- *Examining the geography of the facility.* The physical layout is an important determinant of the required security measures and equipment.
- *Will the various security systems be independent or combined?* Access control, alarms, closed-circuit television, and all other systems should be taken into consideration.
- *Should the security system be combined with other functions?* Energy management, time-and-attendance monitoring, and other functions that may be integrated should be considered.
- *Local control or a commercial central station?* The control center should be located in a secure area for monitoring, management, and response of the security system.

Principles of Access Control

A complete access control system performs three essential functions within the security system:

1. Limiting access through a portal to a defined list of authorized persons
2. Creating an alarm if illegitimate access or activity is detected
3. Providing a record of all accesses for use in postincident investigation

Not all systems provide all of these functions.

To identify authorized persons, all access control systems use one or more of three basic techniques, which have been described as involving something a person knows, something a person has, and something a person is or does. Physically, examples of these three security methods are the combination lock, the portable key, and the physical attribute.

The combination lock is also called a stored-code system; the code is a series of numbers that is stored both in the user's memory and in the lock mechanism, and entry of the correct code by the user with a rotary dial or a set of push buttons allows access. Access control systems universally use a set of push buttons for entry of the code in a combination lock system, and they are usually known as keypad access control systems.

The portable key operates on the principle that if the prospective admittee possesses an object that itself contains the proper access code, that person is qualified to be admitted; the ordinary metal key and lock is the simplest example of such a system. Although ordinary metal keys are easily duplicated and ordinary locks are easily picked, there are key-and-lock systems that are the equal of many modern card-access systems in both security and price; both post office boxes and bank safe-deposit boxes are opened with metal keys (and in both cases the portable-key system is combined with other elements to make up an effective total security system).

The most common form of portable-key access control uses a plastic card with a magnetic stripe as the key, but there are also a variety of sizes and shapes of tokens, metal and plastic keys, and even pens and rings. The code is embedded in these devices by various means, and the key is recognized by a mechanism that automatically reads the code when the key is inserted in a slot, groove, or hole.

Another method of portable-key access control (which is discussed later) uses proximity cards that emit a signal that can be picked up by a badge reader to open doors for authorized persons. Often, card access devices are combined with employee badges to minimize the temptation to allow someone else to use the access control card or to prevent an intruder from using a lost or stolen card.

The physical-attribute system, which is also examined later, is based on recognizing a unique physical or behavioral characteristic of the person to be allowed admittance. In the past, this characteristic has been the human face, and the access control system consisted of a guard who compared the actual face with a picture badge or ID card; this is still the most widespread physical-attribute system in use today. There are also automatic and semiautomatic systems using faces, fingerprints, hand geometry, voiceprints, signatures, and the pattern of blood vessels on the wrist and the retina of the eye.

An access control system is not necessarily a personal identification system, and not all personal identification systems are used for access control. The following categorizations of access control systems may be useful:

- *Universal code or card:* All persons who may be admitted know the same code or carry a card containing the same code, and the access control system opens the portal when it recognizes the code.
- *Group coding:* Persons have a code or card-code that identifies them as part of a group to be admitted to a particular area or at a particular time.

- *Personal identification systems:* A unique code number or set of physical attributes is assigned to each person, and the access decision is based upon whether that particular individual is to be admitted to that place at that time. Personal identification systems have other applications as well, including time-and-attendance monitoring and job-cost accounting data collection.

Weaknesses, Combinations, and Features

There are fundamental weaknesses in all of these basic techniques that automation cannot change. A code can be divulged to an accomplice or observed during entry. A key can be stolen, lost, copied, or given to an accomplice. These situations can occur whether the code and key are meant to open $1.98 locks or are recognized by $100,000 computer systems. Physical-attribute systems have inherent false-acceptance and false-rejection errors, and the two kinds of errors are usually balanced against each other.

Combinations of techniques can greatly increase the security of a system. For example, a code-plus-key system requires that the prospective admittee inserts the key into a reader and enters the proper code using a keypad. This removes many of the weaknesses of the two simpler systems; it also costs more than either of the simpler systems alone.

Other features that can improve the security of an access control system are:

- *Tamper alarms:* If a perpetrator can gain access by smashing or opening the electronic controller, the security level obviously has been diminished. The controls should not be accessible from the unprotected side of the portal, and a sensor should be provided that can detect an attack on the unit and create an alarm.
- *Power-fail protection:* Some units have internal batteries so that an access control device continues to perform its function even if power fails.
- *Fail-safe or fail-soft protection:* The equipment must be expected to fail, however infrequently. There should be a mechanical-key bypass to allow access under failure conditions. When failure occurs, the portal defaults to either permanently open or permanently closed.
- *Code changes:* An effective element of the security system can be the periodic changing of the access codes. Both the code that the person has or knows and the code within the access control equipment itself must be changed.

Keypad Access Control

Keypad access control devices use a combination-lock technique for access control; they require that a correct sequence of numbers is depressed on a set of push buttons or selected from a displayed sequence of numbers using a single push button to gain access. The mechanism may be mechanically operated, in which case the positions of the push buttons operate a mechanism similar to the tumblers in an ordinary lock, allowing the bolt to be manually operated or closing a switch that may operate an electric door strike. Most keypad devices are electronically operated, with the sequence of push buttons being decoded by logic circuits and the door being electrically unlocked.

As in all combination-lock devices, the level of security that is provided depends on the number of combinations available. The number of combinations provided depends on the following factors:

- The number of keys or code numbers provided
- The number of key depressions required to enter the code
- Whether a key may be repeated in the code sequence
- Whether multiple keys may be depressed at one time

Most keypad access control systems use a ten-key pad and a four-digit repeating, nonmultiple code. However, there are systems that use from 5 to 16 keys and from 2- to 10-digit codes, and the number of code combinations ranges from 720 to more than 4 million.

The simplest method of attacking a keypad control system is to try all possible numerical combinations. The defenses against such attack are:

- *Number of combinations:* The greater the number of combinations, the longer the time needed to try them all.

- *Frequent code changes:* A large number of combinations require the perpetrator to try them over a period of days or weeks; changing the code during the period requires the attacker to begin all over again.
- *Time penalty (error lockout):* This is a feature available with many keypad systems. It deactivates the system for a selected period of time after entry of an incorrect number, so unauthorized persons cannot quickly try a large number of combinations.
- *Combination time:* This option is available with most keypad systems. The system controls the amount of time allowed to enter the combination. Because authorized persons can readily enter their numbers, anyone taking excessive time is likely to be unauthorized.
- *Error alarms:* After an incorrect number has been entered (or in some cases, two or three incorrect numbers), these alarms are activated. This option prevents unauthorized persons from trying a large number of incorrect combinations.

Keypad Options and Features

The most significant options and features found in keypad access control systems are:

- *Master keying:* This option allows supervisory persons access using a code that overrides any restrictions (e.g., time-of-day restrictions) on the code provided to end users, and it usually allows the changing of the ordinary code using the keypad itself.
- *Key override:* Sometimes a metal-key override capability is provided for emergency and supervisory use. If this feature is chosen, it must be recognized that the system has been weakened by allowing both keypad and metal-key access.
- *Door delay:* The length of time that the door is unlocked and can be held open without alarm is controlled and usually is adjustable.
- *Remote indication:* There is usually an electrical means of providing a remote indication (at a guard station or central monitoring facility) that a portal is open.
- *Visitors' call:* A special button may be designated so that persons not possessing the combination may request entry.
- *Hostage or duress alarm:* In the event that an authorized entrant is physically coerced into opening a portal, a hidden alarm can be sounded by depressing an extra or alternative digit.
- *Personal identification:* A few keypad systems provide individual access codes for each authorized person.
- *Weatherproof units:* These are provided by many manufacturers for use on outdoor portals. There are also many forms of indoor units, some with attractive decor, and glow-in-the-dark and lighted keypads.

Most keypad access control devices are self-contained, stand-alone devices intended to operate a single portal using a common code. There are also those that obtain their intelligence from a central control unit that can control multiple portals and may also provide logging, space-and-time zone control, and other relatively sophisticated features. In addition, most manufacturers of card-access systems now offer the option of adding keypad access, thus providing a card-plus-keypad system, as discussed in a later section.

Strengths and Weaknesses of Keypad Systems

The cost of a simple, single-door keypad access control device with simple electronic keypads begins in the $100 range. The keypad alone, with rudimentary electronics, can be bought for as low as $20, but the organization must then add door strikes and battery or power supplies. Mainstream commercial-grade protection begins in the $100 range for mechanical and electrical keypads, and the electrical versions require an equal additional expenditure for a reliable electric strike and other necessary equipment. Installed costs can range from $200 to $500; for pure combination-lock-level access control, without penalties or gadgetry, these units are worth the expense.

Therefore, the first positive attribute of a keypad access system is that it is the least expensive means of providing electronic access control in place of — or in addition to — the conventional metal lock and key. Some other positive attributes are:

- Keypad access control can be made very secure if it provides many possible combinations and is installed as part of a system of secure, frequent code changes.

- Changing the code in a keypad system is a quick and simple process, unlike rekeying a lock-and-key system.
- Keypads are especially effective in combination with other forms of access control (e.g., cards or personal attribute systems).

On the negative side, some characteristics of keypad access systems that should be considered before the security of an operation is entrusted to these devices are:

- The code can be divulged without penalty. An insider can reveal the code to an accomplice, who then can gain illicit entry.
- Longer codes provide better security but also encourage authorized persons to write them down rather than memorize them. Therefore, they can be stolen more easily.
- The code can be determined by trying many combinations, if the precautions described are not implemented.
- The code can be observed as it is entered. Some manufacturers offer privacy panels to prevent such observation. One manufacturer provides a random and always-changing placement of the digits on the keypad, using an LED display, so that the numbers cannot be deduced by observing the positions of the depressed keys; another has a rolling single-digit display that is selected by a single push button, preventing an observer from determining what digit was selected.

The two most serious defects in the keypad access system are being able to divulge the code without penalty and the observability of the code numbers; for these reasons, keypad access should never be used alone except in minimum-security applications.

Portable-Key Access Control

A portable-key access control system admits the holder of a device (which may be a plastic card or other device) that contains a prerecorded code. The device is inserted into a reader, and if it contains the code that the reader requires, the portal is unlocked. This process is no different in concept from the operation of ordinary metal keys and locks. Modern systems, however, use keys that are more difficult to duplicate, and these systems can provide complex logic, identification, control, and logging functions that a simple key cannot. It should be recognized, however, that some versions of the metal lock-and-key system provide at least as much security as the simplest versions of card-access, at comparable cost.

The plastic, wallet-size card is overwhelmingly the most popular device used for portable-key access control systems. It is offered by 97 percent of the vendors, though 10 percent of these vendors offer other forms of portable keys as well. The second most popular device is a key-shaped token, usually plastic but sometimes metal; Medeco offers a standard metal key that contains an integrated computer circuit. Some versions are small enough to fit on an ordinary key ring. There are also metal cards of various sizes and several other kinds of metal-and-plastic tokens, strips, pens, and even finger rings. There is some merit in selecting a standard system to avoid dependence on a single vendor. On the other hand, there is some additional security conferred by using a relatively unique device.

Coding Methods

Various techniques and technologies are used to store the access code on or in the key device. Many of the early automated systems used simple visible bar codes that were read by photocells. Others used Hollerith-coded cards with punched holes identical to those in conventional computer cards, which were read by a punched-card reader. Some of these systems are still available. Other cards contained an electrical diode matrix reader, and the card made an electrical connection with the reader. These may be viewed as an ancestor of the modern smart card; they functioned with as much intelligence as they could, using the available technology.

Currently, most devices are magnetically encoded, and there are three basic types. The bank-card type has a magnetic stripe. The code is recorded magnetically onto the stripe and can be read, erased, and altered using conventional magnetic tape technology. Because this technology is well-known and readily available, the cards are easily corruptible, and several additional safeguards have therefore been developed for situations requiring

high-level security. Some vendors encrypt the data on the card so that even if it is read, it is not useful to the perpetrator. Many users, including banks, use a keypad in conjunction with the card reader, so a code must be entered in addition to an acceptable card. Malco Systems has invented a technique called watermark magnetics, which embeds a code during the card manufacturing process; the code cannot be altered and can be read only by a special reader.

The second type of magnetic encoding uses bits of magnetic material — magnetic slugs — embedded into the card during manufacturing. It is read by an array of magnetic-sensing heads to determine whether there is a slug at each of the possible positions. Wiegand-effect coding is currently the only popular magnetic-slug method in use. Each Wiegand slug incorporates a small bit of wire that is heat-treated under torsion, resulting in a magnetic snap-action. This creates a consistent signal over a wide range of reading speeds, unlike conventional magnetics, in which the read signal is proportionate to the speed of the card past the reader. Wiegand-effect coding yields superior performance in swipe readers, for example, in which the user manually moves the card past the read heads.

The third type of magnetic encoding is a descendent of the magnetic slug. It has a sandwich construction with a sheet of magnetic material in the center of the card; spots can be magnetized at various positions on the sheet, thus creating coding to be read by a magnetic-sensing head. These are usually called barium ferrite cards (named for their magnetic material).

There are several nonmagnetic coding techniques, many that are unique to a specific vendor who has developed the technique for a particular purpose, to be used only in its product line. There have been embedded-slug systems using capacitive and conductive particles that were sensed capacitively; none are known to be currently available. There was once a card using radioactive slugs that were read by a Geiger-counter type of apparatus (it was not enthusiastically received). There are embedded-slug devices using nonmagnetic metal slugs, which are read by eddy-current sensors similar to airport metal-detecting equipment. There are several devices coded by tuned circuits and read using radio waves; because these do not require the insertion of the card or token into a reading mechanism, they are categorized as proximity access control devices (discussed later in this chapter). In addition, there are several devices that use bar codes (frequently infrared-encoded so as not to be visible). There are also holographically encoded devices; several of these have come and gone since the first one was introduced by RCA in 1973.

The smart card is the latest manifestation of a portable key, though it has been highly touted and widely tested for a decade. The smart card comes in various grades of intelligence; it contains one or more integrated circuit chips, varying amounts of memory, sometimes a battery, and even a keyboard and display. Access codes are stored using various forms of encryption and manipulation algorithms and are communicated electronically to the access control system when requested.

The number of possible combinations of cards, personal identifiers, different companies and facilities within companies, time zones, and other factors that can be controlled by an access control system is determined by the number of binary digits that can be encoded on or in the access control device. Ten to forty binary digits will inherently provide 10^3 to 10^{12} combinations respectively, and the digits beyond those needed for pure access control can be used for such purposes as personal information.

In systems that have more than the number of codes required to merely open a portal (and nearly all do), the extra digits can be used to store the employee's number, shift of work, or other useful information. Encoding this information allows control over employee access by time of day and by area of the facility. It can also provide a unique identifying number for each person, which is automatically entered into a log showing who passed through which portal at what time, thus allowing the system to be used as a time clock. With individual identification, cards can be easily deauthorized when an employee is terminated or the card is lost or stolen. Other features such as antipass-back and in-out readers (discussed later) are also made possible when individual identification is provided.

The ease of counterfeiting the credential in a portable-key system is largely determined by the encoding mechanism. Optical bar codes and Hollerith punches are clearly visible, recognizable, decodable, and duplicatable. Magnetic stripes require more expertise and equipment, but do not pose a problem for the professional with some equipment and resources; the specifications are published by the American National Standards Institute, and anyone can purchase an encoder for $2000. Although embedded materials provide another step in security, analytic equipment is capable of detecting and cracking the code. Smart cards are merely very portable computers, and they are vulnerable to most hackers of respectable skill. Organized crime, competitive corporations, and foreign governments all have sufficient resources to breach such security measures.

Portable-Key Options and Features

Options and features available with portable-key access control systems include:

- *Access device:* This can be a card, plastic key, metal token, or other device.
- *Coding means:* Available technologies include magnetic stripes, Wiegand-effect codes, bar codes, Hollerith punches, barium ferrite, and integrated circuits.
- *Individual identification:* This is the ability to identify particular people at access.
- *Maximum number of portals:* Until recently, manufacturers created systems that were designed for niches of a particular size (e.g., one door, a dozen doors, or hundreds of doors), and the user could select a system well suited to the organization's needs. With the advances in computer and communications systems technology, most systems are physically capable of being connected to a virtually unlimited number of doors. This does not necessarily mean that the manufacturer's software or understanding extends to a system with a large number of portals.
- *Space and time zones and access levels:* These are means of controlling access to particular areas by particular persons at particular times.
- *Keypad:* Most systems allow key-plus-keypad access control to be implemented.
- *Alarm handling:* Most access control equipment provides the ability to recognize and report or act on a specified number of electrical contact closures (e.g., alarm points). These points could be door-open contacts associated with the access control function, or they could be unrelated points (e.g., smoke detectors or intrusion alarms).
- *Degraded-mode capability:* This defines the level of control that survives under failure conditions (i.e., the local controller may provide a less-intelligent form of control if the central computer fails).
- *Code changes:* This defines whether the user can recode cards or tokens or whether new ones can be purchased if code changing becomes necessary.
- *Time-and-attendance monitoring:* Data collection capability is available with many systems.
- *Antipass-back:* This is a feature whereby after a person's card has been used to pass through a portal, the card must exit before it can again be used to enter; this requires that readers are provided both for entrance and exit. Some vendors offer timed antipass-back, a version in which a certain amount of time must elapse before the card can again be used to enter.
- *Individual lockout:* This provides the ability to invalidate a single individual card.
- *Computer interface:* If a standard form of communications interface is provided, the access control equipment can be easily linked to other security or facility management or central database systems.
- *Limited-use cards:* These are useful for visitors or contractors. The sundown card expires on a particular date. The one-time card can be used only once; the limited-use card can be used only a certain number of times.
- *Dual-key access (two-person rule):* Two valid users must insert their cards for the portal to open.
- *Guard tour:* This provides a means of recording that patrolling guards make their appointed rounds at the appointed times.
- *Duress or hostage alarm:* This option is less easy to provide in a pure portable-key system than in a system with a keypad. Methods include running the card through backwards or pushing the card past an over-travel stop on an insertion reader.

Strengths and Weaknesses of Portable-Key Systems

The cost of a simple card reader begins in the $65 range and can go as high as $300. Intelligent single-portal systems with electric strike, power supply, and door contacts may provide some time-period control, individual lockout, and ability to be upgraded by being attached to a central computer; these are in the $500 to $1000 range, and another $2000 can add a logging capability.

Centrally controlled systems begin in the $2000 to $5000 range for mainstream, medium-scale access control and cost about $15,000 for relatively sophisticated features and a large number of terminals. These systems can cost hundreds of thousands of dollars when facility management capabilities are added. To this must be added the cost of the portal equipment. In most cases, costs of about $2000 per portal procure a satisfactory system, including the cost of installation and wiring.

The cost of the access control card or token must be considered during selection of a system. Most of the conventional plastic cards can be obtained for $1 to $2 each in reasonable quantities; the addition of logos, employee pictures, or pocket clips can drive this into the $4 to $6 range. Smart cards are three to four times higher.

The positive attributes of portable-key systems are sufficiently strong to make this method of access control by far the most widely used. The most important assets of portable-key systems are:

- They are pickproof. There is no means of operating the locking mechanism without having an access card that contains the proper code.
- They provide identification of the owner of the card. This is the most important feature. Individuals can be controlled as to when and where they are allowed to enter doors, a log can be kept of what person opened what door at what time, and the access privileges of a particular person can be changed or eliminated at any time.
- Many valuable features can be provided if needed. The two-person rule, sundown cards, antipass-back, timekeeping, and other options are available.
- They can be installed at reasonable cost for the performance they provide.

There are, of course, negative aspects of portable-key systems, namely:

- Cards can be lost, stolen, or given to an accomplice, and the possessor of the card will be granted all of the access privileges of the owner.
- Cards can be copied. This is true regardless of what manner of coding they employ; higher-technology encoding merely requires higher-technology counterfeiting.
- A duress alarm is more difficult to implement in a card system than in a keypad, and few card-access systems have duress alarms.
- The cost per portal is four times that of a keypad and thirty times that of an effective metal-key system, and in many applications it may not be warranted. In addition, if some of the more sophisticated features are not used, the card system may not provide higher security.
- The cost of the card or other forms of portable-key security can be a significant expense if there needs to be a large number of cardholders.

Combinations of individual access control techniques can give the user the best of both worlds, minimizing the defects and maximizing the positive attributes of the individual systems. For example, push-button access control devices are simple, reliable, and inexpensive, and their keys cannot be lost or stolen. However, the keys can be given away without penalty, and there is usually no personal identification capability. All persons possessing the correct code will be accepted by the code recognition unit. Card and other portable-key access control systems can have personal identification capabilities and can be made virtually pickproof; however, cards can be used by nonauthorized persons.

Key-plus-keypad systems combine the positive attributes of both these simpler systems. The person requesting admittance must possess the portable key and must know the numbers to use on the keypad. The numbers may be the same for every entrant, or each may have a different code to remember, or the code can be derived from information on the coded key or be related to the date on the calendar. Other combinations are also in common use; for example, card-plus-face, as on the picture badge, or keypad-plus-fingerprint, using automatic fingerprint recognition equipment.

Portable-key systems are indeed the mainstream in electronic access control, and they are used in every kind of application. When combined with keypad or personal-attribute systems, they provide sufficient security for such demanding applications as automated teller machines and high-security installations of the U.S. government.

Recommended Course of Action

Every security decision requires the balancing of risk and expenditure, and in choosing an access control system for a facility, the data center manger must decide what expenditure is warranted for the solution to the security problem. A total security and life safety system encompasses perimeter control, internal surveillance, access control, fire detection, walls and barriers, guards, employee screening, and audit trails. In many installations, measures are in place for many or all of these aspects, and the data center manager must weigh the costs of new or additional security measures.

The keypad access control system is simply a combination lock that is quicker to operate and more difficult to defeat and that has more features and options than does the version sold at the corner hardware store. Such features as hostage alarms, error alarms, and remote sensors can be valuable in many cases. Push-button systems cannot be employed alone in situations in which there is a large risk of collusion (because the combination can be divulged without penalty) unless one of the few systems with individual identification is employed. Keypad systems can cost ten times what common locks cost, and the increased security and extra features are well justified in many cases.

The card-only system is equivalent to a conventional lock and key, but it is more difficult to duplicate and can have many additional features. When equipped with personal identification, individual control, and access logs, these systems are virtually undefeatable by an amateur. The risk of lost and stolen cards is still present, and entry may be gained before the card's loss is known and its access privileges canceled. Card-only systems can cost 50 times as much as common locks and can provide sufficient additional security to justify that cost when the security needs require it; additional features and side benefits, such as collecting time-clock information, can also help justify costs.

Because no amount of ultra-high technology can create a card that is immune to loss or theft, it does not make much sense to pay a great deal of money for exotic coding techniques. Although sophisticated codes require more effort and resources to crack and duplicate, it will be done if the stakes are worth it. In addition, the security of card systems is not highly dependent on the code or its embodiment.

Card-plus-keypad systems plug the loss and theft loopholes in card-only systems and the collusion loophole in keypad systems; they cost little more than card-only systems and provide substantially increased security. The increased security provided by adding a keypad to a card system may well allow the use of a simple stand-alone system rather than a much more expensive, centrally controlled system requiring options and expensive wiring. Card-plus-keypad systems can therefore be less expensive than sophisticated card-only systems.

Proximity Access Control

Proximity access control defied all logic a decade ago by becoming well entrenched and then boosting its primary — and for a while only — promoter, Schlage Electronics, to the top in sales of access control equipment. The technology was more cumbersome than conventional card or keypad access, the cards and readers were more expensive, the reliability was (perhaps marginally) lower, and proximity still meant that in most cases a user had to extract the card from wallet or purse and place it against a reader instead of passing it through a slot.

Proximity access control continues to capture a significant and increasing market share, which supports half a dozen principal vendors. In addition, nearly all significant access control system vendors now feel compelled to offer proximity readers, though most vendors purchase the equipment from the six primary manufacturers and then affix their own brand or label on the equipment.

Proximity access control systems perform the usual functions of unlocking a portal, powering up a computer terminal, or disarming an alarm system by using a device that is in the possession of the person desiring admittance, but there is no necessity for physical or electrical contact between the coded device and the reading and controlling mechanism or system. Some proximity systems operate as card-access systems do, without requiring the card to be inserted into a reader; others are actually keypad systems without wiring between the keypad and the access control system. Some are automatically sensed when they come into the vicinity of a reader; some require an intentional action by the person possessing them.

In every access control system, a code must be communicated from the user-carried device to a reading mechanism; in keypad or card systems, this communication takes place electrically over physical wiring. In a proximity system, it is accomplished with electromagnetic (including radio and other derivative forms), optical (including infrared), or sonic (including ultrasound) transmissions.

Principles of Operation

There are two basic classes of proximity access control systems: those in which the user initiates transmission of the code to the system (e.g., the garage door opener) and those in which the system senses the presence of a coded device without the user's performing any action at all. These two classes are called the user-activated and system-sensing proximity systems, respectively.

The user-activated systems must incorporate a power source in the device carried by the user. This is a battery in all of the current units, but devices having other power sources are known to be in development. The types of user-activated systems are:

- *Wireless keypads:* The user depresses a sequence of keys on an ordinary keypad, and the coded representation of the keys is transmitted by radio (in one case by infrared light); the system detects the transmission and decodes it.
- *Preset code:* The code is set into the device by means of jumpers or switches (the garage door opener is the most common preset-code system), and the user depresses a single key that causes the code to be transmitted — by radio, ultrasound, or infrared — for the system to detect and decode.

The system-sensing systems implement a variety of technologies, range in cost, and operate at widely differing distances. Some require power from a battery inside the portable device, and some use power absorbed from the interrogating system. The several types are listed in the following sections.

Passive Devices

These devices contain no power source and communicate the code to their interrogator by reradiating the interrogating radio frequency (RF) signal at a frequency (or frequencies) different from the original. The most common technique incorporates tuned circuits in printed wiring on the card. This is similar to the operation of most electronic article-surveillance antishoplifting systems. One system uses a crystalline structure on the surface of the card.

Field-Powered Devices

These devices contain an active electronic circuit, including code storage electronics and an RF transmitter, along with a power supply circuit capable of extracting sufficient electrical power from the RF interrogating field to accomplish a transmission of the code in response to the interrogating signal.

Transponders

These devices are automatically operated two-way radio sets. The device, which contains a radio receiver, a radio transmitter, and code storage electronics, is battery powered. The system transmits a coded interrogating signal that is received by the device, and then the device transmits a return signal containing the access code. This operation is a wireless form of the poll-response process through which a computer communicates with its network of terminals, similar to the method used in air traffic control to identify airplanes to ground controllers.

Continuous Transmission

The device is battery powered and contains a radio transmitter that continuously transmits the entry code. When the device is a certain distance from a protected portal, the transmission is detected and the code is received by the system. Continuous transmission requires more battery power than the other battery-operated methods do; the batteries must be recharged every night.

