of third-party intellectual property (images, text, code) without appropriate license arrangements	Low to moderate	Procedural and personnel controls; financial controls mitigating risk
	System penetration (internal source)	Malicious insiders attempting to access restricted data	Moderate	Strong authentication; strong access control; use of internal firewalls to segregate critical systems

Weaknesses within operating procedures may expose an enterprise to risk not controlled by technology. Proper change management processes, security administration processes, and human resources controls and oversight, for example, are necessary. They may also prove disruptive in highly regulated environments, such as financial services or healthcare, in which regulatory agencies require complete sets of documentation as part of periodic auditing requirements.

GLBA/HIPAA

Title V of the Gramm–Leach–Bliley Act (GLBA) has imposed new requirements on the ways in which financial services companies handle consumer data. The primary focus of Title V, and the area that has received the most attention, is the sharing of personal data among organizations and their unaffiliated business partners and agencies. Consumers must be given notice of the ways in which their data is used and must be given notice of their right to opt out of any data-sharing plan.

However, Title V also requires financial services organizations to provide adequate security for systems that handle customer data. Security guidelines require the creation and documentation of detailed data security programs addressing both physical and logical access to data, risk assessment, and mitigation programs, and employee training in the new security controls. Third-party contractors of financial services firms are also bound to comply with the GLBA regulations.

On February 1, 2001, the Department of the Treasury, Federal Reserve System, and Federal Deposit Insurance Corporation issued interagency regulations, in part requiring financial institutions to:

- Develop and execute an information security program.
- Conduct regular tests of key controls of the information security program. These tests should be conducted by an independent third party or staff independent of those who develop or maintain the program.
- Protect against destruction, loss, or damage to customer information, including encrypting customer information while in transit or storage on networks.
- Involve the board of directors, or appropriate committee of the board, to oversee and execute all of the above.

Because the responsibility for developing specific guidelines for compliance was delegated to the various federal and state agencies that oversee commercial and financial services (and some are still in the process of being issued), it is possible that different guidelines for GLBA compliance will develop between different states and different financial services industries (banking, investments, insurance, etc.).

The Health Insurance Portability and Accountability Act (HIPAA) will force similar controls on data privacy and security within the healthcare industry. As part of HIPAA regulations, healthcare providers, health plans, and clearinghouses are responsible for protecting the security of client health information. As with GLBA, customer medical data is subject to controls on distribution and usage, and controls must be established to protect the privacy of customer data. Data must also be classified according to a standard classification system to allow greater portability of health data between providers and health plans. Specific guidelines on security controls for medical information have not been issued yet. HIPAA regulations are enforced through the Department of Health and Human Services.

As GLBA and HIPAA regulations are finalized and enforced, regulators will be auditing those organizations that handle medical or financial data to confirm compliance with their security programs. Failure to comply can be classified as an unfair trade practice and may result in fines or criminal action. Furthermore, firms that do not comply with privacy regulations may leave themselves vulnerable to class-action lawsuits from clients or third-party partners. These regulations represent an entirely new type of exposure for certain types of organizations as they increase the scope of their IT operations.

Cyber-Terrorism

The potential for cyber-terrorism deserves special mention. After the attacks of 9/11/01, it is clear that no area of the world is protected from a potential terrorist act. The Internet plays a critical role in the economic stability of our national infrastructure. Financial transactions, running of utilities and manufacturing plants, and much more are dependent upon a working Internet. Fortunately, companies are coming together in newly formed entities such as ISACs (Information Sharing and Analysis Centers) to determine their interdependency vul-

nerabilities and plan for the worst. It is also fortunate that the weapons used by a cyber-terrorist do not differ much from those of a cyber-criminal or other hacker. Thus, the same risk management formula discussed above should be implemented for the risk of cyber-terrorism.

Insurance for Cyber-Risks

Insurance, when properly placed, can serve two important purposes. First, it can provide positive reinforcement for good behavior by adjusting the availability and affordability of insurance depending upon the quality of an insured's Internet security program. It can also condition the continuation of such insurance on the maintenance of that quality. Second, insurance will transfer the financial risk of a covered event from a company's balance sheet to that of the insurer.

The logical first step in evaluating potential insurance solutions is to review the company's traditional insurance program, including its property (including business interruption) insurance, comprehensive general liability (CGL), directors and officers insurance, professional liability insurance, and crime policies. These policies should be examined in connection with a company's particular risks (see above) to determine whether any gap exists. Given that these policies were written for a world that no longer exists, it is not surprising that traditional insurance policies are almost always found to be inadequate to address today's cyber-needs. This is not due to any *defect* in these time-honored policies but simply due to the fact that, with the advent of the new economy risks, there comes a need for specialized insurance to meet those new risks.