Proximity Access Control Features and Functions

Proximity systems vary widely in performance, cost, and convenience. No single choice is best for all applications. Some parameters to be considered are:

- *Activation distance:* The distance at which a proximity system can be triggered varies from two inches to nearly fifty feet, with the battery-powered tokens providing the greatest distance.
- *Hands-off vs. triggered devices:* Some devices require the user to push buttons or keys; others require no action and thus need not be removed from pocket, wallet, or purse.
- *Concealment:* Because there is no need for accessible and visible keypads or card readers, most proximity systems can be installed so that the presence of an access control system is not obvious. This precaution in itself can add to the security of an installation.
- *Physical protection:* Because radio and optical waves can pass through such materials as cement, wood, brick, and bulletproof glass, most proximity access control systems can be easily protected from assault and vandalism by placing the interrogating unit behind a barrier.

- *Form and size of device:* Proximity tokens come in a range of sizes — from one that could fit into an empty medicine capsule to cigarette-pack size.
- *Code changes:* Passive cards and most field-powered devices have codes that are embedded and cannot be changed. All of the other devices (which are more expensive) allow the code to be changed by means of internal switches, jumpers, or an external programming unit.
- *Cost of token:* The system cost for proximity access control differs little from the cost of a conventional card-access system. The cost of the tokens varies widely from the high end of standard cards ($4 to $7) for the passive card versions, to the $10 vicinity for field-powered devices, to $15 to $75 for active tokens, and $100 or more for the rugged, sophisticated tags used in manufacturing applications.

Strengths and Weaknesses of Proximity Access Control Systems

Proximity access control systems offer several unique features:

- The user is not required to remove a card from the wallet and pass it through a reader, but must be within the prescribed range of the reader.
- Because the readers can, in most cases, read through such materials as wood or plastic, the reader can be concealed, both to hide its presence from intruders and to protect it from vandalism.
- Because the reader can be placed within a wall, for many products it can be made to read on either side of the wall, thus providing both card entry and card exit using a single reader.

The disadvantages of proximity access control systems are:

- The more popular systems have a range of only a few inches; this requires that the user hold the wallet or purse very close to the reader, which somewhat reduces convenience.
- Because the proximity systems are wireless, they are susceptible to errors caused by transmissions and reradiations from sources exterior to the security system.
- Systems that have substantial reader range can have problems discriminating when more than one token-holder is within their field, because they can receive multiple transmissions.
- The cost of proximity access control systems is, in general, higher than that of card-access systems with equivalent features.
- Some proximity systems have a relatively low code capacity, though there is no inherent technical limitation for most kinds of systems.

There are many applications for which proximity access control is quite beneficial, such as those in which persons must open portals while burdened with packages or driving a vehicle. The ability to hide the reader within a wall is also important to applications in which vandalism can be expected and adds to the security of the system. The long-range systems are also used in personnel-locator and personnel-tracking systems, because they can detect a token-holder within the space under surveillance, without any action on the part of the token-holder. Most systems, however, are installed in conventional access control applications, in which card access would have done as well, and these system-sensing, passive-card systems must be considered part of the established mainstream of access control products.

Physical-Attribute Access Control Systems

The ultimate in reliable access control would uniquely identify a person and admit that person and only that person, regardless of whether the person possessed a particular coded token or knew a particular code. This ultimate system would be based on recognition of one or more physical attributes of the person. Automated systems for performing such a function have been available since the early 1970s; they are variously called physical-attribute systems, personal-characteristics systems, and biometric systems.

For two decades, access control industry experts have predicted widespread use of these systems, saying that only the cost problem stood in the way. For the past five years, these predictions have come almost entirely from those who have a vested interest in the technology, as the market share of physical-attribute systems has dwindled from insignificant to miniscule and the vendors have struggled, disappeared, or sold out. Although these systems eventually may predominate, the immediate prospects seem less promising than they did a decade ago.

Physical-attribute identification systems of the nonautomated variety have been in use for centuries (i.e., recognition of the human face by guards). In this century, picture-badge systems were introduced, allowing the guard to compare the face on the card with the face of the person; such systems use the human face as the unique physical attribute and are still in use in high-security installations of the U.S. government, on passports, and on the drivers' licenses of many states (which have become the most commonly accepted form of identification for banking and credit transactions). Two other physical attributes are also well-accepted means of personal identification: the signature and the fingerprint.

Many automated and semiautomated identification systems using these three basic physical attributes have been developed. Some are still available and are in common use. Three additional physical attributes have been added to most recent systems: the geometry of the hand, the characteristics of the voice, and the pattern of the blood vessels on the wrist and the retina.

Facial Recognition Systems

Access control using recognition of the human face is the most venerable form of access control. There is no fully automatic system using the face as the physical attribute. There are, however, semiautomatic (or machine-assisted) facial recognition systems that are really improvements on the concept of the picture badge; instead of the picture being carried on a card outside the system's control (and therefore subject to counterfeiting), the reference picture is stored internally (on microfilm, video tape, or disk) and presented to the guard for comparison with the actual face. An employee number is used to retrieve the reference picture from the file, thus making this a sort of face-plus-keypad system. Such systems cost several thousand dollars per portal. This kind of stored-face system has been offered by various vendors over the past two decades, beginning with Ampex in 1972.

A new form of machine-assisted facial recognition system has achieved considerable popularity during the past few years. Begun on the seemingly unpromising premise that users would be willing to pay $30,000 or more for a computer and video ID badge-making machine — rather than a $5000 film-based setup — video ID systems have burgeoned into full-fledged access control systems that present the photo of any person stored in the system at any remote station so that a guard can make the comparison with the real person.

There are also face-based access control systems that present a side-by-side display of a prospective entrant's face along with the picture ID that the person presents. These systems are remote picture-badge inspection systems.

A simple form of face-based access control is becoming commonplace in multiunit housing and is also offered for single-family homes. This is the video intercom, which allows the occupant to both speak with a visitor and see the visitor's face before opening the door.

Signature Comparison

The signature is the basis for personal identification in millions of financial transactions every day. When a signature comparison is made — usually at the bank teller's window — it is done by a teller who has no training in the subject, but is aided with the use of a personal identification number (PIN). There are a number of machine-assisted methods for facilitating signature verification by automating the presentation of the signature to the teller; these are not typically used for access control.

There is no fully automated system offered for signature comparison — for example, pattern recognition of a previously written signature against a file signature. All fully automated systems use the manner in which the person writes the signature as the physical attribute — pressure, acceleration, and speed — not the appearance of the finished signature. This technology was developed by the Stanford Research Institute (SRI) during the 1970s, and several companies, including IBM, have promoted it.

Fingerprint Comparison

Fully automatic fingerprint-comparison systems have been available for 20 years from a continually changing cast of vendors. There is, in fact, a substantial and very productive automated fingerprint search operation in place at the FBI, making 14,000 searches a day through a file of 23 million prints, and from which stems the technology of the commercially offered access control systems.

Two fundamental approaches have been taken to the problem of automatic recognition of fingerprints. The first is through pattern recognition — comparison of the form, whorls, loops, and tilts. The second and most

accurate is the recognition of the singular points that are the endings and splittings of ridges and valleys, called minutiae. There is also a semiautomatic system that presents the reference print and the actual print of the person in a form convenient to make the recognition decision. The fully automatic systems generally cost in the range of $5000 per portal.

Hand Geometry Systems

Hand geometry as a physical attribute on which to base an access control system stems from a 1971 study by SRI in which glove measurements for U.S. Air Force pilots were statistically measured, with the aim of reducing manufacturing variability and increasing inventory efficiency. SRI concluded that human hand geometry is a distinct, measurable characteristic that can be related to individuals. In addition, SRI concluded that standards can be established that greatly reduce the probability of cross-identifying a particular individual.

On this premise, Identimation Corp. introduced an access control system in 1972 during a time when interest in physical-attribute identification systems was at its peak. Most of the efforts were concentrated on the more conventional attributes of face, fingerprint, and voice, and the professional pattern-recognition community skeptically viewed handprint recognition. Yet the Identimation system survived in the market until it was abandoned by Stellar Systems, Inc. in 1988. Other introductions of hand-geometry products have been made, without great success.

Prices of hand-geometry systems are comparable to those of sophisticated card-access systems.

Retinal Pattern Recognition

In 1983, a personal-attribute access control system was introduced that was based on the premise that the pattern of the blood vessels on the retina of the human eye is a unique identifier, following research presented in a 1935 medical paper. Blood-vessel pattern systems have been introduced from time to time, but none has endured. These mechanisms are best suited for controlling physical access to secure areas with a low volume of traffic because:

- They are too slow to avoid unacceptable backups during significant traffic times (e.g., shift changes).
- Hygiene problems may arise from placing the eye against the eyepiece.

Voice Recognition

Despite considerable research and development work over 20 years, there was no offering of a voice-based access control system product until 1985, when there were two introductions. Voice recognition may prove to have certain significant advantages over other physical-attribute systems: the input device can be an ordinary telephone handset, and the internal workings are entirely electronic and should continue to decrease in cost. Other systems require mechanics, optics, and other relatively expensive technologies. Successful technology has proved elusive, however, and the voice-access companies are either defunct or dormant.

An Assessment of Physical-Attribute Access Control

Although industry experts predicted for a decade that physical-attribute systems were the future of access control, that future has continued to be much further away than was anticipated. A large part of the problem is cost: the per-portal cost can be more than twice that of a sophisticated card-access system. The second problem is the absolute unavoidability of false-acceptance and false-rejection errors. Even though the physical attribute itself may be unique, the measurement of it may be imprecise. The questions that a designer of a security system must resolve when considering physical-attribute systems are:

Is the system really more secure than the alternatives?
If it is more secure, is it worth the added cost?
Can the attribute be faked, resulting in potential penetration risk?
Is any one attribute more reliable than the others?

As always, there is no standard or universal answer. Each security situation must be analyzed and choices made that are appropriate for that system.

The error rate of a personal-attribute system depends primarily on how it is used within the total system. If the prospective entrant presents a finger (or face, voice, hand, eye, or signature) to the system and the system is required to determine whether this fingerprint exists among a (possibly huge) file of acceptable persons, a relatively high error rate can be expected. If, however, an identifying card or PIN is also presented, the system is required to determine only if the fingerprint does or does not match the fingerprint that is on file for that person; very low error rates, in the tenths to thousandths of a percent, can be achieved with a personal-attribute system that uses this technique. Of course, such a system is really a combination system — attribute-plus-card or attribute-plus-keypad — which always results in increased security.

In addition, there is some concern that the digitized signal of a biometric reader could be captured and played back to bypass the reader and thus defeat the system, though this concern is related more to computer system access than to physical access to a restricted area. Another biometric access control system currently being marketed involves keyboard dynamics, which records the key strokes used to type in a password or passphrase and compares them with the actions of a person trying to gain access. This is similar to the signature comparison process. This system appears to be quite accurate but also is probably more appropriate for computer access control use.

The bottom line on personal-attribute access control systems is that when combined with card or keypad, they are accurate and reliable and provide excellent security; whether they provide sufficient additional security over a card-plus-keypad system to justify the substantial increase in cost must be determined by the buyer.

As to which personal attribute is the most effective identifier, all of the attributes currently used are roughly equivalent in accuracy. High technology does not by itself provide high security; satisfactory security is provided by a well-designed total security system.

Recommended Course of Action

Physical-attribute systems will one day be the ultimate in access control, but they have yet to achieve any important acceptance or to stand the test of time in the mainstream of access control applications. Still, the data center manager must keep abreast of developments in this and other physical access technologies. To keep their new security systems from becoming obsolete in the near future, they should consider:

- *Smart cards:* Massive investments by major credit card companies have not yet resulted in widespread use of these cards. In security applications, smart cards, like biometrics, are too expensive for what they deliver. Marketing pressure will inevitably result in some penetration of these cards into access control applications; currently, however, they have limited popularity and use.
- *Universal cards:* There are already systems that can use almost any coded card as an access control card rather than requiring the procurement of new and special cards. Despite some yet-to-be-resolved legal questions over how universal cards may be used, their use could be an interesting and cost-reducing trend.
- *Wireless systems:* These can reduce costs by eliminating a great deal of expensive installation and wiring. Such systems will continue to become more popular, including some of the simpler proximity access devices (e.g., wireless tokens and keypads).
- *Physical-attribute systems:* Although these systems have achieved credibility as an access control means, they have yet to solve the cost-justification problem, and they have achieved no user following. There will be a continuing trend toward reduced prices, but these systems will be viewed as top-of-the-line and justifiable only in particular situations for most of the next decade.
- *Proximity access systems:* These systems will continue to capture a significant share of the card-access market, using the new capabilities conferred by increasingly intelligent devices at increasingly lower costs. Proximity access may well exceed ordinary card access in popularity in the future, but biometrics will ultimately dominate the market.

SOFTWARE PIRACY: ISSUES AND PREVENTION

Roxanne E. Burkey

INSIDE

User Ignorance, Software Licensing Methods, Effect of Changing Technology, Costing of Staying Up with Technology, Legal Issues and Enforceability

INTRODUCTION

Software piracy comes in many forms. The definition of software piracy is using a software without paying for the rights to that use. With just this basic definition, the issue is stealing. The problem that begins the controversy includes defining when someone knows they have stolen the software, versus whether that is a defensible stance for an individual to take. After all, stealing is still stealing. Therefore, if stealing is wrong for ethical and legal reasons, why is there an issue and what is the best way to decide a solution?

The difficulty in dealing with software piracy is understanding the issues that make it a problem. Issues included and worthy of discussion to understand all sides of the problem are:

1. User ignorance, which plays a large role in individual software stealing
2. Vendors' lack of standardization of software licensing methods
3. Swiftly changing technology, which reduces monitoring abilities
4. The cost to stay up with technology
5. The legal issues and enforceability

Clarifying the point of the problem is the first step to solving the problem. Education of the user/busi-

PAYOFF IDEA

Software piracy represents an ethical as well as business challenge to individuals and businesses alike. The impact on vendors who supply software and the user community at large could limit the growth of the industry for many years if these issues are not addressed. Awareness of the problem and the steps needed to permanently raise the conscientiousness level is necessary for our societal growth. This issue is not one that can be swept under the rug and forgotten about. For vendors to take the entire responsibility to imitate changes to prevent piracy will cost businesses money as well as the trust of the software vendor community.

ness community and oversight by groups like Software Publishers Association (SPA) provide an industry method of problem solution. The ethical issues then become part of the moral fabric of both the individual and business organizations. The following discussion details the issues and provides an ethical foundation for solution.

USER IGNORANCE

Blaming the issue of piracy on someone else is much easier. For that matter, blaming most things on someone else is much easier. Individuals should take responsibility for their actions. When they find any problems that need changes, they should voice those requests to the proper audience. Users blame the piracy issues on the software vendors. The licensing agreements contained within the software package are confusing and potentially misleading. There are no industry standards for licensing agreements. To complicate matters further, the technology changes have also altered ways multiple users in the network type of environment access software.

Privately used software is installed by a variety of users. Some users have little understanding of the information systems they are using. They follow the directions from the vendor for the software installation. Frequently, the first step to software installation states, "Make a copy of the enclosed diskettes using a standard DOS command." The purpose for this activity is to have a set of archival diskettes in case a problem develops with the original set. It is not to provide copies to friends and relatives. They then use this archival set only if reinstallation is necessary.

Purchasing software is somewhat misleading. The purchase does not mean one owns the software lock, stock, and barrel, but rather that the vendor is allowing the use of their information. They provide documentation for gaining the most benefit from using the software and outline what application best suits the software. They do, however, retain all rights to the code contained within that software. The vendor holds the copyright on the software, not the buyer. A lack of understanding of this agreement is the main reason piracy as a crime is overlooked by the ignorant user.

The buyer (user) must read all of the fine print contained in the software package. This provides the acceptable guidelines for copying the software, copying the documentation, exporting the software, and the agreement as viewed by the vendor. When purchasing software, an agreement exists between the purchaser and the software vendor. That agreement essentially states that the vendor is responsible for the performance of the software as they designed it. Users frequently do not realize that the breaking of the seal on the package often constitutes their acceptance of the software and all the agreements that act demands.

In the business environment, the user may not have knowledge of whether the copy of software being accessed is a legal copy or not. Information technology experts within the organization should ensure that copies available for the users are legitimate copies. Users should not bring software from home for their work PCs, nor bring software from work for their home PCs. Users often believe they have rights to the use of the software despite their PC's location. They design single-user software for loading onto one workstation or PC. If one is fortunate enough to have multiple PCs in the home, each usually requires a separate software copy.

Keeping users from accessing or using illegal software in the work environment is the job for the information technology personnel. IS personnel often monitor the work areas to insure no illegal software is present on the company equipment. When illegal software is found, they may erase the program and then limit that user's access to the system. Outside auditors could construe the simple activity of replacing a PC in the work environment and transferring the software on the hard drive to the new PC without erasing it from the original PC, as software theft. Therefore, having an understanding of the licensing agreements of the vendors used by the business is necessary for the information technology staff. This should include the number of users or workstations that access the software. They must inform management when they reach the license limits of users for a software, and acquire additional software or licenses depending upon the vendor's agreement.

Management often lacks a clear understanding of the liability associated with using illegal software. The penalties for illegal usage, once explained by the information technology staff, should become the foundation for the development part of the policy of the organization regarding software. Once these policies are in place, companies need to adhere to the guidelines and enforce appropriate disciplinary action.

Piracy and Internet Shareware

Many individuals are on the Internet. This communication method provides for access to many types of shareware software. Much of this software is distributed to aid communications between the Internet user community. These programs are typically not copyright protected. The only issue regarding this type of software distribution is the possibility of virus transfers to a user. If they overcome this issue through virus-checking processes, then users can readily share this type of software without fear of penalty.

Individuals, businesses, and learning institutions must adhere to the same set of rules regarding copyrighted software. A clear understanding of the agreement between the buyer and the vendor is essential to an effective method of loading, handling, and sharing software. Despite how indi-

viduals perceive the sharing of software, the federal law protects software that is copyrighted. The user is required to read and understand the agreement from each individual vendor, including the rules established for use of the vendor's software. Clearly, there is no defense for user ignorance regarding this form of stealing. Each user has the obligation to question his/her employer regarding the legitimacy of the software being used to avoid being a party to illegal software usage. Stealing is wrong. Ignoring someone else who is stealing is also wrong. Individuals should not steal software, nor allow themselves to be a party to this illegal activity.

VENDOR STANDARDIZATION

The multiple ways in which vendors issue software licenses — either by machine, user blocks, simultaneous use, file servers, and/or sites — are extremely confusing to the user and/or technical support staff. Some vendors allow the same diskettes for installation on a single machine with archival copies generated by the user. Some software will automatically prohibit access when it determines that the maximum allowed simultaneous usage has been reached. Some software can be readily copied, while some cannot. There is, however, very little standardization.

Microsoft™ has developed special encryption coding into its newer software to prohibit copying the software. This is done to prevent a backup or copy routine from working on another machine. If, however, the software requires reinstallation, the original media must be utilized for this purpose. Most vendors do not have the vast resources required to take this extra step in the software development process and seemingly trust the user community to do what is right. Documenting the licensing agreements with each software package places the burden of responsibility firmly on the user, regardless of how the vendor's software allows for copying.

Each vendor's package will contain the written copyright notice. This outlines the items covered under the copyright. They may include the documentation, software (regardless of media), time frame, and company location. They then provide the licensing agreement terms. This details the rights the vendor is granting to the user. These generally include:

1. The acceptable use of the software specified by number of computers, users, etc.
2. Transfer agreement of the Software and Documentation
3. Backup specifically for archival purposes
4. Problems with unlawful copying
5. The removal or alteration of the proprietary notices
6. Unlawful decompiling or reverse engineering of the software
7. Warranty information

8. Specifying the designated use of the software for fee services or personal use
9. Government licensing agreements
10. Export law assurances
11. Other special restrictions

Software vendors are slowly recognizing that standards are necessary to help crack down on piracy. They are using organizations like the SPA and National Computer Ethics and Responsibility Campaign association (NCERC) to find out the problems from the user community vantage point. They recognize that revenue losses are not recoverable and are taking steps to make it easier for the user. Software is too easily transferred from one area to another with very little effort. The technology that creates the need for the software also creates the ability to do it very quickly and blind to all but the most sophisticated users. Software in the PC environment is more complex in distribution than the mainframe environment. The processes and procedures to successfully keep up with the software are not always available in the business organization, and the private user would not normally consider incorporating this activity into their environment.

In a large business environment, which is technology oriented, this can pose a major inventory monitoring problem. It is extremely difficult in a fluid technology environment to keep up with what is running on which machine without the proper controls in place and functioning.

Whether standardization of licensing agreements is present or not, it is still wrong to take or use something without permission. In the case of software, the vendor issues permission on the guidelines for use of the software to the buyer (user). Using a copy of software is illegal. Taking something that does not belong to you despite your understanding is also wrong.

TECHNOLOGY EXPLOSION

The technology explosion in recent years has influenced most of the nations of the world. Businesses are fully aware of the need to use technology to help maintain a competitive edge in the world marketplace. Knowing this is happening and controlling it are two distinctively different exercises. The very methods of data transmission, media availability, and increased user capabilities, and the power of personnel computing, have created a technology monster in many aspects. Ever more users can reach more information in a single day than ever imagined. To meet this information explosion, developmental efforts to safeguard information has become an evolutionary process based on which problem requires addressing. So it is with protection from piracy.

Software developers are developing more effective ways of safeguarding their copyrighted information. The code is increasingly complex. Encryption is a method currently used by more and more software developers to protect their information. The problem with exporting software from the U.S. in an encrypted format is that it crosses government agencies. Rules are vastly different between the Department of Commerce, which handles most export issues, and the State Department's Office of Defense Trade Controls, which views the encrypted software in a different manner. This causes delays in exporting the products because of restriction guidelines in place within the State Department. It is difficult to export something like software when viewed in the same way as a jet fighter. Efforts to change the restrictions, separating the products types, and still protect U.S. companies competing in the global market by allowing encryption capabilities are being addressed by Congress. Until they alter these rules, the capability of other countries to trade encrypted products will hurt U.S. companies.

Many encryption algorithms are offered via the Internet to help reach the source codes for various copyrighted materials. More complex algorithms are required to stay ahead of the competition and the pirates waiting for the newest and best software products. In addition, Internet access typically opens a system to access by anyone else who has the ability to break into a system. Preventative measures, especially on large wide area networks, include firewalls, virus protectors, encryption of secure data areas, and access tracking programs area available to reduce access and stealing. These measures are needed because data access can provide a competitive edge through stealing someone else's information.

Most businesses have a respect for technology and want the benefits it offers to their competitive edge. They frown on businesses acquiring an edge in unethical manners. Business will help lobby for changes to laws and develop safeguards to protect their business information and trade secrets, as well as protect the rights of software developers to protect the products used by businesses. Business professionals, for the most part, expect the rights of their companies and respect the rights of others. Once they are informed of a problem and presented with the money and ethical issues, they take steps (as with piracy) to change accordingly. It would not be surprising to learn that businesses would band together, much like countries do, to eliminate doing business with those companies they find not adhering to the copyrights of others.

ECONOMIC ISSUES

Technology is a very expensive commodity. Many individuals and companies do not feel they can afford the cost to be competitive. The black market over the past 7 years for software has provided individuals with good copies of the software at less than half the retail price. In some cas-

es, the registration numbers have been in line with the vendors' actual number sequences, causing vendor technical support staff to also support these illegal copies. In these cases, the software vendor is taking a double hit for pirated software. The estimated losses, in gross revenues, to software vendors is in the billions of dollars. The cost of running their software support without the revenues is a hidden cost not part of the generally accepted loss figures.

The economic impact to the software vendors is significant. It costs both time and money to develop and support software applications. The loss of revenues is certainly the primary issue. Close on the heels of this issue is the one of extra development costs to foil would-be thieves. Developing encryption methods and gaining the required approvals is a significant investment. To move forward with technology and keep ahead of foreign competition, especially from Japan, requires all the resources of a software developer to be focused on the newest media available and the next generation of business requirements. The long-term effect of doing battle to protect rights already theirs is to increase costs to the paying user or limit the development dollars. In either of these scenarios, the business and individual user lose.

The issue remains constant. It is wrong to steal. Others end up having to pay the price for the thieves. It hurts short term and long term when someone steals from another. The impact of the stealing is potentially on the competitiveness of U.S. vendors versus foreign vendors. If this activity is not stopped by both businesses and individuals, the long-term effect could be a limitation on continued development by U.S. software vendors. Businesses are in business for profits and the technology industry is no different.

LEGAL CONCERNS

Software piracy is a federal crime. The thief is liable to the software vendor as well as penalties for breaking a federal law. The penalties are substantial under tort laws: Electronic Communications Privacy Act, Computer Security Act, Computer Matching and Privacy Protection Act, and Uniform Trade Secrets Act. Individuals and/or businesses found guilty of stealing software are liable for compensatory and statutory damages up to $100,000 for each illegal copy found on site. On top of these costs, the federal conviction could include up to 5 years imprisonment, defense attorney costs, court costs, and statutory damages of up to $100,000. In one case, an insurance company was found guilty of illegal software from three major software vendors on their computers. The settlement costs included $266,436, plus the costs to replace the system software.

More and more companies are being investigated. The reasons for this are varied. The SPA relies on its watchdogs in the field. Larger companies

have been the primary targets of investigation into software piracy. These companies typically have the wider range of technology usage. The software utilized by these companies is more standardized throughout the organization. They often have IS groups that are in charge of setting up equipment for remote office locations. Without the clear policy defined within the organization regarding software licensing, the tendency to save money on departmental budgets and save installation efforts can be easily overlooked. Most IS professionals are aware of licensing agreements. Many of them advise the organization of the legal ramifications of not adhering to these agreements. Unless the business organization is committed to ethical purchasing and usage of software, the IS professional does not have the required backing he/she needs to perform the responsibilities of his/her job. If this is the case within an organization, the cost/benefit analysis never made the impression it should have with management.

Businesses are making policies regarding software copying within their office environment. Many include the policy as part of the new-hire paperwork. It often includes prohibiting the making or accepting of unlicensed copies of software, providing manuals to the employees for the software they are to utilize, and centralizing the purchase, installation, and license registration for all company software. This not only helps ensure that the employees are aware of the policies regarding software, but also provides a mechanism to track the software used within the company. Many companies also perform periodic audits of the personal computers and the licenses on file.

There are steps that organizations can perform to comply with federal laws. These include the education of management regarding copyright infringement, standardized software for company use, central points to gather purchase documentation, scheduled review for registration with software vendors, destruction of any illegal copies found on systems with appropriate disciplinary action toward the offending employee, standards for installation/registration of new software, and scheduled audit reviews by responsible IS staff. In following these guidelines, most organizations can avoid serious problems from an outside audit of their systems. Most IS professionals will advise management of known problems. If the policies are in place for management to listen, then expensive and embarrassing consequences can be avoided.

The legal issues of software piracy are straightforward and to the point. Prosecution of holders of illegal software will be swift and expensive to the extent the laws will provide. Companies found to frequently use illegal software in this country will find the legal system fully functional. By law, software piracy is illegal. The laws are enacted to protect the rights of persons or businesses. Therefore, individuals and businesses have no rights to illegal copies of software. For an individual or business to continue this practice, with the laws currently in place, is wrong.

CONCLUSION

The issue raised by software piracy is an ethical one. The solution includes:

1. More user education
2. Increased standardization among vendors
3. Stronger methods for preventing software replication
4. Improved monitoring capabilities to keep pace with changing technology
5. A clearer understanding of the economic impact to the end user
6. Stiffer legal ramifications for thieves
7. Improved ethical awareness of the very act of stealing

Organizations and individuals suffer from the outcome of software piracy. By raising awareness of the seriousness and consequences of this crime, IS managers can help thwart this type of theft.

Auditing the Electronic Commerce Environment

Chris Hare, CISSP, CISA

With the proliferation of Internet access and the shift to performing some brick-and-mortar transactions online, the need for stability and reliability in the E-commerce arena is becoming increasingly apparent. E*Trade, one of the many successful E-commerce sites, depends completely on its online presence to stay in business. An outage, regardless of cause, can potentially cost millions of dollars. For example, consider the distributed denial-of-service (DDoS) attacks against Yahoo! and CNN. Once a way to stop the attack had been found, thousands of dollars were spent to facilitate the system cleanup, in addition to the lost revenue. This chapter describes a methodology to assess the security and reliability of E-commerce. Based on this author's previous experiences with risk assessment, security, reliability, and Web "touch and feel – ease of use" can be identified as critical to the ongoing success of E-commerce. The approach described in this chapter can assist any E-commerce Web site owner, manager, or auditor in identifying and securing some of these key risk areas.

It Is Possible to Get Your E-Commerce Infrastructure under Control

The most significant challenge in the development and implementation of one's E-commerce environment will be gluing it all together. Success is dependent on a careful marriage of process, technology, and implementation to achieve the end result. Achieving the final goal depends on a comprehensive strategy, understanding legal and export issues, the processes in use, as well as the technology available to perform the work. Design the environment with confidentiality, integrity, and availability as priorities — not as after-thoughts.

Strategy

Do not get caught up in the waves of technology and methods of doing things. Technology is only one part of the entire puzzle. One uses technology to implement already-operational manual processes to reach a larger market. The operational aspect drives the technological requirements, which in turn affect the overall development of the required systems. The implementation of the project is often affected by changing business and legal needs rather than by changes in technology.

Strategy is the key to the development of an effective E-commerce implementation. The people within an organization must have a vision they can use to drive their planning and development activities. This vision determines the goals senior management has and lays the groundwork for how to measure success. Without a strategy, it will be impossible for you, your employees, your shareholders, and customers to determine if you have achieved anything.

Strategy must also be based on the business decisions that an organization will make. The existing corporate policies must be reviewed and implemented to provide consistency in dealing with the public, regardless of the medium the customer uses to access one's services.

Technology Is Only the Method of Implementing Desire

One's team will use the strategy to establish goals they can translate into project plans and then into manageable activities to meet the strategy. When developing an E-commerce strategy, one must consider:

- What are you trying to achieve by moving to E-commerce?
- How closely is your electronic commerce strategy aligned with your existing corporate strategy?
- What existing corporate business processes must be integrated?
- Who is going to use the service? Is it business-to-business, business-to-consumer, or both?
- Who is going to use the services being offered?
- What do our customers want us to offer?

Armed with the answers to these questions, it becomes possible to start addressing the technology solutions that may provide the implementation. As illustrated in Exhibit 130.1, the technology solution is complex and involves many components. Before choosing the individual components to achieve the technology implementation, one must understand how each component in the business process interacts with the others.

Legal

It is a challenge for most companies to ensure compliance with the legislation of the country where they are located or the countries in which they do business. There are local, state, national, and international laws. There are additional regulations, depending on the industry and whether you are a publicly traded company. However, doing business electronically poses new challenges.

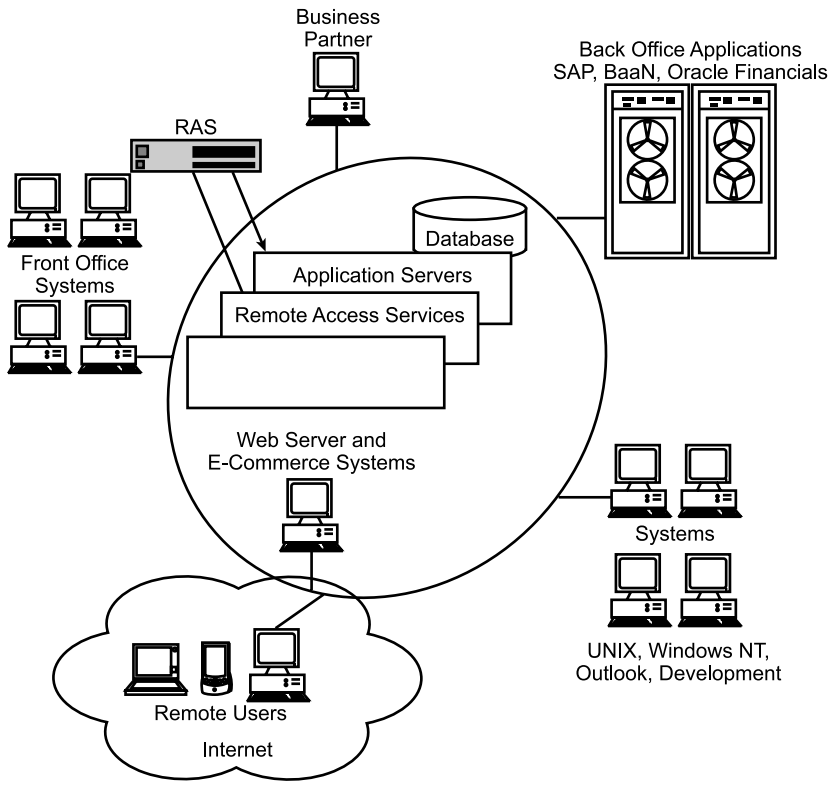

EXHIBIT 130.1 E-commerce system infrastructure.

Privacy

Consumers are concerned about the privacy of their information, while you are concerned about the privacy of information they provide to you or you share with them. Aside from legal requirements in various parts of the world regarding the privacy of information, it would not be good business not to provide privacy controls. If consumers are aware that you do not take this into consideration, they will not do business with you electronically.

The privacy issue can mean some real challenges for an organization. For example, during 1999, the European Union (EU) enacted standards surrounding privacy and the protections of information. The EU stated it might choose not to do business with companies or countries that do not implement similar privacy standards. Consequently, one should specifically state what the organization's privacy policy is. This demonstrates a commitment on the organization's part to the protection of its consumer's information.

Solving the privacy issue means that technical implementers will use words like encryption, digital signatures, and digital certificates. These are technologies used to provide the privacy components to help increase the protection of information sent and received while users interact with an electronic business site.

It is the privacy issue regarding consumer purchasing habit information that led to the development of Secure Electronic Transaction (SET) protocols by Mastercard and Visa, as illustrated in Exhibit 130.2.

All transactions must be properly secured to prevent the loss, through transmission or unauthorized access, of important business information. This must be calculated into the strategy. Doing so will mitigate the risk of information loss and poor performance or reliability from improperly implemented processes or technology.

Export Controls

Export controls are established by governments to regulate export of materials to countries considered dangerous or not in support of the national interest. Most countries do this and in some situations, such as encryption technologies, there are countries that prevent the import of the material.

Compliance with relevant export control legislation is strongly advised. The punishments for noncompliance can be significant, depending on the country and the material exported. Recent years have seen changes in some export rules, again specifically surrounding encryption. Countries have been adopting changes in encryption import/export rules in an effort to allow their producers to compete in the global marketplace.

It is important to review import/export legislation when developing an E-commerce infrastructure. There may be information or technology affected by these rules and they may impact to whom one can deliver the service and resulting products.

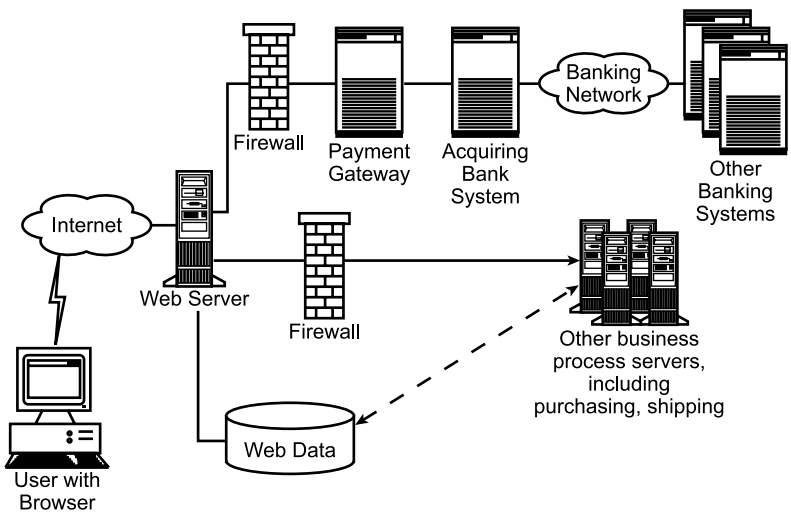

EXHIBIT 130.2 Sample SET transaction environment.

Legislation

Legislation is a major area for many companies. There is a variety of legislation controlling how privacy issues are handled and how business is conducted in general. Much of this legislation is not limited to electronic business. Internet laws and regulations pertain to everything from intellectual copyright to cyber squatting (registering URLs for profit).

The use of a qualified attorney is highly recommended due to the diverse issues and laws involved. With the assistance of an attorney, one should carefully consider the impact of law on the ability to get one's electronic business into full gear.

Considering the vast nature of the law, some areas of concern include, but certainly are not limited to:

- What national and international laws are applicable to E-commerce?
- How is legislative compliance ensured?
- What countries is the business prohibited from selling to through E-commerce?
- Are there distribution agreements and contracts that can be held in force electronically?
- Do the businesses support digital signatures, and are they considered legally binding within the business' jurisdiction?
- How are domestic and international disputes resolved?
- Is there technology or information requiring export permits before it can be available through the E-commerce infrastructure?

Project Management

With the strategy defined, the team can proceed to define the manageable activities resulting in the actual development and implementation of the infrastructure. However, project management is geared more toward ensuring that everyone understands what work must be done, the timeline in which to do it, and how much to budget.

There are a lot of pitfalls in allowing the team to implement electronic commerce services without project management. It will be difficult to gauge where the project is, and even more difficult to determine when it is finished and how much it will cost.

Project management provides the needed controls to define the project, and ensure it meets the business requirements and is completed on time and within budget. A project management strategy is critical to define the tasks required to complete the project. The project plan defines who owns the project and related sub-projects, and how users will be involved in the definition, development, and testing of the E-commerce implementation.

The project manager defines the work breakdown structure and establishes the milestones to measure progress on the project. The project manager allocates responsibilities and manages cost and resource budgets.

Without effective project management, the E-commerce project can become an expensive, never-ending endeavor that fails to meet the business needs.

The ability to plan a project and then properly implement it allows for accurate cost control and planning decisions. Things to consider:

- Does the project plan accurately define the end objectives in a measurable fashion?
- Are there adequate people and other resources to deliver the project on time and without unplanned resource costs?
- Has a standard project management review been conducted?
- How are project costs captured?
- Is the project on track from both a work and a financial perspective?

Reliability

The E-commerce infrastructure must be available whenever a customer wants to use it (availability), and it must operate as the customer expects it to (integrity). Most people do not realize it but reliability is a major component of security. Consumers want to have confidence that when they go shopping online, the merchant

they want to deal with will have all of its systems operating so that they can browse the catalog, enter their order, have any payment transactions properly completed, and then see the order arrive in a reasonable timeframe.

But what happens when things go wrong? Customers need to have a method of contacting the merchant so they can advise that merchant of the problem and seek an acceptable resolution. However, reliability reaches beyond getting problems fixed. It includes the ability of an organization to know there may be a problem now or in the future. How will the performance of the system be measured? How does one resolve a problem for which one of the service providers is responsible?

Performance

The ability of the systems to provide a reliable, friendly, and valuable experience is essential. Users have high expectations about content, access to the services, and quickly finding what they are looking for. Performance, in the eye of the user, is measured by how long it takes to get the information displayed on their screen. A fancy Web site with numerous animations and pretty graphics may be eye-appealing once fully downloaded, but most users get frustrated and are not likely to revisit if the merchant's home page takes forever to load on their system. Develop for the smallest system, and it will work on all others that need to access it.

The customer's view of performance is affected by the capacity planning of the merchant's Internet access and the servers used to offer the customer services. Failure on the part of the merchant to contemplate the actual level of performance one wants people to have will impact that merchant in the end. Capacity planning surrounding the network and server performance must be tempered by how many users one expects to have access to the site.

Having a plan to quickly respond to performance issues regardless of their cause is essential to stay ahead of customer demand. This translates into having capacity planning expertise on the team. These experts monitor performance on a daily basis to maximize the number of customers who can use the site and ensure there is adequate capacity to handle the increased number of users tomorrow.

Architecture

The second component in addressing reliability has to do with the overall system and network architecture. What systems are involved in delivering the service to customers? It is important to understand how they interact with each other in providing the service. Just as capacity planners are important, E-commerce architects who understand the market are critical. Security professionals who understand security architectures to protect the overall corporation and how to implement them are also essential.

Measuring Performance

The collection of metrics for capacity planning, customer satisfaction, and usage is imperative. Operational statistics are collected as part of operating the business and include such items as technology outages and usage. These operational statistics are generally used to provide information regarding problems and assist in determining where efforts should be focused to correct operational problems. Help desks or customer service areas can be invaluable for recording these kind of metrics.

As all of the operational statistics are collected, they must be analyzed and collated into metrics to report the state of the operation. How is the E-commerce environment working? How many customers have used the site? How much was spent and what was bought? However, metrics must be combined from across the organization to establish the strategic indicators used by top management to determine how the organization is doing and what they should be concerned about. This relationship is illustrated in Exhibit 130.3.

Some things to consider surrounding operational statistics and metrics include:

- What efforts are being made to collect, report, and validate the available metrics?
- What metrics are available from the internal and external service providers?
- Determine the reporting structure for these metrics.
- Determine how these metrics are used.
- What process is in place to use the metrics to create feedback to improve the system or correct problems?

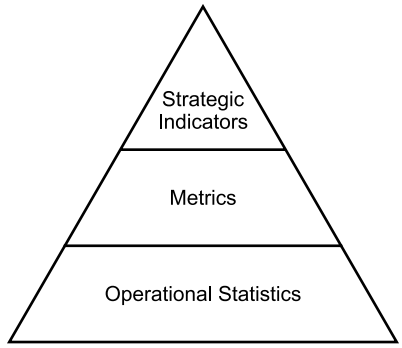

EXHIBIT 130.3 Operational statistics to indicators.

Problem Resolution

The primary users of an E-commerce site are its customers. However, sometimes things go wrong, or customers have questions arise during their visit and would prefer to talk with someone regarding the issue. Consequently, they need to have a place to report these problems or ask their questions.

This requires the implementation of a customer call center where problem reports regarding the Web site can be taken and directed to the correct support groups for resolution, or product questions asked and answers provided. Effectively operating this customer call center requires the use of a call tracking system capable of tracking the customer's issue and a history of what was done to provide resolution.

If operating a global company — and face it, if you are running an E-commerce site, your consumer audience will be global — you will need to establish a method for people to reach you in real-time from anywhere in the world.

The customer call center must be able to respond quickly to customer needs and provide the information they are requesting in a timely fashion. Doing so establishes confidence in the mind of the consumer about your abilities and enhances their buying experience.

When considering the call center, the following questions should be considered:

- How do both you and the customer evaluate satisfaction level?
- How long does it take to solve a problem once reported? Is the customer satisfied with the resolution? Is follow-up necessary?
- What are the common problems reported and what has been done to rectify them?
- What problem tracking and resolution system is in use?
- Are problems recorded so that metrics can be obtained and trending reasonably retrieved?

Service Level Agreements (SLAs)

Service level agreements (SLAs) establish the terms of service, including expected operational performance and problem escalation and resolution. Both issues are important in E-commerce activities. The operational performance of the service provided is critical because poor performance means the E-commerce services will be unavailable to the customer. This in turn can negatively impact both the bottom line and the image of the company on the Internet.

Timely resolution of problems is also important for the same reasons. Customers expect service level timelines for issues to be met. What SLAs are there with service providers, and are there penalties if they do not meet their commitments?

SLAs are also used to assist in measuring the capabilities of your service providers and are useful to have when renewing contracts. Having collected and maintained good information regarding performance and issue resolutions, one will have more success negotiating changes in the contract and price due to good or bad performance in the service delivery.

Things to remember when reviewing the SLAs in place for an E-commerce environment include:

- Obtain SLAs from suppliers such as ISPs and network providers.

- What quality-of-service provisions are in the SLAs? Are the service providers meeting these agreements?
- Do the service providers and your own organization maintain records on their performance?

Maintaining the Business

The ability of the infrastructure to recover from a systems failure, connectivity loss, or other issue is essential. Order entry for product sales is a critical activity that must be maintained. How will the organization handle the partial or complete loss of its E-commerce infrastructure? Are appropriate plans in place to maintain the E-commerce business?

Business continuity and disaster recovery planning form important elements in any business, but are not centered solely on the E-commerce services being offered. Business continuity is centered on maintaining the business operations after a fatal systems failure. For example, can E-commerce operations be maintained if several systems suddenly fail?

These are important questions to ask support organizations. If the organization is heavily dependent on the ongoing operation of the E-commerce environment, then a failure for even a short period of several hours can have disastrous effects on the business. If operating an enterprise based more on "foot traffic," one may be able to afford the downtime.

However, in today's information age, when an online business is offline, everyone hears about it — very quickly.

Areas of concern surrounding business continuity include:

- Has a business impact analysis been conducted to determine how important E-commerce is to the survival of the organization?
- Are the Web servers and other systems involved in the E-commerce delivery part of a contingency plan?
- Are there backup procedures, dependable backups, and regular data and system recovery testing?
- Is the status of systems monitored to maintain integrity and operation?

Development

As mentioned previously, customers will remember their experience with an E-commerce system based on how it worked for them. Consequently, the development of a consistent interface is required and can only be achieved through good development practices.

Standards and Practices

The key method of ensuring that consumers have a positive experience with an E-commerce site is to establish development standards and practices. These are independent of the "look and feel" established as their interactive experience.

The site developers use standards and practices to provide information and methods on how the applications will be developed. This includes things such as code standards, security, and how information submitted from the consumer will be validated and protected. Accordingly, security needs to be designed into the application from the start and not included as an after-thought.

Developers will make decisions regarding how they will develop and write their particular part of the system based on their previous experience or education. These differences make it difficult for ongoing maintenance and subsequent troubleshooting and issue resolution.

Change Control and Management

Change control is a critical part of the overall development/production cycle. Proper change control reduces the risk of improperly tested application code being placed into production, causing problems with data integrity, confidentiality, or reliability. It is also used to identify the changes that are made from day to day to the application code and allows for proper issue resolution and developer education.

A major issue with the development of application code is the fact that it is often put into production systems and "debugged" while customers are using it. This type of activity not only impacts the development of the system, but also affects the user's perception of the E-commerce site and the online presence of your enterprise.

Proper change control ensures that development code is tested in a development environment and is able to process not only the accurate information that the consumer provides, but also handling errors in the input, made either deliberately or accidentally.

Proper processing of information that is collected on the Web site affects business operations. Failure to process it correctly may result in improper or incorrect charges to the consumer, or delivery errors resulting in lost merchandise and increased costs.

When assessing the configuration and change control environment, one must consider:

- Software release change and version control, including both the application code and operating system changes.
- Is it possible to maintain a stable operating environment in today's fast-paced world? Is it possible to automate the change process?
- Development, implementation, and migration standards.

Connectivity

Connectivity is specifically concerned with the technologies used to establish network connectivity to public and private networks, how available bandwidth is calculated, and how the network is designed. E-commerce is very dependent on a successful network design and adequate capacity to ensure that consumers can get to a Web site, especially during the winter holiday season.

This means adequate Internet connectivity speed and capacity, and similar connectivity into your corporate network if applicable to your E-commerce design. Many network design people are leaders in their field, but adequate network capacity can be easily overlooked.

A network can also be overbuilt, having too much capacity and other resources built into it that ties up an enterprise's resources unnecessarily. It is necessary for the enterprise to have good technical management and network design staff to take the marketing and sales plans and build a network that will handle expected traffic and scale appropriately as demand increases.

The network staff must understand that an E-commerce site must be located in an appropriate place. This means that if one intends to operate on a global scale, one may want to consider having multiple locations to ensure the best connectivity and performance for the consumer. This can increase the complexity of one's environment in the process and in turn increase one's dependency on good planning.

Part of this planning includes redundancy, which in turn forms part of one's contingency and business continuity planning. If one component or location becomes unavailable for any reason, one is able to maintain presence and continue operation of E-commerce enterprises.

Consumers are looking for a positive, encouraging experience when interacting with an E-commerce environment. Failing to provide this experience reflects negatively on your online presence. This may result in a perception that the company is not prepared to handle E-commerce and consumers will be reluctant to conduct business with your site.

In reviewing network connectivity, remember to consider:

- Location(s) of E-commerce sites
- Network capacity
- Maintaining and monitoring of network availability
- Network topology
- Redundancy of the network
- Security
- How secure are transmission links
- Do you use a switched network
- Is any form of virtual private network (VPN) used in E-commerce delivery

Security

There are four major components that make up the security area:

1. Client or user side of the connection

2. Network transmission system
3. Protection of the network information during transmission
4. User identification and authentication

Protection of the network security elements and the computer systems that reside in the E-commerce infrastructure is a major portion of protecting the data integrity and satisfying legal and best practices considerations. This level of protection is addressed through various means, all of which must be working cooperatively to establish defense-in-depth.

As seen in Exhibit 130.4, the layering is visualized as a series of concentric circles, with the level of protection increasing to the center. Layer 1, or the network perimeter, guards against unauthorized access to the network itself. This includes firewalls, remote access servers, etc. Layer 2 is the network. Some information is handled on the network without any thought. As such, layer 2 addresses the protection of the data as it moves across the network. This technology includes link encryptors, VPN, and IPSec.

Layer 3 considers access to the server systems themselves. Many users do not need access to the server but to an application residing there. However, a user who has access to the server may have access to more information than is appropriate for that user. Consequently, layer 3 addresses access and controls on the server itself.

Finally, layer 4 considers application-level security. Many security problems exist due to inconsistencies in how each application handles or does not handle security. This includes access and authorization for specific functions within that application.

There are occasions where organizations implement good technology in bad ways, which results in a poor implementation. For example, the best firewall poorly configured by the user will not stop undesirable traffic to a site, or a database security system that has all of the data tables granted for "public" access does not protect the data they contain. This generally can lead to a false sense of security and lull the organization into complacency.

Consequently, by linking each layer (see Exhibit 130.5), it becomes possible to provide security that the user does not see in some cases, and will have minimal interaction with to provide access to the desired services. Integration between each layer makes this possible.

The same is true when implementing security within the E-commerce environment. It must be considered at all layers: the client, the network, the perimeter, and the associated servers. The Web interface has four primary layers: the operating system, the CGI programs, the Web content, and the Web server. Each layer is dependent on the components of the other layers working correctly.

Client Side (User)

Clients interact with the E-commerce infrastructure through their Web browser. The users, however, have certain expectations about how the interaction will look, act, and perform at their computer. For the experience to be a positive one, certain programming considerations must be addressed during design, development, and implementation.

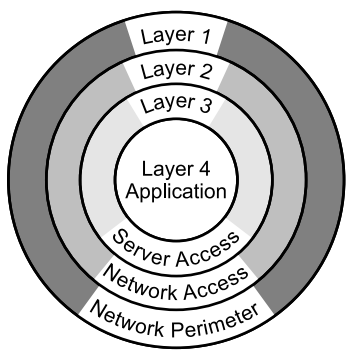

EXHIBIT 130.4 Levels of protection.

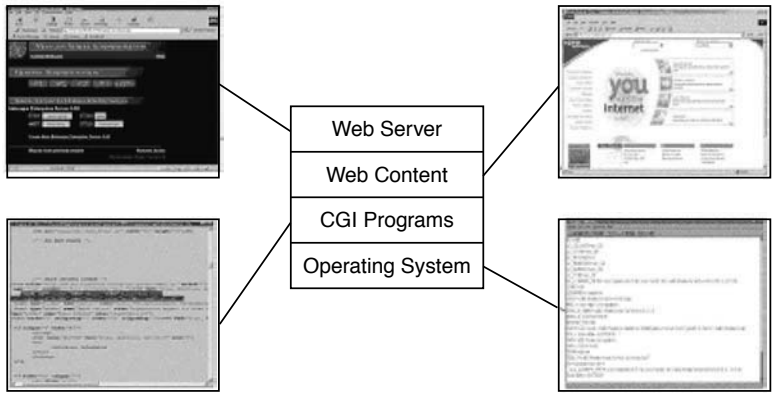

EXHIBIT 130.5 Linking layers.

The experience the user has will be different across the different browser implementations, and choosing to support browser extensions that are not supported by other browsers is not a good business decision. The HTML, dynamic, and graphic content must be compatible with the different Web browsers available. E-commerce applications must consider this requirement. Not all users will want to enable extended features in their browser, such as cookies, Java, and JavaScript. This greatly affects the functionality that can be offered in the design of the application.

The users and businesses that will use a service may not be connected directly to the Internet. They may be using a proxy server to provide security or cache network requests. They may also be using a slow-speed network link. These factors must be included in the design to maintain a positive experience.

When considering client-side issues:

- Examine what types of Web browsers and proxy servers are in use and in what operating environments.
- Determine how a customer registers for E-commerce access.
- Determine the ease of use of the E-commerce interface.
- Decide what applications will be used to develop the interface.

Firewalls

The firewall is an integral part of an E-business architecture. It is accepted that any computer directly on the Internet with no protection is a sacrificial host. One can expect it will be compromised at some point. Although it is not reasonable to hide everything behind the firewall, every system not needing to be directly visible to the Internet should be protected by a firewall. Additionally, no connections from any unprotected systems should pass directly through the firewall to the corporate network.

However, a firewall can be bolstered by the network design through the use of demilitarized zones (DMZs) and service networks (see Exhibit 130.6). The DMZ protects its systems through filters and access control lists in the routers. The service network is a separate network connected to the firewall. Any system that does not need direct Internet connectivity and does not need to be on the corporate network is put in the service network.

The customer interacts with the systems in the DMZ. Additional services required to provide the customer with their experience are obtained by systems in the services network. Any additional information that must be retrieved from systems on the corporate network is retrieved by the intermediate servers. Although this seems to be an overly complex arrangement, there is a high degree of security inherent in the design. The systems outside the firewall have no ability to connect to the corporate network. The firewall is configured to only allow connections from the DMZ to the service network, and then only to specific IP addresses and network services. The systems in the service network are then authorized to connect with systems in the corporate network for the required information.

The use of intrusion detection systems and periodic evaluation using vulnerability assessment tools is also highly recommended as part of an E-commerce security architecture due to the nature of the service and likelihood of attack.

When considering the firewall and network security implementation, examine:

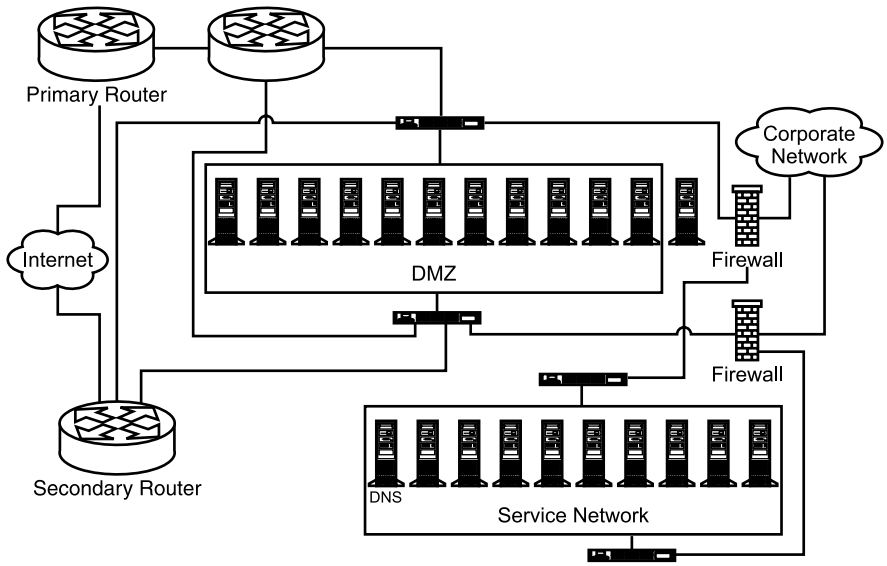

EXHIBIT 130.6 Demilitarized zones (DMZ) and service networks.

- Vulnerability reports of all network elements using a network vulnerability tool such as Cybercop or ISS
- The DMZ systems to determine if they are "hardened" to reduce the potential attack points
- How the Web client and server negotiate SSL encryption and what encryption strengths are offered
- Non-HTTP ports opened through the firewall(s) for browsing and analyze security implications
- The firewall topology
- Firewall configuration files
- Access control lists of network devices
- Network communication protocols
- Configuration management on the network security elements

Securing the E-Commerce Server

The E-commerce server consists of a variety of components all connected together to provide the business service. Multiple systems are used to reduce the complexity of any single system in an effort to improve the chances of properly securing each system. These services include the HTTP or Web server itself, personalization systems, directory systems, e-mail gateways, and authentication systems.

Directory Services

Directory services provide a mechanism for maintaining an online repository of registered users and their related information. By using a central repository for this information, any of the systems requiring authentication data or information regarding the user can access it. Additionally, applications can query information regarding the user, including their mailing information when ordering or requesting hardcopy information or when products are shipped to them.

Several directory systems are available, but those based on X.500 and Lightweight Directory Access Protocol (LDAP) technology provide the highest level of integration and availability.

Because all of the information regarding the users is stored in a central repository, special care must be taken to protect the information on those systems and provide authenticated and secure transmission channels for the data. The repository must have high availability, as many systems will be dependent on its ability to provide the information when requested. As previously stated, the consolidation of the data makes it easier for the administrators to provide confidentiality and maintain integrity while the information is stored and during transmission across the network. One can argue that the consolidation of the data also makes the system

a target for attack. However, the centralization also provides network security personnel with the opportunity to protect the system.

When evaluating the directory services provided, consider:

- How much data will be stored
- How quickly must the directory provide the response
- How many queries can the directory handle at a single time
- What security functionality is integrated into the directory
- Does the directory support authenticated connections
- Does the customer understand that this data is being stored

Mail Server

Electronic mail is a key component in any E-commerce infrastructure. It allows for the delivery of information from the E-commerce infrastructure systems to a user or business. Customers depend on e-mail to request information and to interact with customer service or support people when questions or problems arise. It can also be used by customers to report things they like or dislike about the experience. E-mail, which is used for many things, should not be used as a transport method for information requiring special protection. Information sent via e-mail is as public as a postcard. Consequently, the distribution of credit card or purchase information, as well as user name and passwords, must not be distributed through e-mail. This can be made possible and secure through encryption technologies such as S/MIME.

The operation of the mail server is critical to the infrastructure. E-mail servers are also regularly used by hackers to access other systems or send unsolicited bulk e-mail, or spam, as they are often not considered to be a major security risk. Many of the available commercial mail servers have idiosyncrasies related to their configuration that both can protect and expose information. Consider the incorrectly configured mail server that allows external users to send e-mail as if they were employees of the company, or using the mail server to relay spam to other mail servers.

Such examples are written and documented on a daily basis in the security industry and are usually related to simple misconfigurations, the use of out-dated software implementations, or not remaining current with software patches.

When addressing e-mail security and availability, consider:

- Which mail transport agents and mail user agents are being used
- Access permissions for the mail transport agent's (MTA) configuration files
- Periodic review of the mail server's delivery and error logs to determine the possibility of misuse
- Probing the MTA for common "exploits" to test vulnerabilities to various attacks
- Evaluating the use of virus protection technologies
- Content management and encryption technologies

Web Server

The Web server can be considered the most critical component in the E-commerce infrastructure. It is required to deliver Web-viewable content to the user, run programs to retrieve or send information to the user or other systems, and perform specific checks to determine the validity of requests. It is expected to be available all the time and to provide responses to the user within an acceptable time period. If users have to wait due to poor network or Web server performance, they will quickly leave your site. Once again they will form a negative perception of the business and not be likely to return.

There are a number of Web servers available, both as commercial and freeware software implementations. If one can afford it, buy a commercial implementation to have quick support when issues arise and gain vendor maintenance for the software. Although the initial expense for freeware implementations may be low, and they are quite robust, the post-installation maintenance and support expenses can be quite high. Consider company turnover and retention of experts to maintain the freeware implementation. It is likely to be much easier to find trained experts on commercial software than someone who is familiar with a tailored freeware implementation.

While configuring the Web server itself, development standards are needed for the design of applications and Web content. The Web server software must not execute on the system with any special or administrative permissions. This reduces the risk of an attacker gaining administrative privileges to compromise the server.

The operation of the server is also dependent on the availability of Common Gateway Interface (CGI) scripts to provide access to applications and forms. CGI programs require careful scrutiny during development and before final production to validate that there are no exposures to poorly written code resulting in security issues. Confidentiality and data integrity have been presented several times. The Web server should be capable of providing encrypted sessions through Secure Sockets Layer (SSL) or Transport Layer Security (TLS). Both SSL and TLS require no additional hardware and both use a server-side certificate. The issuance of a certificate for a site is beyond the scope of this chapter. Several reputable firms can issue certificates for Web servers.

Using SSL or TLS, the organization and customer can be confident that the information being displayed or sent is protected while in transit across the network.

When reviewing the Web server, consider the following:

- Review the user ID and account permissions the Web server runs under (i.e., root, administrator).
- Determine which Web sites are public and which are controlled access.
- Analyze access permissions for HTML documents, ASP and CGI, directories and scripts.
- Examine Microsoft IIS or other Web server application configurations and log files.
- Determine how requests received by the Web server from the browser are verified.
- Determine how requests sent to a back-end processor are verified as completed.
- Examine Web-based applications and database connectivity, including Java, JavaScript, and XML.
- Check for the existence of well-known ASP and CGI scripts and utilities that pose a security risk.
- Examine Web and proxy server configuration files.
- Check the Web server configuration files and certificates to enable SSL communications.
- Analyze high-availability components in the E-commerce service.
- Evaluate operating system and Web software patch levels and configuration files on critical servers.
- Evaluate application patch levels and configuration files.
- Determine how external E-commerce systems authenticate to internal systems.
- Consider the certificate authority that issued the server certificate and if there is a method for the customer to validate the authenticity of the certificate.
- Evaluate the requirements of non-repudiation features.
- Evaluate CGI scripts and review the program code.
- Consider Web content management.

Operating System Security

All of the components previously described rely on the foundation services provided by the operating system. Although each of the individual application components can be made more secure, without a strong, secure foundation, other efforts are affected. Today, the vast majority of E-commerce systems run on either Windows NT or UNIX operating systems. Each of these environments has its own advantages and disadvantages and system vulnerabilities.

Windows NT Operating System

Windows NT is a popular operating system used to perform specific computing tasks in any infrastructure. Proper configuration of the operating system is essential. If not properly configured and security is not properly implemented, it can be trivial to compromise.

Windows NT relies heavily on the registry to provide both operating system and application configuration settings. Several key services in Windows NT operate at the same network service port. This can provide a remote user with the ability to probe the system and collect important registry information. With this information in hand, such as disk sharing information, user names, and system configuration details, a successful attack can be launched against the system.

When using Windows NT as an E-commerce operating system platform:

- Conduct a scan of all Windows NT systems providing E-commerce services using both host- and network-based vulnerability scanners. Analyze the results and attempt to exploit them on the operating system to gain unauthorized access.

- Review unnecessary services and ports.
- Review registry settings and operating system patch levels and configuration files on critical servers.
- Evaluate configuration and change management on the operating system components.
- Implement virus protection technologies.

UNIX Operating System

The UNIX operating system provides a multi-user, multi-processing environment used for many different tasks. Like Windows NT, however, improper configuration of the security modules and operating system can make it trivial to compromise. UNIX is a much more popular E-commerce environment than Windows NT. Despite the relative maturity of the operating system, new problems with UNIX implementations are discovered on a weekly basis. The visibility of some of the new security issues even makes it to the news media due to the dependence in the computing world upon this operating system.

Like Windows NT, UNIX is not intended to be a secure operating environment. Any security expert can provide a multitude of ways to defeat the security systems on either operating system. Considerable effort is required to "harden" the operating system and reduce the vulnerabilities in the E-commerce environment. As a multi-user operating system, UNIX has a large number of network-based services providing major parts of the system's functionality. Many of these services and ports are not necessary in order to provide E-commerce functionality. These services are often exploited to initiate confidentiality, data integrity, or system availability attacks.

When using UNIX as an E-commerce operating system, be sure to:

- Conduct a scan of all UNIX systems providing E-commerce services using host- and network-based vulnerability scanners. Analyze the results and attempt to exploit them on the operating system to gain unauthorized access.
- Review unnecessary services and ports.
- Evaluate operating system patch levels and configuration files on critical servers.
- Evaluate configuration and change management on the operating system components.

Back Office Applications

The E-commerce infrastructure has communications paths to various back office applications, including search engines, Oracle, BaaN, and SAP, to facilitate the ordering of products from the catalog. These systems are sufficiently protected, as well as the data sent across the network, to restrict protected information access. In addition, there are specific performance and security considerations for these applications.

Search Engine

The search engine is used to find specific documents or Web pages within the E-commerce environment. The quality of the search engine responses depends on how fast this "crawler" can traverse the Web links and pages to produce an index for the location of relevant material. Most search engines perform this work in two stages. First, the search engine "crawls" through the Web pages and collects information. Second, it builds a searchable index for use later when the user requests the search.

Different search engines offer different levels of performance in the collection of this information. This affects the validity of the search results when the user requests the search. If pages that exist cannot be found when the search is requested, the user will think the information does not exist. Consider the negative perception this can have on the user's experience at the Web site. If pages no longer exist or contain irrelevant information appear, the user will become frustrated.

For example, consider the graphs in Exhibit 130.7. Both graphs illustrate basic system activity for two different search engines running on exactly the same hardware. The system on the top makes much better use of the system's resources during the crawling and indexing phases. This improved use of system resources suggests the engine is working effectively. The graph on the bottom shows much lower resource utilization, suggesting the engine may not be capable of handling the workload despite the hardware resources.

User interaction with the search engine is also critical. If the search engine itself has not been properly implemented, it is possible for performance, including the search, to be slow, due either to the software or the

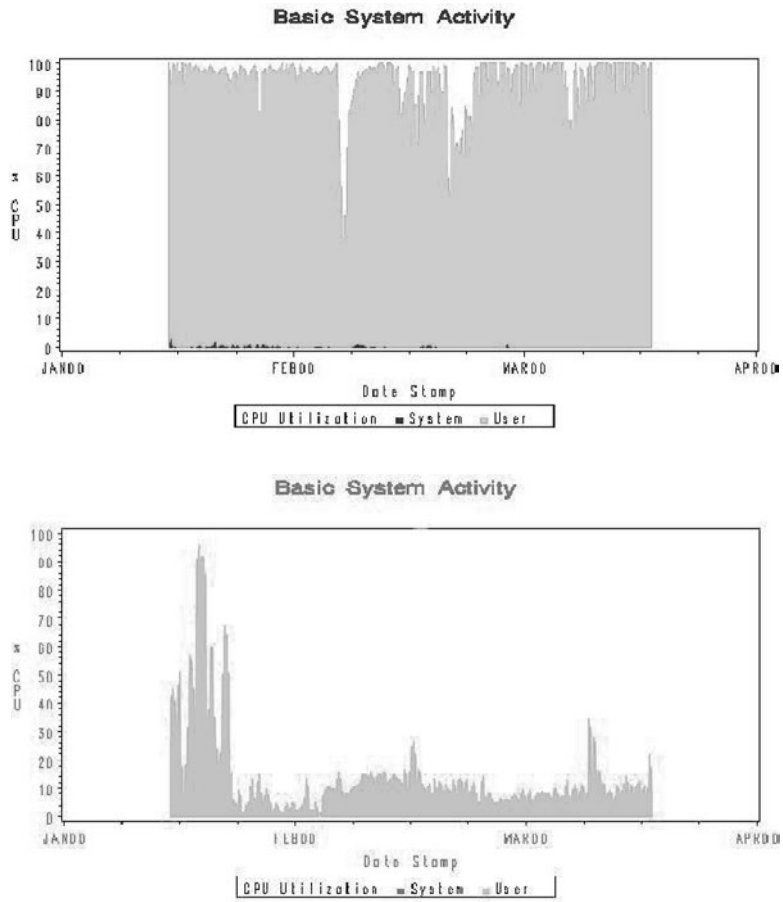

EXHIBIT 130.7 Basic system activity for two different search engines.

hardware on which it is running. Some search engine implementations do not handle simultaneous searches well. Careful review of the product, combined with simulated load testing, is required prior to implementation.

When evaluating the search engine, review:

- How well the crawling and indexing features work
- The success rate and relevance of the returned documents
- The CPU and LAN utilization
- How quickly search responses returned to the user
- The vendor's reputation

The back office systems provide information to the E-commerce user over which the organization wants to maintain strict control. In general, these same systems will be used to provide the day-to-day operations for the rest of the company. Because they are generally within the protection of the corporate network, they can be considered protected. The "hard and crunchy" network perimeter is becoming less and less practical as more and more users and customers are demanding services and access technologies. However, the issues previously presented regarding development, application, and operating system configuration must all be applied here as well.

Communication to these systems from the external E-commerce system is controlled by the firewall. The firewall will only allow specific external systems to communicate with specific internal systems to minimize the risk of total compromise in the event of an attack.

Being successful in implementing connectivity and protecting these back office systems is dependent on a thorough understanding of how data is moved from one system to another, what protocols and transport

methods are used, who creates the data, who processes it on the receiving computer, and the sensitivity of the information itself.

When evaluating and implementing connectivity to back office systems, one must:

- Evaluate protection of sensitive organizational data
- Evaluate configuration management on the back office components
- Evaluate the use of virus protection technologies
- Evaluate database configuration and administration practices
- Evaluate order transmission from the Web site to the order management system
- Evaluate the order fulfillment process

E-Nough!

This chapter has discussed the components of E-commerce architecture and identified what the organization should focus on when developing its environment or preparing to perform an audit. This chapter is by no means an all-encompassing examination of each of the technology areas, but is intended to show the reader the relationship and dependencies of various components that make up an E-commerce environment.

The implementation of an E-commerce environment allows any corporation to economically achieve global presence and enter the global marketplace successfully. In fact, some retailers have no or few storefront (bricks-and-mortar) premises due to E-commerce.

This is a challenging and fast-paced world where it is so important to be first, be visible, and be remembered. Do it fast, be quick, and do it right; if you do not, you blow it.

This is the nature of E-business. If one does not get it right the first time, one will not have enough time to fix it later. This is our E-dilemma!

Acknowledgments

Very special thanks to my colleague and close friend, Mignona Cote. Her insight into many areas in technology, business, and risk areas have taught me many things. Without her assistance, this work would not have been completed.

Improving Network-Level Security through Real-Time Monitoring and Intrusion Detection

Chris Hare, CISSP, CISA

Corporations are seeking perimeter defenses without impeding business. They have to contend with a mix of employees and non-employees on the corporate network. They must be able to address issues in a short time period due to the small window of opportunity to detect inappropriate behavior.

Today's Security Perimeter: How to Protect the Network

Many companies protect their networks from unauthorized access by implementing a security program using perimeter protection devices, including the screening router and the secure gateway. A screening router is a network device that offers the standard network routing services, and incorporates filters or access control lists to limit the type of traffic that can pass through the router. A firewall or secure gateway is a computer that runs specialized software to limit the traffic that can pass through the gateway. (The term "secure gateway" is used here rather than the more generic term "firewall.")

Although on the surface they seem like they are doing the same thing, and in some respects they are, the router and the secure gateway operate at different levels. The screening router and the secure gateway both offer services that protect entry into the protected network. Their combined operation establishes the firewall as shown in Exhibit 131.1.

Establishing firewalls at the entry points to the corporate network creates a moat-like effect. That means that there is a "moat" around the corporate network that separates it from other external networks.

The Moat

Although the moat provides good protection, it reduces the ability of the organization to respond quickly to changes in network design, traffic patterns, and connectivity requirements (see Exhibit 131.2). This lack of adaptability to new requirements has been evident throughout the deployment of the secure gateways within numerous organizations.

One of the major complaints surrounds the limited application access that is available to authorized business partner users on the external side of the firewall. In some situations, this access has been limited not by the authorizations allowed to those users, but to the secure gateway itself. These same limitations have prevented the deployment of firewalls to protect specific network segments within the corporate network.

Many organizations are only connected to the Internet and only have a need to protect themselves at that point of entry. However, many others connect to business partners, who are in turn connected to other networks. None of these points of entry can be ignored.

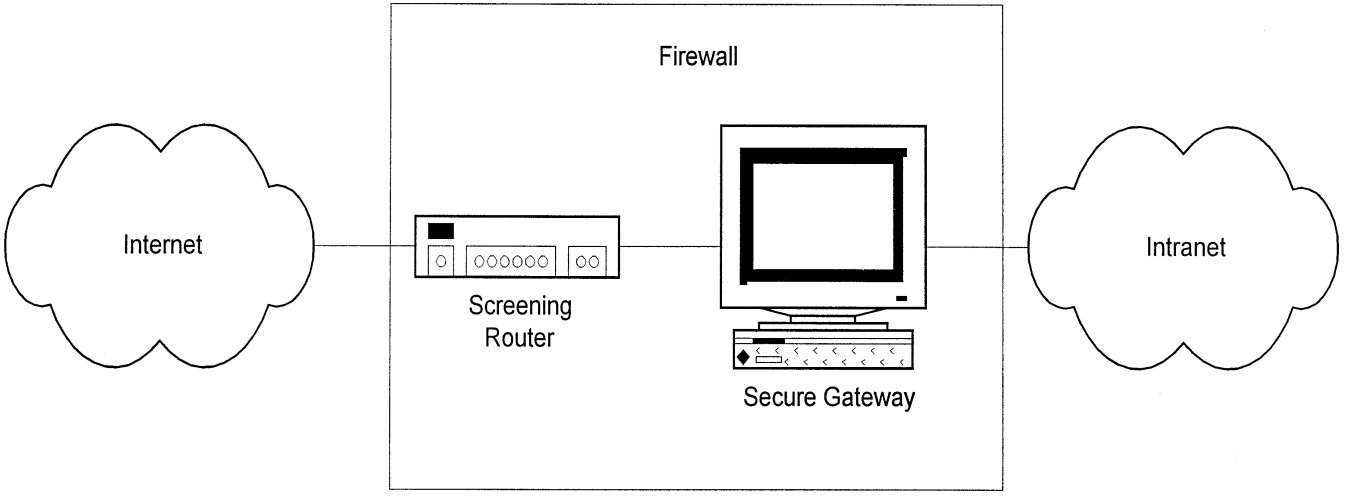

EXHIBIT 131.1 The firewall is composed of both the screening router and the secure gateway.

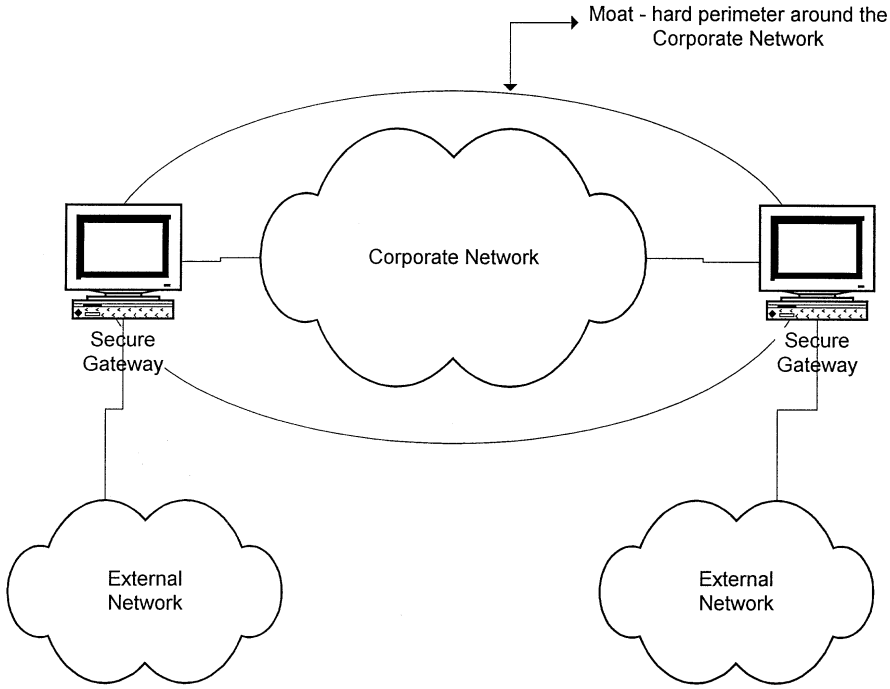

EXHIBIT 131.2 Establishing firewalls at the entry points to the corporate network creates a moat-like effect.

It is, in fact, highly recommended that today's organizations establish a centralized security team that is responsible for the operation of the various security devices. This places responsibility for the operation of that infrastructure on one group that must do the planning, implement the system, and take action to maintain it.

The Threat of Attack

The threat of attack comes from two major directions: attacks based outside the corporate network and attacks based from within. The moat security model, which is working effectively at many organizations, addresses the "attack from without" scenario. Even then, it cannot reliably provide information on the number of attacks, types of attacks, and their points of origin.

However, the moat cannot address the "attack from within" model, as the attack is occurring from within the walls. Consider the castle of medieval times. The moat was constructed to assist in warding off attacks from neighboring hostile forces. However, when fighting breaks out inside the castle walls, the moat offers no value.

The definition of an intrusion attempt is the potential possibility of a deliberate unauthorized attempt to:

- Access information
- Manipulate information
- Render a system unreliable or unusable

However, an attack is a single unauthorized access attempt, or unauthorized use attempt, regardless of success.

Unauthorized Computer Use

The problem is that the existing perimeter does not protect from an attack from within. The major security surveys continually report that the smallest percentage of loss comes from attacks that originate outside the organization. This means that the employees are really the largest threat to the organization.

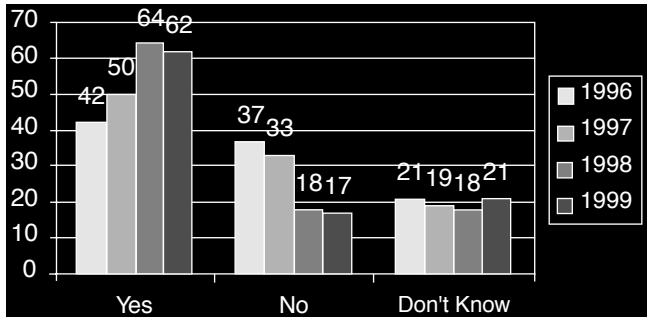

EXHIBIT 131.3 Computer Security Institute 1999 Survey.

The Computer Security Institute conducts an annual survey of its membership in conjunction with the FBI Computer Crime Unit. In the 1999 survey, the question was asked: "Has your organization experienced an incident involving the unauthorized use of a computer system?" (see Exhibit 131.3). As indicated, there was an overwhelming positive response, which had been climbing over the previous three years, but which saw a slight drop in affirmative response. Many organizations could answer "Yes" to this question, but there is also a strong element of "Don't Know." This element is because the only unauthorized use one is aware of is what is ultimately reported or found as a result of some other factor.

The cost of the information loss is staggering, as illustrated in the following information (also from the CSI Survey). From that survey, it is evident that unauthorized insider access and theft of proprietary information has the highest reported cost. Given the potential value of the technical, R&D, marketing, and strategic business information that is available on the network, more and more companies need to focus additional attention to the protection of the data and securing the network.

Financial Losses

The financial impact to organizations continues to add up to staggering figures: a total of over $123 million as reported in the survey (see Exhibit 131.4). The survey identified that there has been an increase in the cost of unauthorized access by insiders, and the cost in other areas has also risen dramatically. The survey also identified that there continues to be an increase in the number of attacks driven from outside the reporting organizations. This is largely due to the increasing sophistication of network attack tools and the number of attackers who are using them.

Intrusion detection and monitoring systems can assist in reducing the "Don't Know" factor by providing a point where unauthorized or undesirable use can be viewed, and appropriate action taken either in real-time or after the fact.

Our Employees Are Against Us

An often-quoted metric is that one of 700 employees is actively working against the company. This means that if an organization has 7000 employees, there are ten employees actively working against the organization's best interests. Although this sounds like a small number of people, the nature of who they are in an organization will dictate what they have access to and can easily use against the company.

A recent American Society for Industrial Security (ASIS, http://www.asisonline.org) "Trends in Intellectual Property Loss" survey suggested that approximately 75 percent of technology losses occur from employees and those with a trusted relationship to the company (i.e., contractors and subcontractors). Computer intrusions involve approximately 87 percent of the insider issue.

Although organizations typically have the perimeter secure, the corporate network is wide open, with all manner of information available to every one who has network access. This includes employees, contractors, suppliers, and customers! How does an organization know that its vital information is not being carried out of the network? The truth is that many do not know, and in many cases it is almost impossible to tell.

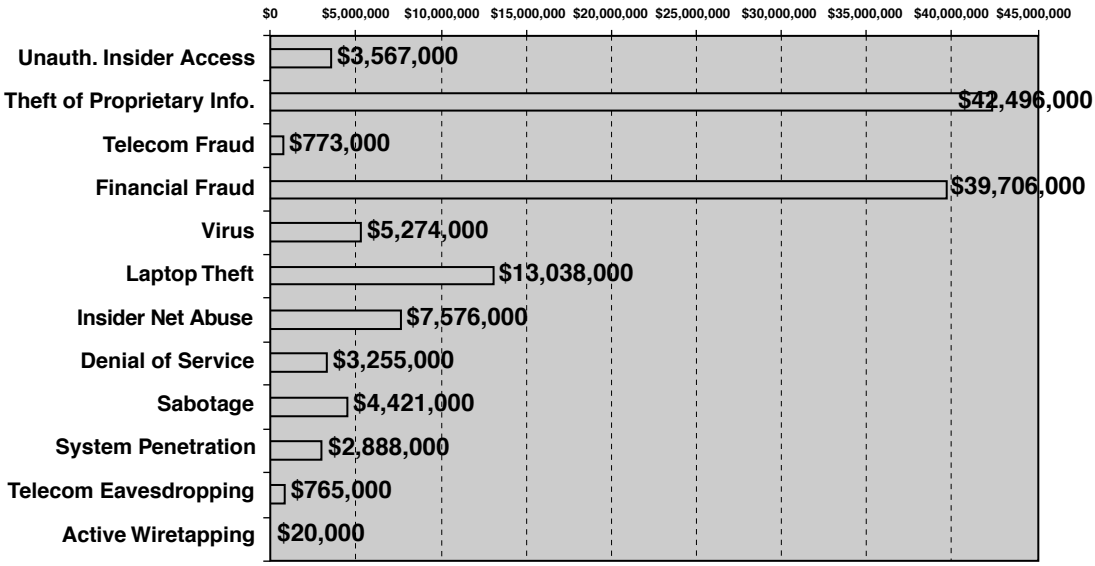

EXHIBIT 131.4 Dollar amount of losses by type.

Where Is the Critical Information?

The other aspect to this is that many organizations do not know where their critical information is stored. This does not even mean where the source code or technical information is stored. That is important, but one's competitors will be building similar products. The critical information is the strategic business plan, bids for new contracts, and financial information. There are various systems in place to control access to various components, but there are problems with the security components in those systems.

Regardless, the strategic business plan will be scattered throughout the corporation on different desktops and laptops. What is the value of that information? Who has it? Where is it going? In the current environment, few organizations can adequately identify the information, let alone where it is stored within the network.

This situation is even worse in government, military, or large corporations where they used to have dozens of filing cabinets to maintain a proper paper trail. Electronic mail has killed the chain of command and the proper establishment of a trail. Information is spread everywhere and important messages simply get deleted when employees leave the company.

The FBI has published a "Top Ten Technology List," which is still current according to the FBI's Awareness of National Security Issues and Response (FBI-ANSIR). This technology list includes:

- Manufacturing processes and technologies
- Information and communication technologies
- Aeronautic and surface transportation systems
- Energy and environmental-related technologies
- Semiconductor materials and microelectronic circuits
- Software engineering
- High-performance computing
- Simulation modeling
- Sensitive radar
- Superconductivity

Many high-tech companies operate within these areas and, as such, are prone to increased incidents of attack and intelligence-gathering operations. Because the primary threat is from internal or authorized users, it becomes necessary to apply security measures within the perimeter.

The Future of Network Security

However, the future of network security is changing. The secure gateway will be an integral part of that for a long time. However, implementation of the secure gateway is not the answer in some circumstances. Furthermore, users may be unwilling to accept the performance and convenience penalties created by the secure gateway.

Secure Gateway Types

There are two major types of secure gateways — packet filters and application proxy systems — and companies choose one or the other for various reasons. This chapter does not seek to address the strengths or weaknesses of either approach, but to explain how they are different.

The packet-filter gateway operates at the network and transport levels, performing some basic checks on the header information contained in the packet (see Exhibit 131.5). This means that the packet examination and transfer happens very fast, but there is no logical break between the internal and external network.

The application proxy provides a clear break between the internal and external networks. This is because the packet must travel farther up the TCP/IP protocol stack and be handled by a proxy (see Exhibit 131.6). The application proxy receives the packet, and then establishes a connection to the remote destination on behalf of the user. This is how a proxy works. It provides a logical break between the two networks, and ensures that no packets from one network are automatically sent to the other network.

The downside is that there must a proxy on the secure gateway for each protocol. Most secure gateway vendors do not provide a toolkit to build application proxies. Consequently, companies are limited in what services can be offered until the appropriate proxy is developed by the vendor.

The third type of firewall that is beginning to gain attention is the adaptive proxy (see Exhibit 131.7). In this model, the gateway can operate as both an application proxy and a packet filter. When the gateway receives a connection, it behaves like an application proxy. The appropriate proxy checks the connection. As discussed earlier, this has an effect on the overhead associated with the gateway. However, once the connection has been "approved" by the gateway, future packets will travel through the packet filter portion, thereby providing a greater level of performance throughput. There is currently only one vendor offering this technology, although it will expand to others in the future.

The adaptive proxy operates in a similar manner to stateful inspection systems, but it has a proxy component.

Whenever a firewall receives a SYN packet initiating a TCP connection, that SYN packet is reviewed against the firewall rule base. Just like a router, this SYN packet is compared to the rules in sequential order (starting

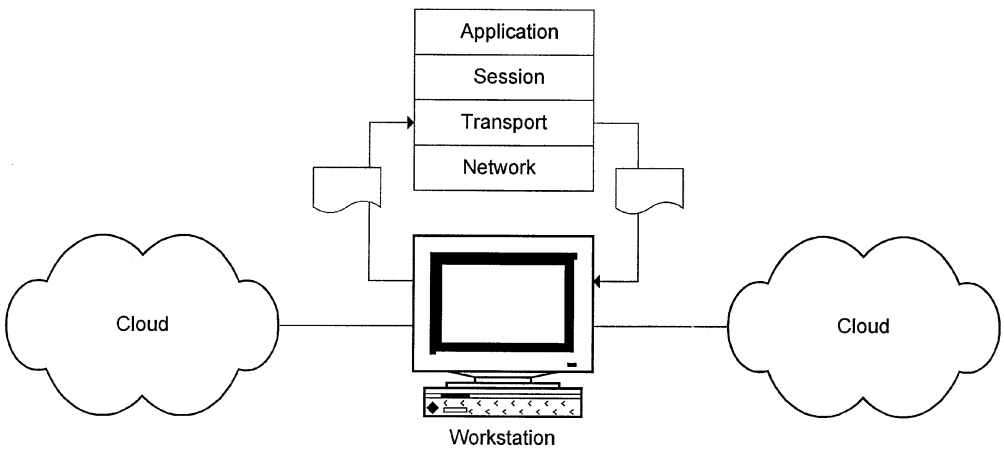

EXHIBIT 131.5 The packet-filter gateway operates at the network and transport levels, performing some basic checks on the header information contained in the packet.

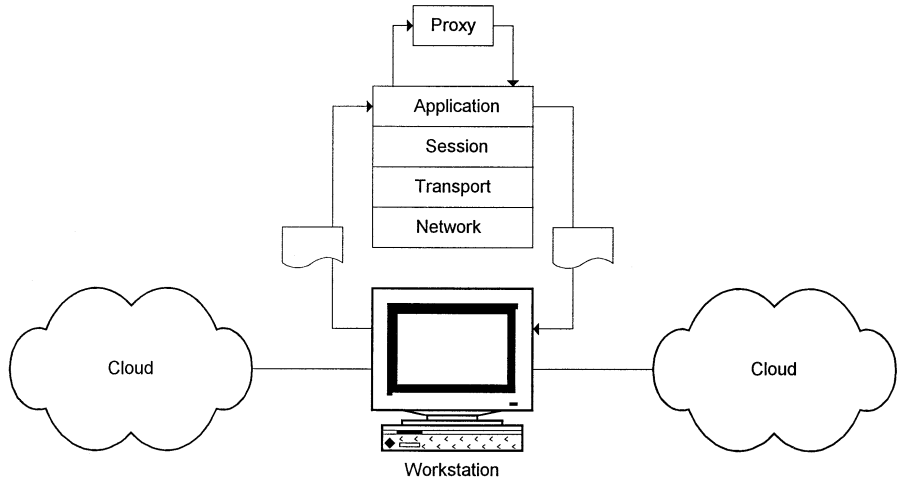

EXHIBIT 131.6 An application proxy provides a clear break between the internal and external network (this is because the packet must travel farther up the TCP/IP protocol stack and be handled by a proxy).

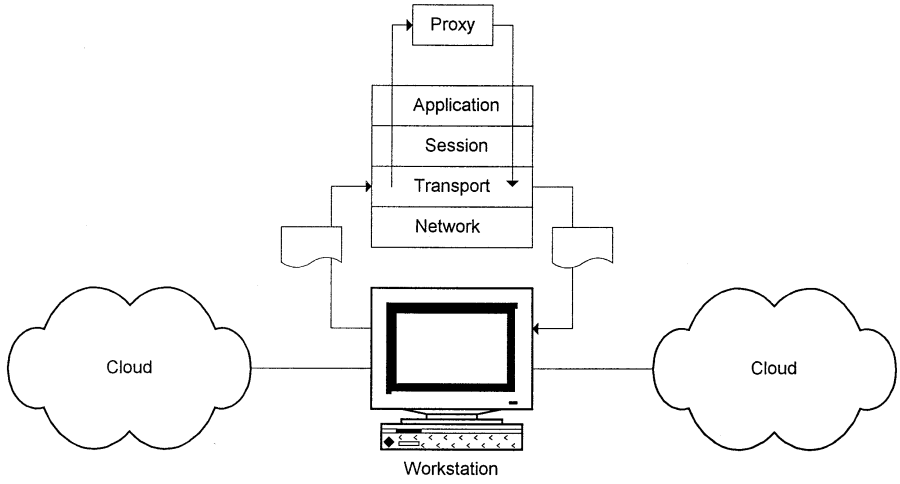

EXHIBIT 131.7 With an adaptive proxy, the gateway can operate as both an application proxy and a packet filter.

with rule 0). If the packet goes through every rule without being accepted, the packet is denied. The connection is then dropped or rejected (RST is sent back to the remote host). However, if the packet is accepted, the session is then entered into the firewall's stateful connection table, which is located in kernel memory. Every packet that follows (that does not have a SYN) is then compared to the stateful inspection table. If the session is in the table and the packet is part of that session, then the packet is accepted. If the packet is not part of the session, then it is dropped. This improves system performance, as every single packet is not compared against the rule base; only SYN packets initiating a connection are compared to the rule base. All other TCP packets are compared to the state table in kernel memory (very fast).

This means that, to provide increased protection for the information within the corporate network, organizations must deploy security controls within the corporate network that consist of both secure gateways (where there is a good reason) and intrusion and network monitoring and detection. Intrusion detection systems are used in a variety of situations.

Security Layering

Security is often layered to provide defense-in-depth. This means that at each layer, there are security controls to ensure that authorized people have access, while still denying access to those who are not authorized (see Exhibit 131.8). As seen in this diagram, this layering can be visualized as a series of concentric circles, with the level of protection increasing to the center.

Layer 1, or the network perimeter, guards against unauthorized access to the network itself. This includes firewalls, remote access servers, etc. Layer 2 is the network. Some information is handled on the network without any thought. As such, layer 2 addresses the protection of the data as it moves across the network. This technology includes link encryptors, VPN, and IPSec. Layer 3 considers access to the server systems themselves. Many users do not need access to the server, but to an application residing there. However, a user who has access to the server may have access to more information than is appropriate for that user. Consequently, layer 3 addresses access and controls on the server itself.

Finally, layer 4 considers the application-level security. Many security problems exist due to inconsistencies in how each application handles or does not handle security. This includes access and authorization for specific functions within that application.

There are occasions where organizations implement good technology in bad ways, which results in poor implementation. This generally leads to a false sense of security and lulls the organization into complacency.

Consequently, by linking each layer, it becomes possible to provide security that the user does not see in some cases, and will have to interact with at a minimal level to provide access to the desired services. This corresponds to the goals of the three-year architecture vision.

Security Goals

Organizations place a great deal of trust in the administrators of computer systems firs to keep things running, and then to make sure that the needed patches are applied whenever possible. It is very important that the

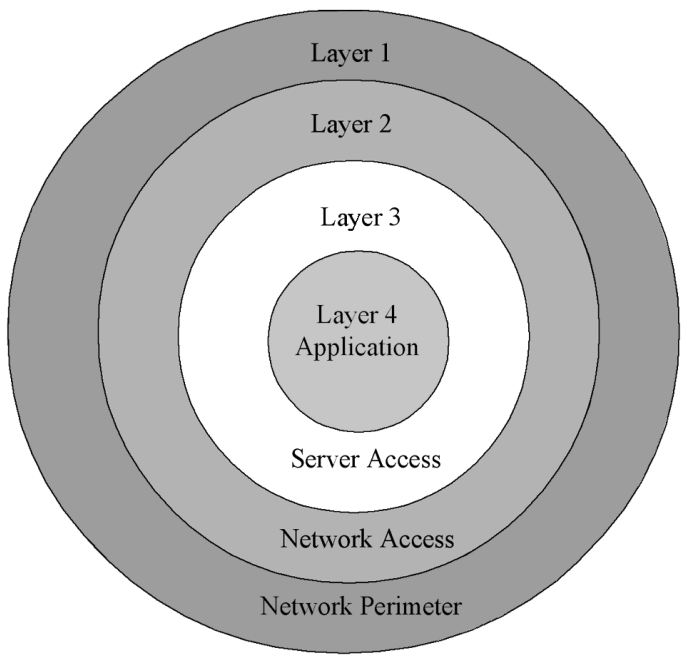

EXHIBIT 131.8 Security layering provides defensive depths (this means that at each layer, there are security controls to ensure that authorized people have access, while still denying access to those who are not authorized).

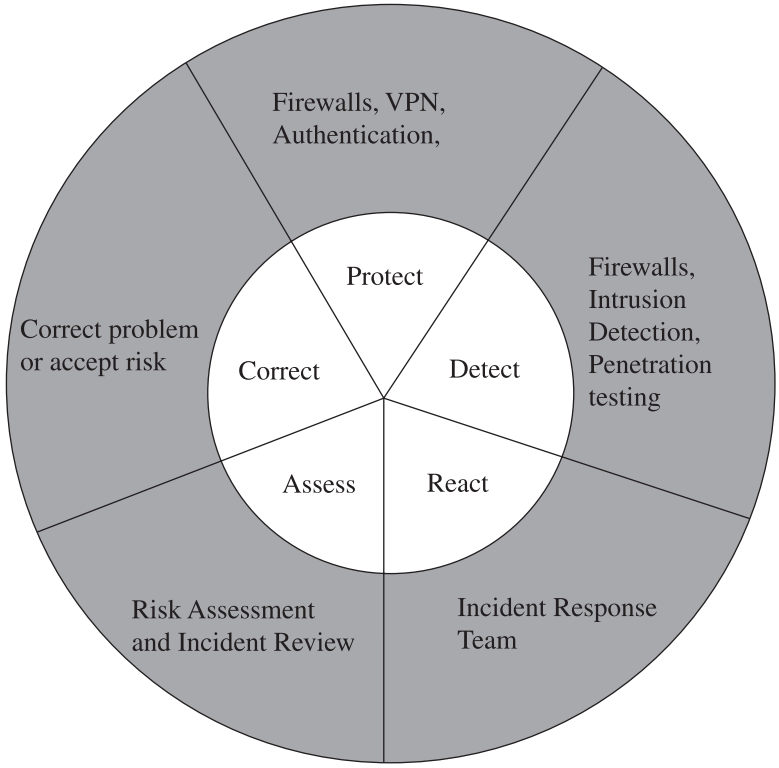

EXHIBIT 131.9 Five essential steps in the information protection arena: protect, detect, react, assess, and correct.

security measures of any system are configured and maintained to prevent unauthorized access. The major threats to information itself are:

- Disclosure, either accidental or intentional (confidentiality)
- Modification (integrity)
- Destruction (availability)

The goal of an information protection program is to maintain the confidentiality, integrity, and availability of information.

Exhibit 131.9 illustrates five essential steps in the information protection arena: protect, detect, react, assess, and correct.

Protection involves establishing appropriate policies procedures and technology implementations to allow for the protection of the corporation's information and technology assets.

Detection is the ability to determine when those assets have been, or are under attack from some source.

To be effective at maintaining the security goals of confidentiality, integrity, and availability, the corporation must be able to react to a detected intrusion or attack. This involves establishing a Computer Security Incident Response Team to review the alarm and act.

With the tactical response complete, the assessment phase reviews the incident and determines the factors that caused it. From there, a risk analysis is performed to determine:

- The risk of future occurrences
- What the available countermeasures are
- A cost/benefit analysis to determine if any of the available countermeasures should be implemented

The correct stage is where the countermeasures or other changes are implemented; or, if the level of risk is determined to be acceptable to the corporation, no action is taken.

Many of today's proactive organizations have the protection side operating well, as it relates to network protection. However, many have no systems in place to protect the internal data and network components.

Likewise, reaction mechanisms may be in place to address and investigate when an incident occurs. This is accomplished by establishing a Computer Incident Response Team to be used when an incident is detected in progress that requires the knowledge of a diverse group of computer and security specialists.

However, for many, their detection abilities are limited, which is the area that intrusion monitoring and detection is aimed at. By improving detection abilities, one can refine both protection strategies and technology, and how one reacts when an incident occurs.

Because today's computer systems must be able to keep information confidential, maintain integrity, and be available when needed, it is highly likely that any expectation of the system being able to completely prevent a security breach is unrealistic.

Types of Intrusion Monitoring and Detection Systems

There are two major types of intrusion detection: host and network based. Host-based products are based on the computer system and look for intrusions into its own environment. These host-based systems are capable of examining their own configuration and reporting changes to that configuration or to critical files that may result in unauthorized access or modification. For example, a product such as tripwire can be considered a host-based intrusion detection system. Changes in the configuration of the system or its files are detected and reported by tripwire and then captured at the next report.

Network-based products are those that are not bound to looking at intrusions on a specific host. Rather, they are looking for specific activity on the network that may be considered malicious. Network-based tools have the ability to find the attack in progress; host-based tools can actually see the changes inside the system. In fact, it is recommended that one runs both types of systems.

There are essentially two types of intrusion detection "engines." These are statistical anomaly detection and pattern-matching detection engines. Statistical engines look at deviation from statistical measurements to detect intrusions and unusual behaviors. The baseline established for the statistical variables is determined by observing "normal" activity and behavior. This requires significant data collection over a period of time to establish this "normal" or expected behavior. Statistical anomaly systems are generally not run in real-time due to the amount of statistical calculations required. Consequently, they are generally run against logs or other collected data.

Statistical anomaly systems offer some advantages. The well-understood realm of statistical analysis techniques is a major strength so long as the underlying assumptions in the data collection and analysis are valid. Statistical techniques also lend themselves better to analysis dealing with time.

However, the underlying assumptions about the data may not be valid, which causes false alarms and erroneous data reported. The tendency to link information from different variables to demonstrate trends may be statistically incorrect, leading to erroneous conclusions. The major challenge to this technique is establishing the baseline of what is considered expected behavior at the monitored site. This is easier if the users work within some predefined parameters. However, it is well-known that the more experienced users are, the less likely they will operate within those parameters.

One drawback to intrusion detection systems is false-positive alarms. A false-positive occurs when the intrusion detection system causes an alarm when no real intrusion exists. This can occur when a pattern or series of packets resemble an attack pattern but are in fact legitimate traffic.

Worth noting is that some of the major issues with statistical engines involve establishing the baseline. For example, how does one know when a user has read too many files?

Pattern-matching systems are more appropriate to run in real- or near-real-time. The concept is to look at the collected packets for a "signature," or activities that match a known vulnerability. For example, a port scan against a monitored system causes an alarm due to the nature of packets being sent. Due to the nature of some of the signatures involved, there is some overlap between the pattern-matching and anomaly detection systems.

The attack patterns provided by the vendors are compiled from CERT advisories, vendor testing, and practical experience. The challenge is for the vendor to create patterns that match a more-general class of intrusion, rather than being specific to a particular attack.

There are pros and cons to both types, but it is recommended that in the development of the tools, both forms be run. This means collecting the packets and analyzing them in near-real-time and collecting the log data from multiple sources to review it with an anomaly system as well.

In a pattern-matching system, the number and types of events that are monitored are constrained to only those items required to match a pattern. This means that if one is interested only in certain types of attacks, then one does not need to monitor for every event. As previously stated, the pattern-matching engine can run faster due to the absence of the floating-point statistical calculations.

However, pattern-matching systems can suffer from scalability issues, depending on the size of the hardware and the number of patterns to match. Even worse is that most vendors do not provide an extensible language to allow the network security administrator to define his own patterns. This makes adding one's own attack signatures a complicated process.

For both systems, neither really has a "learning" model incorporated into it, and certainly none of the commercial intrusion detection systems has a learning component implemented in it.

Why Intrusion Monitoring and Detection?

The incorporation of intrusion monitoring and detection systems provides the corporation with the ability to ensure that:

- *Protected information is not accessed by unauthorized parties; and if it is, there is a clear audit record.* Organizations must identify the location of various types of information and know where the development of protected technologies takes place. With the installation of an intrusion detection system within the corporate network, one can offer protection to that information without the need for a secure gateway. The intrusion detection system can monitor for connection requests that are not permitted and take appropriate action to block the connection. This provides a clear audit record of the connection request and its origination point, as well as preventing the retrieval of the information. There is no impact to the authorized users.
- *The ability to monitor network traffic without impact to the network.* A secure gateway is intrusive: all of the packets must pass through it before they can be transmitted on the remote network. An intrusion monitoring system is passive: it "listens" on the network and takes appropriate action with the packets.
- *Actively respond to attacks on systems.* Many implementations of intrusion monitoring systems have the ability to perform specific actions when an event takes place. Those actions range from notification to a human to automatic reconfiguration of a device and blocking the connection at the network level.
- *Information security organizations understand the attacks being made and can build systems and networks to resist those attacks.* As attacks are made against the organization, reviewing the information captured by the intrusion monitoring system can assist in the development of better tools, practices, and processes to improve the level of information security and decrease the risk of loss.
- *Metrics reporting is provided.* As in any program, the ability to report on the operation of the program through good quality metrics is essential. Most organizations do not know if there has been a successful penetration into their network because they have no good detection methods to determine this.

Implementation Examples

As more and more organizations enter the electronic business (E-biz) forum in full gear, the effective protection of those systems is essential to being able to establish trust with the customer base that will be using them. Monitoring of the activity around those systems will ensure that one responds to any new attacks in an appropriate fashion, and protects that area of the business — both from financial and image perspectives.

Implementing an intrusion monitoring and detection system enables monitoring at specific sites and locations within the network. For example, one should be immediately concerned with Internet access points and the extranets that house so many critical business services on the Internet.

Second, organizations should be working with information owners on the FBI's top-ten list on how to handle corporate strategic information. That venture would involve installing an intrusion monitoring system and identifying the information that people are not allowed to access, and then using that system to log the access attempts and block the network connections to that information.

The following examples are intended to identify some areas where an intrusion monitoring system could be installed and the benefits of each.

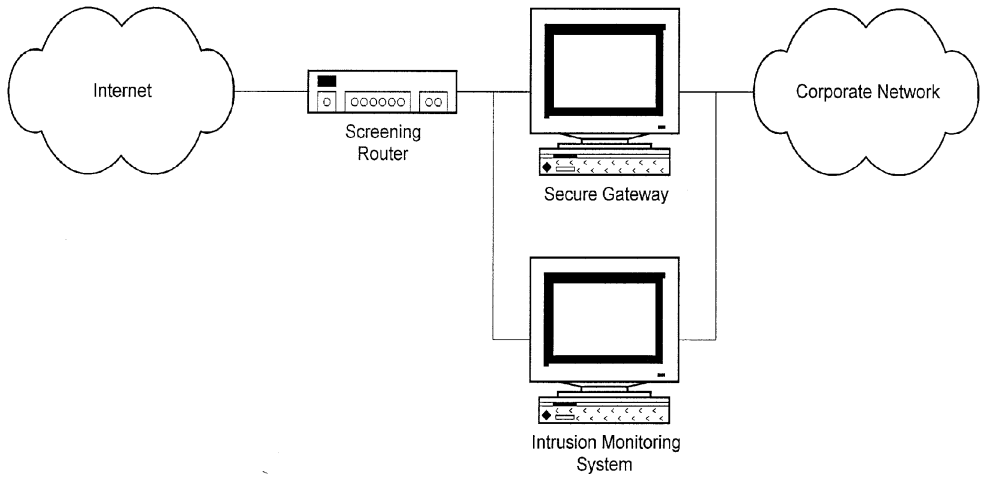

EXHIBIT 131.10 An intrusion monitoring system is configured to monitor the networks on both sides of the fiirewall.

Monitoring at the Secure Gateway

In Exhibit 131.10, the intrusion monitoring system is configured to monitor the networks on both sides of the firewall. The intrusion monitoring system is unable to pass packets itself from one side to the other. This type of implementation uses a passive or nonintrusive mode of network data capture.

To illustrate this, first consider the firewall. The firewall must retransmit packets received on one network to the other network. This is intrusive as the packet is handled by the firewall while in transit. The intrusion monitoring system, on the other hand, does not actually that the packet should be handled. It observes and examines the packet as it is transmitted on the network.

This example also lends itself to monitoring those situations where the traffic must be passed through the secure gateway using a local tunnel. As this provides essentially unrestricted access through the secure gateway, the intrusion monitoring system can offer additional support, and improved logging shows where the packet came from and what it looked like on the other side of the gateway.

Using an intrusion monitoring system in this manner allows metrics collection to support the operation of the perimeter and demonstration that the firewall technology is actually blocking the traffic it was configured to block. In the event of unexpected traffic being passed through anyway, the information provided by the intrusion monitoring system can be used by the appropriate support groups to make the necessary corrections and, if necessary, collect information for law enforcement action.

Monitoring at the Remote Access Service Entry

A second example involves the insertion of an intrusion monitoring device between the RAS access points and their connection to the corporate network (see Exhibit 131.11). In this implementation, the intrusion monitoring system is installed at the remote access point. With the clear realization that most technical and intellectual property loss is through authorized inside access, it makes sense to monitor one's remote access points. It is possible to look for this type of behavior, active attacks against systems, and other misuse of the corporate computing and network services.

Monitoring within the Corporate Network

As mentioned previously, there is no ability to monitor specific subnets within the corporate network where protected information is stored. Through the implementation of intrusion monitoring, it is possible to provide additional protection for that information without the requirement for a secure gateway.

Exhibit 131.12 reveals that the protected servers are on the same subnet as the intrusion monitoring system. When the corporate network user attempts to gain access to the protected servers, the intrusion monitoring

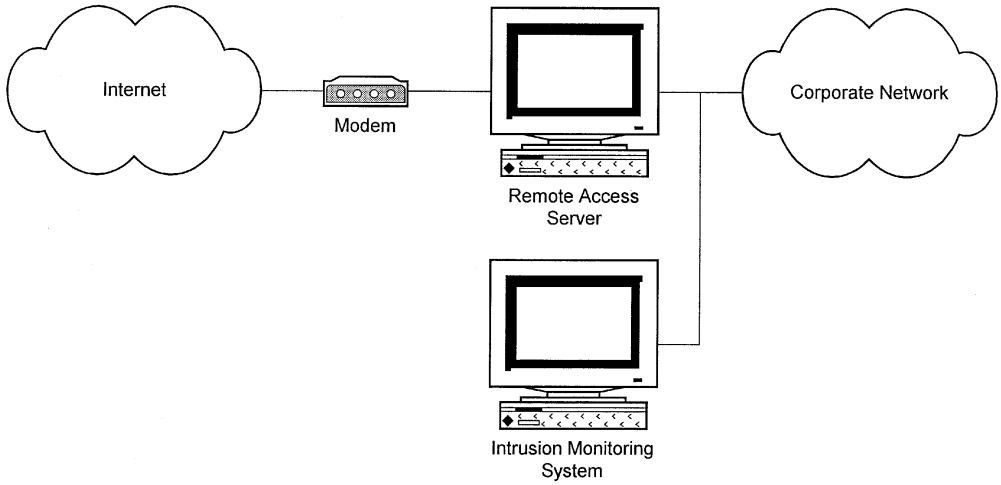

EXHIBIT 131.11 The intrusion monitoring system is installed at the remote access point.

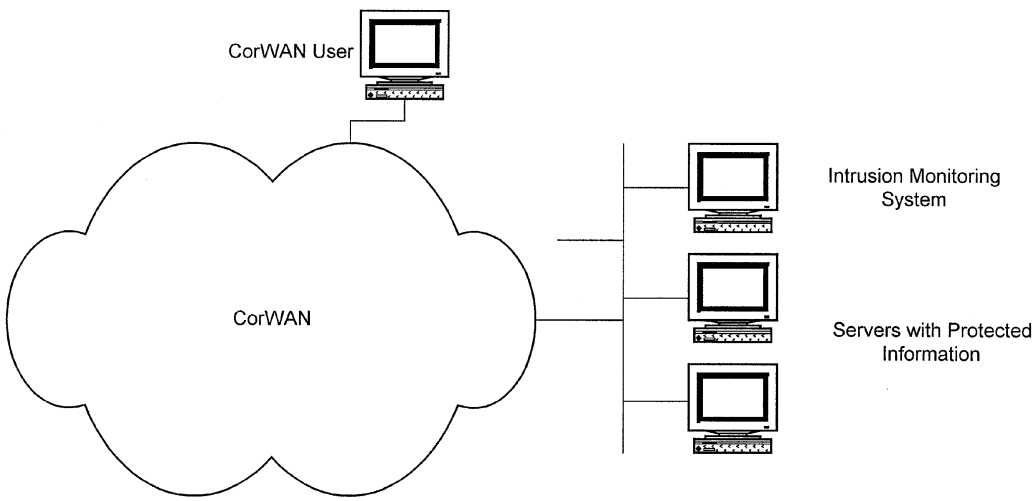

EXHIBIT 131.12 Protected servers are on the same subnet as the intrusion monitoring system.

server can log and, if configured, intercept the connection attempt. This also means that some guidelines on how to determine where to add an intrusion detection system within the corporate network are required. In many organizations, the corporate network is extensive and it may not be feasible to monitor them all.

Monitoring the Extranet

This will facilitate monitoring attacks against externally connected machines or, in the event that a proper extranet has been implemented, by monitoring any attacks against the systems connected to the extranet. However, in this instance, two IDSs may be required to offer detection capabilities for both the extranet and the firewall, as illustrated in Exhibit 131.13.

In this illustration, all activity coming into the extranet is monitored. The extranet itself is also protected as it is not directly on the Internet, but in a private organizationally controlled network. This allows additional controls to be in operation to protect those systems.

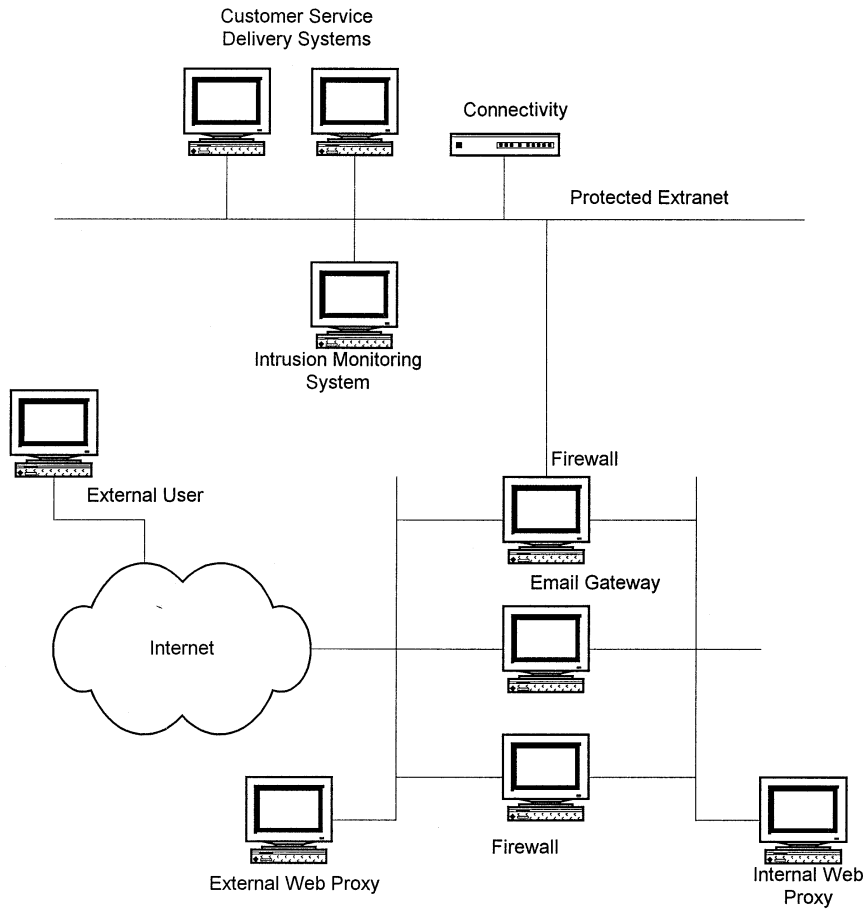

EXHIBIT 131.13 Two IDS systems may be required to offer detection capabilities for both the extranet and the firewall.

Security Is Difficult to Quantify

Security is a business element that is often very difficult to quantify. This is because security is a loss prevention exercise. Until something is missing, most people do not bother with it. However, application of an intrusion monitoring system external to network access points can provide valuable information that includes metrics describing the state of the security perimeter.

Aside from the monitoring component, some intrusion detection systems offer the ability to block network sessions where they are deemed inappropriate or undesirable. These systems offer additional opportunities. Deployment of secure gateways can be problematic as the services that are available to users on the external network are reduced due to limitations at the secure gateway. Using the blocking technology, it may be possible to deploy an intrusion monitoring and detection system to monitor the traffic, but also block connection requests to protected information or sites.

Proactive and Reactive Monitoring

The situations illustrated in Exhibits 131,10 through 131.13 are proactive implementations of an intrusion detection system. The other implementation (not illustrated here) is reactive. A proactive approach calls for the installation and operation of the system in an ongoing mode, as well as ongoing maintenance to ensure that the intrusion monitor is processing information correctly. A reactive mode approach involves having an

intrusion monitor system ready for installation, but not actually using it until some event occurs. The operation of an effective intrusion monitoring systems involves both of these elements.

However, there is the concept of real-time and interval-based intrusion detection. Real-time implies that the monitoring agent is run on a continuous basis; interval-based means that the monitor is run as needed, or at intervals. Vulnerability scanning is also seen as a form of intrusion detection by exposing holes in an operating system configuration. This is interval-based monitoring, as it cannot be done all the time.

Information security organizations are often focused on the prevention aspect of network security. They operate systems that are intended to limit access to information and connectivity. This is a proactive activity that requires ongoing analysis and corrective action to ensure that the network is providing the services it should, and that it is properly protected.

Computer Incident Response Team

The benefits of the intrusion detection system (i.e., the ability to detect undesirable activities) will be lost without the ability to respond to it. This is done most effectively through the operation of a Computer Security Incident Response Team (or CSIRT). Most CSIRT teams are modeled after the Carnegie-Mellon Computer Emergency Response Team.

The object of the CSIRT is to accept alarms from intrusion detection and other sources. Its role is to review the incident and decide if it is a real incident or not.

The CSIRT must include personnel from corporate and information security, internal audit, legal, and human resources departments. Other people may be called in as required, such as network engineering and application providers.

Normally, the alarm is provided to a small group of the CSIRT to evaluate. If it is agreed that there is an incident, then the entire CSIRT is activated. The operation of the CSIRT becomes a full-time responsibility until the issue is resolved. There are a variety of potential responses and issues to be resolved in establishing a CSIRT. These are well covered in other documents and will not be duplicated here.

The CSIRT forms an integral part of the intrusion detection capability by evaluating and responding to the alarms raised by the intrusion detection systems. As such, the personnel involved must have time dedicated to this function; it cannot take a back seat to another project.

Once the tactical response is complete, the CSIRT will closely evaluate the situation and make recommendations for review to prevent or reduce the risk of further occurrence. In the protection cycle, these recommendations are used to assess what further action is to be taken.

This being the case, a decision to implement intrusion detection is a decision to implement and support a CSIRT. Intrusion detection cannot exist without the CSIRT.

Penetration and Compliance Testing

The best method to test security implementation is to try it out. A penetration test simulates the various types of attacks — both internal and external, blind and informed — against the countermeasures of the network. Essentially, a penetration test attempts to gain access through available vulnerabilities.

Penetration testing is part of the detection strategy. Although intrusion detection capabilities are required to monitor access and network status on an ongoing basis, penetration is an interval-based targeted approach to testing both the infrastructure, and the detection and reaction capabilities.

Penetration testing should be done as part of the network security strategy for several purposes:

- *To provide confidence or assurance of systems integrity.* Vulnerability scans often do not include attempts to exploit any vulnerability found, or any of the long list of known vulnerabilities. This is because many of the systems being tested currently are in production. A successful penetration test could seriously affect normal business operations. However, the integrity of the system can be effectively tested in a nonproduction role.
- *To verify the impact of the security program.* Penetration testing is used to determine if the security program is performing as it should. There are a number of different products and services that work together to provide this infrastructure. Each can be evaluated on its own, but it is much more complicated to test them as a system.

- *To provide information that can be used in developing and prioritizing security program initiatives.* Any issues found during a penetration test can alter and affect the direction of the security program priorities. Should a major issue be found that requires correction, the security program goals may be altered to provide a timely resolution for the issue.
- *To proactively discover areas of the infrastructure that may be subject to intrusion or misuse.* People do not install an alarm system in their house and never test it. The same is true here. Ongoing evaluation allows for the identification of components in the infrastructure that may be less secure than desired, not operating as expected, or contain a flaw that can be exploited. Taking a proactive stance means that it becomes possible to find and correct problems before they are exploited.
- *To provide information that can be used in developing and prioritizing policy initiatives.* Policy is not cast in stone; it must be updated from time to time to reflect the changing needs of the business. Penetration tests can assist in the testing and development of policies. This is done using the information learned from the testing to evaluate whether one is compliant with the policies, and if not, which is correct — the implementation or the policy.
- *To assess compliance with standards and policies.* It is essential that the infrastructure, once in operation, be compliant with the relevant security policies and procedures. This verification is achieved through penetration testing, or what is also known as protection testing. Protection testing is the same as penetration testing but with a slightly different objective. Penetration testing attempts to find the vulnerabilities; protection testing proves that the infrastructure is working as expected.
- *To provide metrics that can be used to benchmark the security program.* The ability to demonstrate that the security infrastructure is operating as expected, and that improvement is visible, are important parts of the program. Metrics establish what has been *and* what is now. It is also possible from collected metrics to make "educated guesses" about the future. By collecting metrics, one also gathers data that can be used to benchmark the operation of our infrastructure as compared to other companies.
- *For preimplementation assessments of systems or services.* It is important that appropriate evaluations are performed to ensure that the addition of new services to the infrastructure, or that are dependent on the infrastructure operating correctly, be certified to ensure that no vulnerabilities exist that could be exploited. When a new application is developed that interconnects both internal and external systems, a penetration test against the application and its server is undertaken to verify that neither holds a vulnerability to be exploited. This also ascertains that if the external system is compromised, the attacker cannot gain access to the corporate network resources.

Types of Penetration Tests

There are essentially three major types of penetration testing, each with their own tools and techniques:

- *Level 1 — Zero Knowledge Penetration Testing:* This attempts to penetrate the network from an external source without knowledge of its architecture. However, information that is obtained through publicly accessible information is not excluded.
- *Level 2 — Full Knowledge Penetration Testing:* This attempts to penetrate the network from an external source with full knowledge of the network architecture and software levels.
- *Level 3 — Internal Penetration Testing:* This attempts to compromise network security and hosts from inside one's network.

Penetration testing is interval based, meaning that it is done from time to time and against different target points. Penetration testing is not a real-time activity.

The process consists of collecting information about the network and executing the test. In a Level 1 test, the only information available is what is published through open source information. This includes network broadcasts, upstream Internet service providers, domain name servers, and public registration records. This helps simulate an attack from an unsophisticated intruder who may try various standard approaches. This approach primarily tests one's ability to detect and respond to an attack.

A Level 2 penetration test assumes full knowledge of the hardware and software used on the network. Such information may be available to meticulous and determined intruders using whatever means, including social engineering, to increase their understanding of your network. This stage of the test assumes the worst-possible scenario and calls to light the maximum number of vulnerabilities.

A Level 3 penetration test, or acid test, is an attack from within the network. This is the best judge of the quality of the implementation of a company's security policy. A real attack from within a network can come from various sources, including disgruntled employees, accidental attacks, and brazen intruders who can socially engineer their way into a company.

Penetration testing should be considered very carefully in the implementation of an overall detection program, but it can lead to the negative side effects one is trying to prevent. Therefore, penetration testing should be used cautiously, but still be used to attempt to locate vulnerabilities and to assess the overall operation of the protection program.

Summary

This chapter has presented several implementations of secure gateway and intrusion detection techniques, while focusing on the business impact of their implementation. It is essential that the security professional consider the use of both network- and host-based intrusion detection devices, and balance their use with the potential for impact within the operating environment.

A key point worth remembering is that the implementation of technology is only part of the solution. There must be a well-thought-out strategy and a plan to achieve it.

Intelligent Intrusion Analysis: How Thinking Machines Can Recognize Computer Intrusions

Bryan D. Fish, CISSP

Risk management is the essence of information security. The most desirable approach is to avoid risk altogether, or prevent the associated threats from occurring. Preventive measures are important, but they sometimes fail to prevent security incidents. To account for this, it is important for organizations to be able to identify and respond to violations of their security policy. A complete risk mitigation strategy must include detective and corrective measures to supplement preventive measures. This chapter examines an artificial intelligence technique for detecting intrusions.

The knowledge of what constitutes an intrusion is key to distinguishing intrusions from authorized activity. It is difficult to express this knowledge in a way that makes sense to a machine, making intrusion detection a difficult problem to solve with computers. In contrast, most security professionals possess this knowledge tacitly, and are readily able to make such a distinction. The economics of human intrusion analysis are not in our favor, as the sheer capacity of today's information systems would overwhelm even a large staff of analysts. What is needed, then, is a system that combines the knowledge and accuracy of human intrusion analysts with the power and efficiency of the computer.

This chapter explores some artificial intelligence (AI) techniques that show promise as an intrusion detection system. The reader is introduced to the basic concepts of AI, and is then provided with an in-depth examination of one way in which AI techniques are being applied to the problem of intrusion detection. There are three objectives:

1. Motivate AI as a general class of problem-solving techniques.
2. Introduce the reader to basic AI concepts.
3. Explore AI intrusion analysis.

The first objective is addressed by contrasting traditional machine processing with human thought. And the second and third objectives are addressed by discussing existing research into AI-based methods of improving efficiency and accuracy in intrusion detection.

Why Artificial Intelligence?

Human intelligence is one of the most powerful and robust systems on the planet. Over the years, scientists have come to learn a great deal about intelligence, and have discovered striking differences between computers

and the human mind. Computers excel at certain tasks, and humans are quite good at others. Artificial intelligence research seeks to develop ways in which computers can become more proficient in the kinds of tasks that are currently best performed by humans.

For the purposes of understanding intelligence, it is useful to distinguish between three types of tasks: mundane, formal, and expert tasks. In general, the capabilities to perform these tasks build on one another. Expert tasks include tasks such as scientific analysis, engineering design, and medical diagnosis. To perform these tasks, one must first be able to master certain formal tasks, such as basic mathematical and logic operations. Execution of these formal tasks relies on one's ability to perform mundane tasks, such as perception, recognition, and language processing in the given problem space.

To be useful, formal tasks must be executed on a well-defined problem. One uses mundane skills, such as perception and reasoning, to understand and define the problem space. Without the refinement one gains through perceptual skills, formal methods are useless. In short, expert tasks require execution of the appropriate formal methods on problems one has come to understand through the application of mundane skills.

Computers do just that — they compute. They are built to perform simple operations using binary arithmetic with tremendous speed and accuracy. By orchestrating millions of these simple operations in a specific manner, one is able to perform more complex functions on a computer. The human mind, on the other hand, is naturally capable of advanced tasks that are difficult to replicate inside a computer. Computers are simply not good at replicating the capabilities of the human mind. Before exploring the ways in which AI research is closing this gap, take a look at two unique capabilities of the human mind: generalization and learning.

- *Generalization*. Humans are able to generalize concepts that are presented to them, and recognize things by their essence in addition to their specific characteristics. Humans identify the definitive characteristics of an input (an object, situation, concept, feeling, etc.) without having to remember every last bit of detail. Because the human mind allows us to understand the essence of an input, humans learn to understand concepts, not just remember objects. This allows them to recognize instances of a concept that may vary slightly from the original instance they learned to recognize.
- *Learning*. Humans differ from machines in their ability to learn from their experiences. If humans are presented with an object today and told it is a square, they will remember that and identify the same object as a square tomorrow, next week, and next year. The human mind has an enormous capacity for storing thought patterns and concepts. By organizing the information based on the manner in which it is likely to be used, the human mind provides the tremendous capability to recall this stored information when needed. This ability to store and recall thought patterns is known as learning.

The Role of Knowledge

Decades of AI research have demonstrated at least one incontrovertible assertion: intelligence requires knowledge. Knowledge provides context for our perceptual skills and a framework for the application of formal methods in problem-solving. Without knowledge, humans have the capability to execute basic skills over and over, but lack the ability to orchestrate these activities in a manner suggestive of intelligence.

Suppose a recipe calls for two onions. Perceptual skills allow one to recognize onions in the pantry. Formal mathematical skills allow one to determine that there is only one onion, and that one more onion is needed. Deciding that one needs to go to the store and purchase another onion is an expert task (although not a particularly challenging one). All of these basic skills are held together by knowledge. One knows where to look for onions that one already has. One knows that one must count the onions to see how many there are. One knows that one must perform simple subtraction to determine how many more are needed. Without all of these pieces of knowledge, one could not orchestrate the mundane, formal, and expert tasks to solve the problem.

Machines excel at executing formal tasks. Tasks such as mathematics and logic can be formally defined and then executed on a computer with tremendous speed and precision. As it turns out, however, it is quite difficult for a machine to perform the mundane and expert tasks discussed previously. This is due, in large part, to the difficulties associated with representing knowledge in a manner that the computer can understand.

Humans have a remarkable capability for creating, storing, recalling, and applying knowledge. Unfortunately, knowledge is inherently difficult to work with in machine space because it tends to be voluminous, difficult to characterize, and in a constant state of change. Furthermore, human knowledge is organized according to the manner in which it is likely to be used. This differs greatly from computer data, which is organized in a

more structured manner. If one expects machines to solve problems in an intelligent manner, one must arm them with the requisite knowledge and the ability to apply that knowledge. To be useful, that knowledge must exhibit certain characteristics:

- Knowledge must capture generalizations.
- Knowledge must be capable of simple modifications, corrections, and updates.
- Knowledge must be useful in myriad situations, even if it is not complete or totally accurate.
- Knowledge must be able to reduce the vastness of its own space to a subset that is relevant to a given situation.

Knowledge-based systems is a term used to describe problem-solving systems that represent specialized knowledge in a useful manner that meets the above criteria, and provide a means for applying it to solve a problem. Neural network pattern matching is one example of a knowledge-based system. This chapter discusses one use of this technique to represent and apply knowledge in the problem space of computer intrusion detection.

A Pattern-Matching Approach to Intrusion Detection

In applying AI techniques to intrusion detection, the hope is to improve the economics of human analysis. One wants to reduce human involvement in the investigation and response process, as well as reduce the number of false alarms they receive when they do get involved. This can be achieved by improving the accuracy of the intrusion detection system, as measured by the false-positive and false-negative error rates. The false-positive rate is the percentage of false alarms generated by the system. The false-negative rate is the percentage of actual intrusions missed by the system. Developing a system with an attractive false-positive rate reduces the number of incidents that must be investigated by a human. In driving down the false-positive rate, however, one must also take care to maintain an attractive false-negative rate to ensure that one does not fail to detect actual intrusions.

Pattern matching is a logical choice for intrusion detection. One of the most significant challenges in intrusion detection is recognizing new attacks. These attacks may be superficial variations of known techniques, or entirely new methods for breaking into systems. In either case, many traditional intrusion detection systems have trouble recognizing the attack. Pattern matching takes advantage of the power of generalization. Rather than performing an exact feature-wise match between a new input and a known pattern, pattern matching attempts to determine whether an input possesses the "essence" of a known pattern. This allows two entities to match even if they vary by some superficial features.

This chapter section examines a conceptual pattern matching intrusion detection system based on two specific AI techniques. A neural network serves as the brain of the system, storing knowledge about the problem space and applying that knowledge to detect intrusions. A self-organizing map is used to perform correlation on the raw data collected, parsing it into chunks that can be processed by the neural network.

One can begin by introducing some basic concepts of intrusion detection and then move on to a more thorough discussion of these two AI techniques and how they can be used to form an intelligent intrusion analysis system. The conceptual system described here has been developed and tested at the Georgia Tech Research Institute, a division of the Georgia Institute of Technology.

Intrusion Detection

The goal of intrusion detection is to identify activities that violate an organization's security policy. There are essentially two approaches to the intrusion detection problem: misuse detection and anomaly detection. Misuse detection systems define attack signatures — patterns of activity that are known to be undesirable. These systems spend their days monitoring system activity for the presence of these signatures, which indicates an attack. For example, if one sees an IP packet cross an interface with all of the TCP flags turned on, one is probably seeing an XMAS scan and can sound an alarm accordingly.

This approach can be effective, but has several drawbacks. It is a difficult and time-consuming task to create an exhaustive attack signature database. Furthermore, a slight variation of a known attack might differ enough from the predefined signature of that attack to cause the misuse detector to miss the event entirely. Because they look specifically for known attacks, misuse detectors usually have difficulty identifying new attacks for

which a signature does not appear in the database. Misuse detectors tend to have fewer false-positives, but more false-negatives.

Anomaly detection systems are based on a different principle. Anomaly detectors define a model of acceptable system activity and attempt to identify behavior that does not fit that model. Anomaly detectors do not know what specific intrusions look like; rather, they know what normal behavior looks like, and flag deviations from normalcy as potential intrusions. For example, assume that software engineers in a company log on to the system between 7 and 9 A.M. every morning during the week, and log out when they leave between 5 and 6 P.M. Further assume that the software engineers never log in to the systems during the weekend. Suppose one comes to work Monday and notices that all five software engineers logged in to the system at 2 A.M. the previous Sunday morning. This behavior stands out as abnormal, and could be a sign of unauthorized activity. By identifying this anomaly, one has identified a potential intrusion.

Anomaly detection systems are good at certain things, but introduce their own challenges as well. It can be just as difficult to model acceptable behavior (perhaps more so) as it is to model explicitly bad behavior. Anomaly detectors have difficulty adapting to abrupt changes in the way people use the system, which can happen frequently in large environments.

The pattern-matching intrusion detection system described in this chapter follows a misuse detection approach. The idea is to leverage the ability of a neural network to generalize its inputs and recognize superficial variations of that input. By recognizing variations of network-based attacks, the system should avoid many of the false-negatives produced by traditional misuse detectors.

Generalization allows the system to recognize when an attack has been mutated slightly, but remains fundamentally the same as its ancestor. The neural network should be able to recognize a variant that might escape a signature-based system. Furthermore, generalization may allow the system to recognize conditions that are indicative of an attack in general, not just a specific attack. If entirely new attacks exhibit these characteristics, the system may be able to identify them without ever having seen them before.

Neural Networks

Before building this system, take a look at some basic neural network concepts. In moving on to the construction of this intrusion detection system, the following discussion looks at some of these concepts in greater depth and extend their basic functionality.

DaVincian principles of intelligence encourage us to look to analogies in problem-solving. Leonardo observed the way that birds fly in order to better understand how people might one day do the same. So, in striving to evolve the computer into a more powerful and efficient problem-solving machine, one is naturally drawn to the most powerful information processing system known: the human mind. Connectionist AI theory conjectures that the very structure of the human brain facilitates the execution of tasks such as perception, reasoning, and learning. So, the theory goes, if one creates computational models based on the brain metaphor (rather than on the digital computer metaphor), computers can develop a proficiency for some of these human-oriented tasks. The neural network is one such connectionist model. Rather than mimicking the operation of the brain exactly, neural networks derive inspiration from the way the brain works, hoping to achieve some of the same capabilities as the human mind.

Neural networks are composed of two basic components: simple processing elements and weighted connections between these elements. Neural networks are highly parallel systems, as the processing elements operate independently of one another. Thus, control of the network is distributed across its processing elements. The weights between the processing elements in a connectionist model encode the system's knowledge.

Neural networks are particularly useful in pattern-matching problems, in which a given input is matched to a known pattern learned through previous experiences. Furthermore, neural networks have shown a penchant for performing approximate matching, in which incomplete or varied instances of a pattern are still recognized. The type of neural network used here — multilayer backpropagation networks — is quite popular, and is estimated to be in use in a majority of practical applications that use neural networks. These networks have a proven record for pattern-matching problems. Multilayer backpropagation networks are examined in more detail later; the focus here is on their simpler predecessor: the perceptron.

The perceptron is the simplest of neural networks. The perceptron is a network that takes an input vector of binary values, a weight vector of real-valued weights, and computes the cross-product of the two vectors. The result is then applied to a threshold function, which produces a binary output for the perceptron (see Exhibit 132.1).

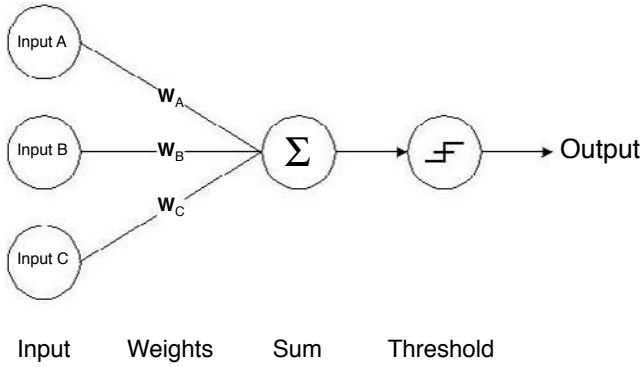

EXHIBIT 132.1 Simple perceptron.

As a pattern-matching system, this network could tell us whether an input matched a single concept, but little more. To form a pattern-matching system capable of distinguishing between several patterns, one can wire multiple processing units to a single input vector. Consider the simple network in Exhibit 132.2 that distinguishes apples, strawberries, and pears. Each processing unit computes a binary value for its corresponding output type (just as the simple perceptron did). The three-element output vector indicates the pattern that the input vector matched. For example, if this network sees a fruit with red skin and white meat (input vector [1,0,0,1]), it will produce the following results in the respective summation processors: Apple 2, Strawberry –2, and Pear –2. The threshold function produces a 1 if the input is positive, a zero otherwise. So, our resulting output vector would be [1,0,0], indicating that the fruit is an apple. Suppose the fruit has red skin and red meat (input vector [1,0,1,0]). The sums would be –2, 2, and –6, respectively. Thus, the output vector would be [0,1,0], indicating that the fruit is a strawberry. This simple network would clearly have trouble in many scenarios (such as recognizing a yellow apple from a pear), but it illustrates the basic concept of perceptron pattern matching.

The knowledge of any neural network is encoded in the weights between its processing elements. In a simple network such as the fruit classifier, it is not manually difficult to manually determine the weights. However, as the networks grow larger — and they must do so to match complex patterns — manual weight determination quickly becomes futile. The power of the connectionist model is that the network learns; it develops its own knowledge through a supervised learning process.

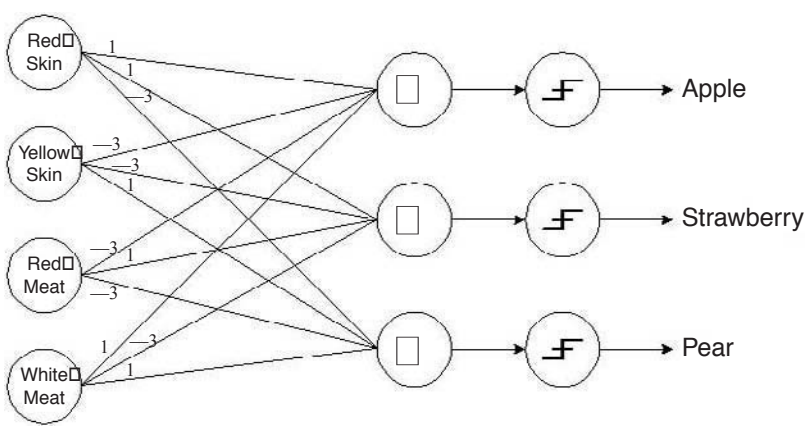

EXHIBIT 132.2 Fruit classification perceptron network.

A Pattern-Matching Intrusion Detection System

In general, the approach to intrusion detection is organized into five phases:

1. *Collect raw data.* For this example, IP packets are used; however, this raw data could be system log entries or any other raw measure of activity in an environment.
2. *Extract data elements from the raw data.* These elements should have meaning, but be basic in nature. In terms of IP packets, data elements might include things such as source and destination address/port, protocol type, flags, and some information about the payload.
3. *Combine selected data elements into a trace.* Related items are collected into a single unit that can be analyzed as a whole. For example, packets within a TCP session could be grouped into a trace.
4. *Evaluate the trace to determine whether it is an attack.* This is where knowledge is applied. Based on human knowledge (or the knowledge of the system), one determines whether the characteristics that indicate an attack are present in the trace being evaluated.
5. *Produce an output.* In this final phase, the system passes judgment on a trace and indicates whether or not it looks like an attack.

This is a generalized approach to detecting intrusions, and most misuse detectors follow a similar methodology. The AI-based approach discussed in this chapter uses this methodology, but applies some advanced techniques along the way with the hope of achieving improved effectiveness. Specifically, the system utilizes a discovery technique known as a self-organizing map to construct traces from data elements, and a pattern-matching technique known as a multilayer backpropagation network to evaluate traces for the presence of an attack. These concepts are presented in more detail later.

This illustration focuses on network-based intrusion detection, but these concepts can be directly applied to other forms of intrusion detection.

Data Gathering and Extraction

The first and second steps of this intrusion detection methodology can usually be accomplished through the application of existing tools and techniques. In the example of IP packets, a network sniffer or promiscuous interface is used to capture packets. A packet decoder can be used to parse and extract data elements from the captured packets. In the case of system logs, a remote logging server can be used to capture all system log entries, and a simple regular expression parser can be used to extract the data elements.

Trace Construction

People are constantly being bombarded with sensory data from many sources. This raw data must be parsed and combined into units on which our minds can operate. Network connections experience a similar phenomenon. They are constantly bombarded with packets with varying sources, destinations, protocols, and options. To use a neural network to recognize attack patterns in network traffic, one must first organize that data into meaningful collections; units of data on which the neural network can operate. This data unit is referred to as a trace.

A self-organizing map (SOM) is one approach to transforming data elements extracted from raw sensory inputs into meaningful clusters on which processing can take place. A SOM is essentially a two-dimensional grid of neuron-like cells. A transform function activates certain cells in the map based on the values present in an input vector. As shown in Exhibit 132.3, the SOM attempts to find correlations between inputs by ensuring that topological neighbors within the map share certain key characteristics from the input vector.

Exhibit 132.3 shows a conceptual representation of a small SOM with two sets of topological neighbors activated. Cells in close proximity to one another (a cluster) are activated when related inputs are presented to the map. A cluster in the map is effectively an index to the input vectors that activated the cells within the cluster. This map shows two clusters, indicating that the input vectors can be logically grouped into two classes. In this intrusion detection system, each of these clusters represents a trace.

The SOM learns to classify related inputs through an unsupervised learning process. In unsupervised learning, the system learns to organize data elements into clusters of related items without any *a priori* knowledge of what those clusters should look like. The network decides on its own how the data elements

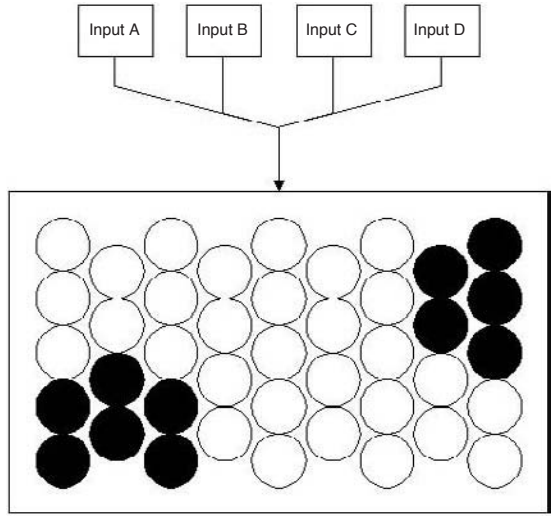

EXHIBIT 132.3 Conceptual SOM activation.

should be grouped. Unsupervised learning is often used as it is here, to discover key features in an input space prior to a supervised learning process.

In SOM learning, the parameters of the transform function are initialized to random values. Each input vector is then presented to the map in sequence. For each input vector, the SOM applies its transform function, which produces a numeric value. That value determines which cells in the map should be activated. The SOM then computes an error function that measures how well the input vectors have been grouped. Based on this result, the SOM adjusts the parameters of the transform function in such a way that would reduce the magnitude of that error function. A small error function indicates a strong correlation between the vectors in a cluster.

The SOM then advances to the next input vector and performs the same operation described above. When all of the input vectors have been processed, one has completed an epoch. The SOM then executes another epoch, processing all input vectors in sequence and adjusting parameters of the transform function accordingly. The correlation between vectors in each cluster improves with every epoch. The SOM continues executing epochs until this correlation reaches a certain predefined threshold. After the learning period concludes, the parameters of the transform function are frozen and the system moves into operational mode.

The output of the SOM is a representation of the data elements indexed by a given cluster. When applied to IP traffic, this representation is a collection of packets, or a trace. This trace becomes the input vector to the pattern-matching system. In addition to applying the trace itself as input to the network, one also computes some basic statistics on the trace (such as average size, packet count, packet frequency, etc.) to feed into the pattern-matching system.

In this system, the SOM produces an output every time the data extracted from a raw IP packet is applied as an input to the map. This produces some interesting temporal analysis capabilities, which are examined momentarily.

Trace Evaluation

The perceptron was previously introduced as a simple pattern-matching system. However, networks composed of simple perceptrons have significant limitations. These networks can only be used on certain types of input spaces that conform to some relatively strict constraints. This is due to the fact that perceptrons can only recognize simple concepts. To form a more robust pattern-matching system, one needs the ability to recognize involved concepts with complex features. This result can be achieved using an extension of the simple perceptron known as a multilayer backpropagation network.

Multilayer networks extend the simple perceptron model by adding another layer of processing units, as depicted in Exhibit 132.4. The layer of hidden processing units is used for complex feature representation.

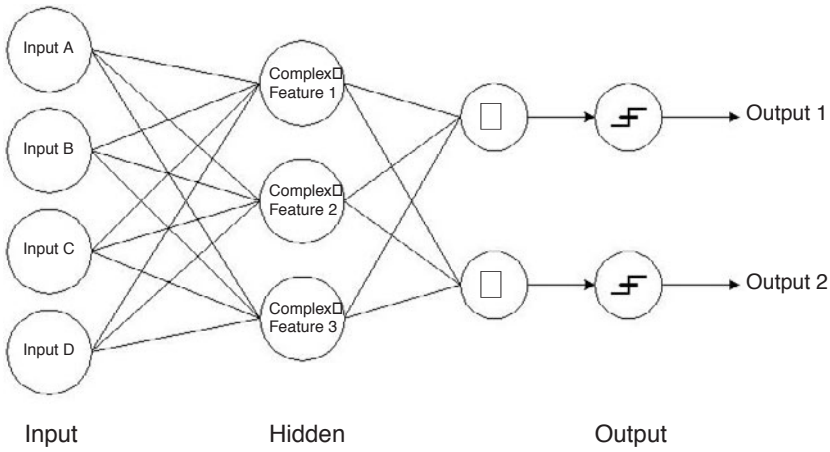

EXHIBIT 132.4 Multilayer back-propagation network.

Each of these hidden units can learn to recognize a single complex feature. A network with multiple hidden units can recognize involved concepts with many complex features.

Learning

Perhaps the most exciting characteristic of neural networks is their capability to learn. The network creates knowledge by developing its own internal representations of key concepts. The power of the neural network is that one does not have to program these concepts into the network; neither does one even have to know what they are. The hidden units start out as a blank slate, and the network is allowed to decide what concepts are key to the overall problem. The network develops its hidden processing units to represent those concepts.

Neural network pattern matchers learn through a supervised learning process. In supervised learning, a series of training inputs and their corresponding correct outputs are presented to the pattern-matching system. This allows the network to learn based on a notion of what the correct answer should be. The network determines the weights that will allow it to correctly match all of the input patterns. If presented with a well-crafted training set, the network can learn to match patterns with tremendous accuracy.

The basic learning algorithm is as follows. All of the weights on the network are initialized to a random value between –0.1 and 0.1. Each input vector is presented to the network in sequence. When presented with an input vector, the network propagates the activations in the input units to the hidden units based on an activation function that produces a real number between 0 and 1. This fuzzy result (as opposed to a strict Boolean 0 or 1 activation) allows one to more accurately reflect the degree to which key features are present in the input vector. Then, activations in the hidden units are propagated to the output units using the same activation function. This entire process is known as feedforward and results in a real number between 0 and 1 in the output elements.

Once the output units have been activated, one can compute an error function between the calculated result and the known correct result. Based on this error, the weights on the network are adjusted in a manner that reduces the magnitude of the error function, and the network moves on to the next input. The weight adjustment process is known as backpropagation.

When all of the input vectors have been processed, an epoch is concluded. The network iterates through as many epochs as it takes to drive the magnitude of the error function down to an acceptable level. Once this process is completed, the network will have learned to recognize the presence of patterns in the input vectors presented to it. As with all neural network learning, the accuracy of the neural network depends solely on the experience it gains on sample patterns during the learning period. Thus, selecting an ample training space is crucial to this process.

In training the intrusion detection system, the system is systematically exposed to both authorized network traffic and to all of the attacks one knows. If the system is trained on only attack traffic, the network would learn to recognize everything it sees as an attack. The converse is true if the system is trained on only authorized traffic. A balance between the two is required to ensure an effective learning process.

Operation

Once the learning process has completed, the weights of the neural network are frozen, and the system is ready for operation. During operation, an input vector (trace output from the SOM clustering map) is loaded into the input nodes of the multilayer backpropagation network. The network propagates the activations in the input units to the hidden units based on the same activation function used in learning. Then, activations in the hidden units are propagated to the output units, just as in the learning process. Once the output units have been activated, one has the result.

Because this result is a real value between 0 and 1, one can take action based not only on the result, but also on the magnitude of the activation. For example, one can apply a threshold function that reports any activation above 0.9 as an attack requiring immediate response, and any activation between 0.75 and 0.89 as an event of interest requiring further investigation.

The System at Work

We will observe how this system evaluates incoming traffic to determine the presence of attack patterns. Exhibit 132.5 is a conceptual illustration of the entire system.

A sniffer is used to capture IP packets. The packet is then decoded, and key data elements are extracted from it. These data elements are packaged as a unit and applied as an input to the self-organizing map. The map clusters this packet with other packets that share key characteristics, and outputs a trace containing the new packet and its topological neighbors. This trace, along with some basic statistics computed on its data, are applied as inputs to the neural network, which propagates activations through the hidden layer to the output layer. Based on the output activation, the trace is identified as an attack, an event of interest, or not an attack.

Detecting a Port Scan

Attackers often perform port scans to identify potential attack targets. Although it does not do any direct damage, one typically treats a port scan as an attack due to its malicious implications. A straightforward port scan is relatively easy to detect: same source address, same destination address, every destination port is tried eventually, etc. However, if the attacker spreads the scan out over time, for example, by probing a single port every few hours, it may be possible to evade the intrusion detection system.

The means by which traces are assembled from data elements produces a unique temporal analysis capability. When packets are added to a cluster, that cluster produces a trace. If clusters are allowed to remain in the SOM for a sufficient amount of time, additional packets will be added to the trace as they are received, although they are spread out over a long period of time. This provides correlation of incoming packets over a long period of time, defeating the slow scan approach to evading an intrusion detection system. The SOM serves as a time-lapse camera, allowing one to correlate events spread out over time into a single trace.

Detecting a SYN Flood

The SYN flood attack has been a particularly popular denial-of-service attack in recent years, and is often used as part of a collaborative attack process. Using two similar traces containing TCP-SYN packets as an example, one can better understand how this system recognizes both an actual SYN flood attack and an apparent SYN flood that is actually just normal Web traffic.

Consider the packet illustrated in Exhibit 132.6. This is a SYN packet, the first packet of a Telnet connection to server. Suppose eight or nine of these packets are seen within one or two seconds of one another, and these packets have:

- The same destination addresses
- A destination port of 23/TCP (Telnet)
- The same source address, with an incrementing source port
- Incrementing sequence and ACK numbers
- The same TCP flags enabled, specifically TCP-SYN

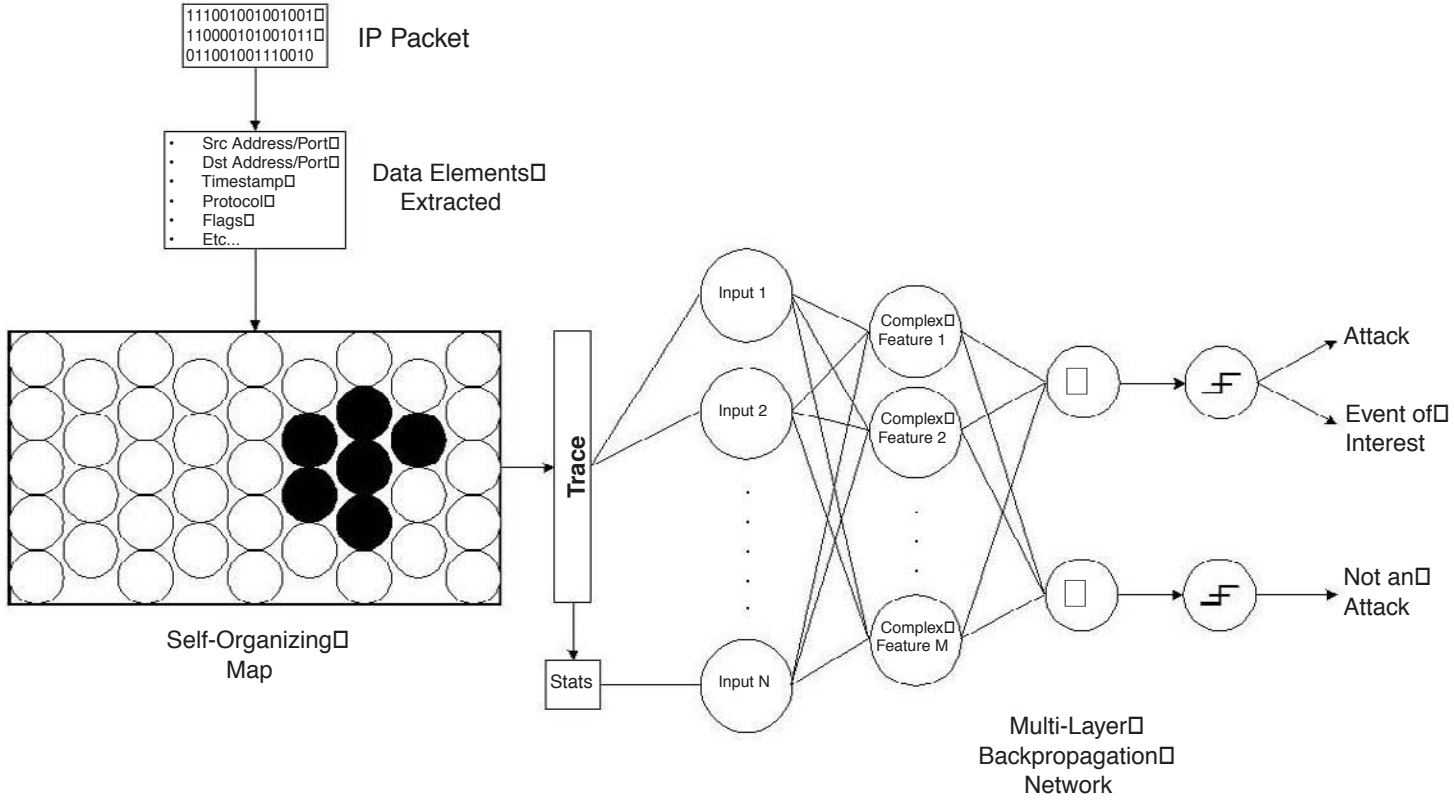

EXHIBIT 132.5 Conceptual layout of pattern-matching intrusion detection system.

EXHIBIT 132.6 SYN Packet

Field	Value
Timestamp	09:30:29.4527
Source Address/Port	attacker:320
Destination Address/Port	server:23/TCP (Telnet)
Flags	S (TCP-SYN)
Sequence Number	1094689872
ACK Number	1094689872

The SOM recognizes that these packets are related to one another and clusters them together into a trace. Each time a similar packet is received, the SOM adds it to the cluster and outputs the updated trace for evaluation by the neural network. Recall that both the trace itself and some basic statistics about the trace (packet count and packet frequency are of interest here) are applied as input to the neural network. In the first few microseconds of this activity, the neural network sees a high frequency of SYN packets, but a relatively low packet count. During the learning process, the neural network learned the packet count and frequency combination that, when associated with the above characteristics, constitutes a SYN flood attack. So, as the SOM clusters more and more of these packets together, all of the above characteristics remain present in the resulting trace, and the packet count and frequency statistics rise. As this happens, the trace pattern begins to match that of a SYN flood attack. When the threshold (defined by an internal representation learned by the neural network during training) is reached, the network produces an output vector indicative of an attack.

The neural network learned to recognize traces that fit the above pattern as an attack by training on actual SYN flood attacks. What happens, then, if one gets a trace that exhibits the following characteristics?

- The same destination addresses
- A destination port of 135/TCP (NetBIOS)
- Varying source address and ports
- The same TCP flags enabled, specifically TCP-SYN

Although the source address and port vary, the neural network is still capable of recognizing this attack as a SYN flood attack. Keep in mind that the system was never explicitly trained on this scenario.

A vector cross-product operation is used to compute node activation functions within the neural network. If the third feature of the original trace is removed, the corresponding element of the input vector would be 0, reducing the result of the cross-product operation. This reduction is proportional to the significance of that feature in the overall description of a SYN flood attack. Because this third feature is not the most prevalent characteristic of the attack, the reduction is relatively small. If all other aspects of the trace remain the same, this reduction may be enough to cause the network to miss the attack.

However, as more packets are received, the packet count will rise, causing an increase in that element of the input vector. This increases the result of the cross-product operation. This increase is proportional to the prevalence of "packet count" as a SYN flood feature. Because this feature is quite significant in the description of a SYN flood, the increase is relatively large, enough to compensate for the reduction caused by the removal of the other feature. This causes the activation function to increase beyond the threshold for alarming an attack.

Now consider another packet, only slightly modified from the original SYN flood example (see Exhibit 132.7). This is a SYN packet, the first packet of an HTTP connection to server. Again, suppose that eight or nine of these packets were seen within one or two seconds of one another, and these packets have:

- The same destination addresses
- A destination port of 80 (HTTP)
- The same source address, with an incrementing source port
- Incrementing sequence and ACK numbers
- The same TCP flags enabled, specifically TCP-SYN

Just as in the previous example, the SOM recognizes that these packets are related to one another and clusters them together into a trace. However, as this trace is presented to the network, it is not flagged as an attack —

EXHIBIT 132.7 SYN Packet

Field	Value
Timestamp	09:30:29.4527
Source Address/Port	attacker: 320
Destination Address/Port	server:80/TCP (HTTP)
Flags	S (TCP-SYN)
Sequence Number	1094689872
ACK Number	1094689872

even as it begins to resemble a SYN flood pattern. The difference between this example and the previous example is the destination port/service. Due to the nature of HTTP, it is normal to see a large number of SYN packets in a sequence such as this. Assuming one has provided the network with HTTP connections as samples of authorized (i.e., nonattack) traffic during the learning process, the network will recognize this distinction and refrain from alarming this activity as a SYN flood. Under the hood of the neural network, this exception to the general SYN flood pattern is represented as a large negative weight from the input node corresponding to a destination port of 80/TCP (or another service likely to trigger false-positive SYN flood alarms, such as 25/TCP or 443/TCP). When that input node is active, this connection strongly inhibits all of the other input features that contribute to a SYN flood activation within the network. Thus, the destination port allows the network to recognize this exception to the general SYN flood pattern.

Extensions to the Concept

This conceptual model can be extended in many ways. A few possibilities are examined here.

It is likely that the system could be extended to deliver not just a ruling on whether the trace is an attack, but also some indication of what kind of attack it appears to be. One of the drawbacks to this approach is that one must provide a great deal of additional information in the training data. This eliminates one of the very advantages of this approach, which was the fact that very little information about the attack training data needed to be provided to the network.

Another extension involves application of a continuous learning model. Rather than freezing the learning process after the network's initial learning period, continuous learning allows the network to periodically adjust its knowledge representation based on its real-world experiences. The goal behind this approach is to allow the system to adapt and learn along with changes in its environment.

One of the challenges with the SOM architecture is that an incoming packet must be assigned to a cluster so that it can be evaluated along with a trace. However, if the SOM misclassifies an incoming packet, one's ability to detect an intrusion may be reduced. Although a network packet may only belong to a single trace, it may fit into several traces until more information is received. An extension of the SOM allows the map to place copies of a given packet into multiple clusters. By doing so, one gives the SOM the opportunity to try to fit a packet into several traces to determine which is a best fit. This introduces a level of fault tolerance into the trace construction scheme.

Challenges and Limitations

In discussing the construction of this conceptual system, the advantages it affords in the intrusion detection game were mentioned. This approach, however, is not without its weaknesses.

Corrupted Learning

Neural networks suffer from tremendous exposure during their learning period. As the network learns to distinguish attacks from authorized behavior, the attacker has an opportunity to create a backdoor of sorts through the neural network. Recall that the network is trained on both attacks and authorized activity. If one does not specifically flag activity as an attack, the system will develop some internal knowledge structure that

allows it to recognize that activity as authorized. The HTTP exception to the SYN flood rule is a good example. The network learns that "if I see certain characteristics in a trace, it is an attack, unless it is destined for port 80/TCP, then it is not an attack." The network learned this exception because authorized HTTP connections were interleaved with the training data. If an attacker were able to surreptitiously insert SYN flood attacks from his network into our training data, the network might learn another exception. This time, the network might learn that "if I see certain characteristics in a trace, it is an attack, unless it is coming from attacker.net." By corrupting the training data, the attacker is able to teach the neural network to allow his attacks to pass, effectively evading the intrusion detection system.

Consider the following, more philosophical problem. Because one derives inspiration from the human mind, the possibility exists that one might introduce the limitations of that model into one's own system. For example, humans can become desensitized over time to certain types of sensory input. People constantly update their knowledge of the world around them. If introduced to small variations on a concept, people update that knowledge to reflect those changes. The cumulative effect of these small variations, when taken over a long period of time, can be dramatic. Cultural desensitization to violence on television is a good example of this. Continuous learning models can cause a gradual shift in the knowledge of a neural network over time. With well-crafted activities, an attacker could contribute to such a shift in knowledge within this conceptual system, effectively desensitizing the network to certain attacks. Over time, the attacker could use this technique to bore a hole through the system. This is similar to a prisoner digging a tunnel out of prison with a spoon.

The Science of Neural Networks

There are several challenges inherent in continuous learning models in a neural network. Continuous learning networks have been known to learn explicit mappings from certain inputs to their corresponding outputs. This is effectively memorization, and eliminates the power of generalization. One way to prevent this from happening is to cease learning once a certain performance level is reached. Another way to avoid this phenomenon is to introduce enough noise into the system to prevent memorization, but not so much as to confuse the network. Finally, one can reduce the number of hidden processing elements capable of storing complex features. This will result in a computational bottleneck that forces the network to learn more compact internal representations of complex features, preventing it from creating an explicit map of every input/output combination. That is, one wants the neural network to be good, but not too good.

There are several challenges inherent in the mathematics of neural network learning. Complex neural networks are often criticized for their slow learning speed. The size of the training space must be several orders of magnitude larger than the size of the network (for fans of complexity theory, the relationship is superlinear). This requires one to present a robust network with an extremely large number of training samples. Because the learning process is iterative by definition, learning can be painfully slow. Researchers have introduced techniques for acceleration that allow the algorithm to proceed naturally for several iterations to settle in on a good learning direction, and then advance progress rapidly in that direction. This has resulted in measurable improvements in neural network learning speeds, but it is still a slow process.

Furthermore, the learning algorithm may settle into a direction that drives the error function to one of several local minima, but not the global minimum. This results in an inaccurate pattern matcher, but it is not intuitive to determine when this has happened. This rarely happens in practice, due in part to the high degree of freedom provided by the high-dimensioned weight space present in most robust networks. However, this is a real problem of which one must be aware.

Practicality

It is not yet clear how well proof-of-concept prototypes will extend from the laboratory to commercial products. Many critics of the practicality of AI in the real world argue that, even if these systems did work, it would require a full-time staff of computer scientists just to keep the system running. Scientific research in this area has made many advances in the past decade, and many of these advances are beginning to find their way into commercial systems. Whether or not AI-based intrusion detection becomes a mainstream technology remains to be seen. The science shows tremendous promise, however; and it may not be wise to dismiss it as impractical just yet. Nevertheless, artificial intelligence is not a panacea, and one must avoid creating a false sense of security stemming from such improvements in technology.

Closing Remarks

As a community of practice, the human collective experience has repeatedly demonstrated that security is a difficult problem. Security problems are rarely black and white; there is almost always a broad spectrum of gray in between. Humans are quite capable of operating within these shades of gray, but computers are deterministic beasts and not readily equipped to do so. The main goal of artificial intelligence work is to enable machines to better solve subjective problems that are currently better suited for humans.

Intrusion detection is one such task. Traditional approaches to intrusion detection are based on the digital computing paradigm. They take advantage of the computer's specialty: executing objective operations with speed and accuracy. These approaches, however, have inherent limitations. Intrusion detection is a fuzzy, subjective task. It is difficult — if not impossible — to fully define that which constitutes an intrusion using the digital computer paradigm.

This chapter has explored an approach to intrusion detection based on the paradigm of the human brain; specifically, a data discovery technique known as a self-organizing map (SOM). A SOM correlates packets in the input space into meaningful traces that one can analyze for intrusions. A neural network pattern matcher analyzes traces for the presence of intrusive activity. These two techniques combine in a conceptual system that approaches intrusion detection in a manner inspired by human thought.

The conceptual system explored in this chapter shows evidence of improved false-negative and false-positive error rates, as observed through the SYN flood example. Systems based on the human brain paradigm show promise as pattern matching intrusion detectors. Perhaps, with continued research in AI, one will see intelligent intrusion analysis systems move from the laboratory into the mainstream.

How to Trap the Network Intruder

Jeff Flynn

The job of securing networks is quite difficult. Probably the most significant reason is system complexity. Networks are complicated. They are so complicated no one person can fully comprehend exactly how they work. The models that govern the designs were developed with this concept in mind and provide a layered view of networks that hide the true complexity. This makes it possible for programmers to work on various layers without understanding all the details of the other layers. Of course, programmers on occasion make mistakes, and these mistakes accumulate. Consequently, the Internet we have come to rely on is vulnerable to a wide variety of attacks. Some of the vulnerabilities are well known. Others are known only to a few or are yet to be discovered.

As the Internet grows, so too does the complexity. The growth of the Internet is still accelerating. Every year, more systems are connected to it than were connected the year before. These systems contain increasing amounts of memory. Larger memories allow programmers to develop larger and more complex programs, which provides the programmers with more opportunities to make mistakes. Larger programs also provide intruders with more places to hide malicious code.

Thus, a good network security manager must be very good indeed. The best network security managers may find themselves performing against the unrealistic expectation that they cannot be overwhelmed. These experts must keep up with all the latest attacks and countermeasures. Attackers, on the other hand, need to know only one or a small combination of attacks that will work against their opponents.

A common response to this situation is to simply fix the known problems. This involves closely monitoring reports from organizations such as

CERT or CIAC. As new vulnerabilities are discovered, the system manager responds appropriately. Unfortunately, the list of problems is also growing at an increasing rate. This can be a frustrating experience for the system manager who is forced to fight a losing battle. Likewise, financial managers are caught. They recognize that there are significant risks, yet no investment in safeguards can guarantee immunity from disaster.

It is hard to assess the extent to which tools have improved the situation. The Internet is a highly dynamic environment and does not provide good control samples for making such observations. The common-sense view might be, "However bad it is, it would be worse if we didn't have these devices." Unfortunately, the tools are not always applied properly and can lull management into thinking the situation is under control when it is not. In this situation, there is no benefit. The impact on the intruders is also quite difficult to assess. Serious intruders go to great lengths to keep their identities and approaches secret. Assessing the threat is, hence, a difficult aspect of evaluating the effectiveness of tools.

ASSESSING THE THREAT

There are many ways to gain a perspective on the threat. Most professionals in the field of network security use more than one. Some ways are more subjective than others. Yet there are several popular choices.

Reading

Several written information sources are available on the subject of network security. These include books, technical articles, newspaper articles, trade journal articles, newsgroups, and mailing lists. Each of these mediums has its strengths. Each also has its weaknesses. Trade journal articles, for example, can be biased and may attempt to use fear, uncertainty, and doubt to motivate buyers. Newspaper articles, although less biased, are driven by readership and limited in technical detail. Technical articles are many times too technical, sometimes describing threats that were not threats before publication. The information found in books is quickly dated. Finally, newsgroups and mailing lists, while providing timely information, are transmitted via networks that are subject to the same attacks we are attempting to prevent.

Experimentation

One way to see how difficult it is for someone to break into your system is to attempt to break into it yourself. The Self-Hack Audit, sometimes called Penetration Testing, is a useful means for finding weaknesses and is likely to improve awareness. Similarly, information warfare games provide true insight into how sophisticated intrusions can occur. Still, both of these methods are contrived and do not necessarily represent the actual threat.

Surveys

The 1997 CSI/FBI Computer Crime and Security Survey summarizes the anonymous responses of security professionals from a wide variety of industry segments. Respondents were asked, "If your organization has experienced computer intrusion(s) within the last 12 months, which of the following actions did you take?" Only 29.3% answered that they reported the incident to law enforcement or their own legal counsel. The remainder answered that they did not report the intrusion, or they did their best to "patch security holes." In fact, although 4,899 questionnaires were distributed, only 563 (11.5%) were returned. Of these security professionals, 99 acknowledged detecting "system penetrations," 101 acknowledged detecting "theft of proprietary information," 407 acknowledged detecting viruses, and 338 acknowledged detecting "insider abuse of net access." Security surveys produce statistics that provide managers with useful information for making decisions. Still, many computer incidents go undetected or unreported. This prevents surveys from being as valuable as they would be otherwise.

Firsthand Experience

Human nature seems to dictate that this is the path that most will follow. Firsthand experience occurs, for example, when a person buys a better lock after he detects a burglary. Firsthand experience involves a real threat, but the response comes after the fact. If the initial attack is sufficiently hostile, a response may be of limited use.

There is also a good chance the initial intrusion may go undetected. Network intruders are quite adept at installing back doors. The process is quite simple and may be the first act taken by an attacker after a successful intrusion. Consequently, it is far more difficult to restore security after a network intrusion than it is to prevent an intrusion. Before an individual decides to make firsthand experience his primary approach, he should ask himself, "Is this the kind of experience I want to have?" If the answer is, "I'm willing to take that risk," he should ask himself, "Is it morally responsible for me to make that decision on behalf of all those who may be affected?" What happens on networks can often affect more than the keepers of a network. A 911 emergency system in Florida that was taken down by network intruders provides a compelling example of this fact.

Measuring

Another option for network security managers is to measure the threat. This is critical, because one certainly cannot well manage what one cannot measure. This chapter has two purposes. The first is to suggest that the use of traps can be an effective way to gain a realistic assessment of the threat without exposing individuals and organizations to unreasonable risks. The second is to identify some of the qualities of a "good" trap.

THE BENEFIT OF TRAPS

Traps are attractive for three reasons. First, traps provide real-world information. If designed properly, the activation of the trap is highly correlated to real intrusions. This is not a contrived threat. The intruders detected are real, and they are targeting a particular organization. Second, well-designed traps can provide these measurements safely. Finally, traps can be used to deter future attacks. The trap response to a triggering event is part of the trap design. This goes beyond what intrusion detection systems provide, which may be considered components of traps. There are only three components to a trap: the bait, the trigger, and the snare.

THE QUALITIES OF A "GOOD" TRAP

It is obvious that a good trap is one that actually catches its prey. Good traps share other qualities too.

A Good Trap is Hidden

A hunter would not expect to catch his quarry if he simply left his trap lying on the ground. Animals are too smart or sensitive for this to work. The hunter must hide the trap, perhaps under a pile of leaves. Similarly, hacker traps should be invisible to the network intruder. Of course, one does not need to hide the bait portion of the trap. One only needs to ensure that characteristics of the bait do not betray the presence of the trap. There are many ways to make traps hard to detect. Devices such as in-circuit emulators, SCSI analyzers, and network protocol analyzers can monitor activities without affecting the behavior of the systems being monitored. Alternatively, log information can be transmitted via one-way connections to systems performing real-time intrusion detection functions. In tracking the activities of German hackers, Cliff Stoll transparently monitored modem ports with dramatic results.

A Good Trap Has Attractive Bait

If a trap is to be effective at luring its prey, it must have attractive bait. The trapper has several options in this area, and great care should be used in the selection. Just as a fly fisherman attempts to "match the hatch," the trapper must select a lure that is appropriate for the environment. In some cases, the bait might be a file or directory entitled "ops_planning." In other cases, it might be a file containing the words "security" or "intrusion detection." A continuous indecipherable sequence of bytes transmitted between two hosts may be sufficient. When selecting the bait, the network security manager should consider the possible goals of the intruder. The goals may have much to do with the business of the targeted organization, although this is not necessarily so. If previous intrusions were detected, the network manager might

determine what sort of things the intruder found interesting. Again, care should be taken to prevent the bait from betraying the trap. If it looks too good to be true, the intruder may decide to look elsewhere and thus avoid detection.

A Good Trap Has an Accurate Trigger

A good trap should trap intruders. It should not trap innocent souls who stumble across it in the course of their normal duties. Consequently, the trigger should be designed so that the probability of a false detection is very low. This is extremely important. The loss of trust and the dissension caused by false suspicions or accusations can be considerable. These events can quite possibly cause more damage to an organization than an actual intruder. Of course, real intrusions can result in serious damage too. Hence, if an actual intruder goes for the bait, the probability of detection should be very close to 100 percent. Trap placement can be a useful means to improve the selectivity of a trigger. If the trigger is positioned in a place where no one should legitimately be, false detections can be greatly reduced. Ideally, a trap should be designed so that the intruder has violated a law before he can activate the trigger.

A Good Trap Has a Strong Snare

If a hunter's trap does not have a strong snare, the quarry may simply destroy the device. Animal traps are effective because they are strong enough to hang onto the animal. Similarly, an effective intruder trap should hang onto the intruder. Admittedly, this is one of the most difficult aspects of designing an effective trap.

The identity of an intruder can be known, and the victim organization can have arrest powers. But if the location of the intruder is outside the jurisdiction of that organization, an arrest may not be practical. Currently, the best intruder traps are those that preserve evidence, involve law enforcement, and, in certain circumstances, attempt to bring the intruder into a jurisdiction where action can be taken.

Complicating matters is the hacker modus operandi of weaving (sometimes referred to as looping or hopping) through the Internet. During this process, the hacker may impersonate one or more individuals, systems, or processes. Thus, the path back to the intruder's lair can take many twists and turns. In some cases, the process of following this path might require penetration of a third-party organization's network. Although this is beyond what most would attempt, it is possible that such action could be deemed legal if done with the proper authority.

By way of analogy, one might compare the situation to that of a police officer in "hot pursuit" or acting under "exigent circumstances." If an

officer is in immediate pursuit of a criminal, and that criminal enters a residence, the officer does not wait for someone to grant him access. The officer does not wait for a warrant. He follows the criminal into the residence, breaking the lock on his way if necessary. If that criminal weaves in and out of one property after another, so too will the officer. This process continues until the criminal is apprehended, the criminal is lost, or the pursuit crosses a jurisdictional boundary. In the case of a jurisdictional border crossing, the officer might continue the pursuit, or he could pass the responsibility to another organization according to preexisting agreements between the various parties involved. Unfortunately, the present situation in the Internet is not so well organized. Perhaps, in time, as more laws and law enforcement personnel find their way into the Internet, the situation will improve.

Good Traps Are Used in Combination

To maximize the effectiveness of a trap, the trapper simply needs to add more traps. Just as a good fisherman keeps more than one line in the water, and perhaps more than one lure per line, the trapper should have more than one trap set. A good rule of thumb might be to count the number of targets an organization presents to a would-be intruder. The number of traps that are set should exceed that number. If the traps set are "good," it is more likely that an intruder will be detected than it is a target will be compromised. The approach scales nicely, allowing the trapping organization to select a security stance appropriate for its particular situation.

Good Traps Are Original

Once an intruder becomes aware of a particular type of trap, it is less likely that he can be fooled again in the same way. Hence, good traps should be unique. This is particularly true for the visible bait component of the trap. Other trap components should also be unique. If an intruder suspects a trap, he might try to trigger it from a safe circumstance. Likewise, he may know how to escape from a snare he encountered previously. The less an intruder can surmise about a trap, the better the trap. Originality in design then becomes the hallmark of a good trap. This fact should be viewed as good news for the network security administrator whose job has become an endless loop of applying patches. By developing traps, the network security administrator can have many opportunities to be creative.

Good Traps Do Not Entrap

Trapping and entrapping are two separate things. The difference is in the relation between the trap and the intruder. If the trap somehow induces someone to commit a crime, entrapment occurs, which adversely effects the strength of the trap's snare. Entrapment can prevent prosecution in

many legal systems, which is an important component of an effective snare. Entrapment is also counterproductive. One of the goals of trapping is to deter intruders. Entrapment techniques produce the opposite result by encouraging intrusions. To keep a trap from becoming an entrapping device, the trapper should make the bait invisible to those who have not yet committed a crime. It should be obvious to the intruder and the trapper that a crime has been committed before the bait has the effect of drawing the intruder to the trigger. Notifications and banners should be used to make this point clear. These should indicate the boundaries of legality. Good caveats should include words to the effect that intrusion is not invited or welcome, various laws will be broken by those who proceed without authorization, use of the system implies acknowledgment of this, and use of the system implies consent to monitoring. The name of the organization being protected is not necessary, but a number to contact for clarification should be provided.

When complete, a trap should resemble the situation encountered with silent burglar alarms found in banks. These are traps too. Banks contain such traps, and there is usually no question as to whether entrapment was involved.

PSYCHOLOGY AT WORK

As mentioned previously, one of the benefits of a trap is that it deters. When a hacker realizes that he is in a situation where he is as likely to encounter a trap as he is to obtain his objective, he is likely to slow his pace. When his partners in crime are trapped (i.e., prosecuted), he may consider abandoning the craft. Few things deter more than well-designed traps. Consider the psychological impact on soldiers knowing they are about to cross a minefield. How much slower do they proceed? How much more effective is this deterrent after a mine is detonated?

AN EXAMPLE TRAP

Once network security administrators are aware of the benefits and attributes of good traps, they should consider a working example. Imagine a host set up behind the perimeter of a networked organization. This system is on a network that is protected by banners and other methods (perhaps a firewall). On the host is a file that contains a short list of phone numbers with corresponding passwords. The passwords are long random sequences of alphanumeric characters. These phone numbers and passwords are the bait. To the intruder, they represent additional access. The trigger is a computer (with software) connected to one of these phone numbers. When an intruder attempts to access the trigger with the correct password, the trigger is activated. The probability that the trap was activated by an actual intruder is quite high. The probability that the trap can

be triggered by someone who did not break the rules is quite low. The telephone line is configured with caller ID (CNID) or automatic number identification, so that once triggered, the source of the call can be determined. This information can be used to draft an affidavit that might allow law enforcement to search the premises for the source of the attack. If the intruder was foolish enough to use his own line to make the call, there may be an opportunity for an arrest. If the intruder is not so foolish, at least the designer of the trap is aware that his barrier was penetrated. He does not need to know how it happened for this to be useful information. The mere fact that the intrusion occurred can be enough to justify investigation and additional investment in protective measures. It should be noted that intruders have circumvented CNID systems.

As an alternative to the snare just described, network security administrators could also imagine a trap that might physically capture an intruder, or someone acting on his behalf. By replacing the password bait with an electronic lock combination, a map, and a street address, one might be able to lure an intruder into a holding area disguised as a wiring closet. The use of the correct combination would notify authorities of the intrusion and allow entry. Once inside, the door would lock again and not allow exit. Great care would be required in the planning of such a trap to avoid physical risk to the intruder. Significant liability would result if harm were to come to the prisoner. It would not be reasonable to leave an intruder locked in a closet any significant length of time. Only when the safety of the prisoner can be guaranteed should such a trap be considered. Still, ideas like this may be attractive. In the event an intruder were to fall for this trap, the authorities would not only have a suspect; they would have probable cause for an arrest.

CONCLUSION

The network intruder can be quite clever and may attempt attacks that have not been previously encountered. Techniques are needed for detecting and deterring such intrusions. Although the use of traps will not necessarily free a network security administrator from the burden of simply patching one hole after another, it may help him to focus his efforts in the areas that are most important. It may also give him the well-needed opportunity to be creative. Perhaps the time has come for the network security manager to become more clever than the network intruder.

Intrusion Detection: How to Utilize a Still Immature Technology

E. Eugene Schultz and Eugene Spafford

Defending one's systems and networks is an arduous task indeed. The explosive growth of the Internet combined with the ever-expanding nature of networks makes simply keeping track of change nearly an overwhelming challenge. Add the task of implementing proper security-related controls and the problem becomes of far greater magnitude than even the most visionary experts could have predicted 20 years ago. Although victories here and there in the war against cybercriminals occur, reality echoes the irrefutable truth that "cyberspace" is simply too big a territory to adequately defend. Worse yet, security-related controls that work today will probably fail tomorrow as the perpetrator community develops new ways to defeat these controls. Also, the continuing rush to market software with more new features is resulting in poorly designed and poorly tested software being deployed in critical situations. Thus, the usual installation is based on poorly designed, buggy software that is being used in ways unanticipated by the original designers and that is under continuing attack from all over.

Schultz and Wack (SCHU96) have argued that InfoSec professionals need to avoid relying on an approach that is overly reliant on security-related controls. Determining the controls that most effectively reduce risk from a cost-benefit perspective, then implementing and maintaining those controls is an essential part of the risk management process. Investing all of one's resources in controls is, however, not wise because this strategy does not leave resources for detecting and responding to the security-related incidents that invariably occur. The so-called "fortress mentality"

(implementing security barrier after security barrier but doing nothing else) in the InfoSec arena does not work any better than did castles in the United Kingdom when Oliver Cromwell's armies aimed their cannons at them. It is far better to employ a layered, defense-in-depth strategy that includes protection, monitoring, and response (cf. Garfinkel and Spafford [GARF96, GARF97]).

Merely accepting the viewpoint that it is important to achieve some degree of balance between deploying controls and responding to incidents that occur, unfortunately, does little to improve the effectiveness of an organization's InfoSec practice. An inherent danger in the incident response arena is the implicit assumption that if no incidents surface, all is well. Superficially this assumption seems logical. Studies by the U.S. Defense Information Systems Agency (DISA) in 1993 and again in 1997, however, provide statistics that prove it is badly flawed. Van Wyk (VANW94) found that of nearly 8800 intrusions into Department of Defense systems by a DISA tiger team, only about one in six was detected. Of the detected intrusions, approximately only 4 percent were reported to someone in the chain of command. This meant that of all successful attacks, less than 1 percent were both noticed and reported. A similar study by the same agency 3 years later produced nearly identical results.

One could argue that perhaps many Department of Defense personnel do not have as high a level of technical knowledge as their counterparts in industry because industry (with its traditionally higher salaries) can attract top technical personnel who might more readily be able to more readily recognize the symptoms of attacks. In industry, therefore, according to this line of reasoning, it would be much more likely that some technical "guru" would notice intrusions that occurred. This reasoning is at best only partially true, however, in that in the DISA studies little attempt was made to cover up the intrusions in the first place. In what might be called "more typical" intrusions, in contrast, attackers typically devote a large proportion of their efforts to masquerade the activity they have initiated to avoid being noticed. This is further supported by the latest CSI/FBI survey (POWER99) that indicated that many firms are unable to determine the number or nature of intrusions and losses to their enterprise from IT system attacks, but that losses and number of incidents are continuing to increase.

The main point here is that effective incident response is important and necessary, but it hardly does any good if people do not notice incidents that occur in the first place. Human efforts to notice incidents, as good as they may be, are in many if not most operational settings inadequate. InfoSec professionals often need something more, an automated capability that enables them to be able to discover incidents that are attempted or actually succeed. The solution is intrusion detection. This chapter covers

the topic of intrusion detection, discussing what it is, the types of requirements that apply to intrusion detection systems, and ways that intrusion detection systems can be deployed.

ABOUT INTRUSION DETECTION

What is Intrusion Detection?

Intrusion detection refers to the process of discovering unauthorized use of computers and networks through the use of software designed for this purpose. Intrusion detection software in effect serves a vigilance function. An effective intrusion detection system both discovers and reports unauthorized activity, such as log-on attempts by someone who is not the legitimate user or an account and unauthorized transfer of files to another system. Intrusion detection may also serve a role of helping to document the (attempt at) misuse so as to provide data for strengthening defenses, or for investigation and prosecution after the fact.

Intrusion detection is misnamed. As a field, it started as a form of misuse detection for mainframe systems. The original idea behind automated intrusion detection systems is often credited to James P. Anderson for his 1980 paper on how to use accounting audit files to detect inappropriate use. Over time, systems have become more connected via networks; attention has shifted to penetration of systems by "outsiders," thus including detection of "intrusion" as a goal. Throughout our discussion, we will use the common meaning of "intrusion detection" to include detection of both outsider misuse and insider misuse; users of ID systems should likewise keep in mind that insider misuse must be detected, too.

Why Utilize Intrusion Detection?

One possible approach to intrusion detection would be to deploy thousands of specially trained personnel to continuously monitor systems and networks. This approach would in almost every setting be impossible to implement because it would be impractical. Few organizations would be willing to invest the necessary level of resources and time required to train each "monitor" to obtain the needed technical expertise. Running one or more automated programs, designed effectively to do the same thing but without the involvement of thousands of people, is a more logical approach, provided of course that the program yields acceptable results in detecting unauthorized activity. Additionally, although many people with high levels of technical expertise could be deployed in such a monitoring role, it may not be desirable to do so from another perspective. Even the most elite among the experts might miss certain types of unauthorized actions given the typically gargantuan volume of activity that occurs within

today's systems and networks. A suitable intrusion detection program could thus uncover activity that experts miss.

Detection *per se* is not the only purpose of intrusion detection. Another very important reason to use IDSs is that they often provide a reporting capability. Again, the worst-case scenario would be relying on a substantial number of human beings to gather intrusion data when each person uses a different format to record the data, in addition to using terms and descriptions ambiguous to everyone but that person. Trying to combine each observer's data and descriptions to derive patterns and trends would be virtually impossible; making sense out of any one observer's data would be very challenging. An effective intrusion detection system provides a reporting capability that not only produces human-friendly information displays but also interfaces with a central database or other capability that allows efficient storage, retrieval, and analysis of data.

How IDSs Work

IDSs work in a large variety of ways related to the type of data they capture as well as the types of analysis they perform. At the most elementary level, a program that runs on one or more machines receives audit log data from that machine. The program combs through each entry in the audit logs for signs of unauthorized activity. This type of program is part of a host or system-based IDS. At the other extreme, an IDS may be distributed in nature (MUKH94). Software (normally referred to as agent software) resides in one or more systems connected to a network. Manager software in one particular server receives data from the agents it knows about and analyzes the data (CROS95). This second approach characterizes a network-based IDS (see Exhibit 31.1).

Note that if the data that each agent sends to the manager has not been tampered with, the level of analysis possible is more powerful than with host or system-based IDSs for several reasons:

1. Although a host-based IDS may not depend upon audit data (if it has its own data-capturing service independent of auditing), audit and other types of data produced within single systems are subject to tampering and/or deletion. An attacker who disables auditing and/or an intrusion data collection service on a given machine effectively disables the IDS that runs on that machine. This is not true, however, in the case of a network-based IDS, which can gather data from individual machines and from passive devices (e.g., protocol analyzers) and other, more difficult-to-defeat machines such as firewalls. In other words, network-based IDSs are not as dependent on data from individual systems.

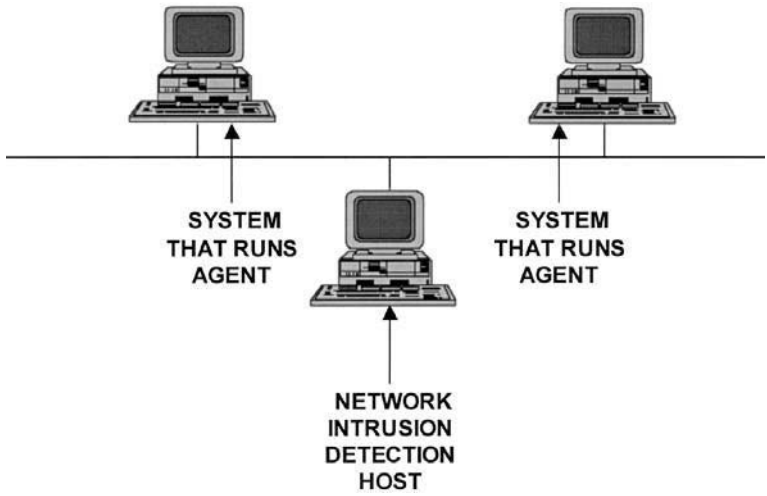

Exhibit 31.1. A Deployment of an IDS in Which Agent Software Running on Hosts Sends Data to a Central Network Intrusion Detection Capability for Analysis

2. Network-based IDSs, furthermore, can utilize data that are not available in system-based IDSs (HERR97). Consider, for example, an attacker who logs on to one system as user "BROWN," then logs on to another system on the same network as "SMITH." The manager software can assign a net ID to each user, thus enabling it to know that the user who has a log-on shell in both systems is the same user. This IDS can then generate an alarm based on the fact that the user in this example has logged on to different accounts with different names. This level of analysis is not possible if an IDS does not have data from multiple machines on the net.

A third form of ID system, currently quite popular, involves one or more systems that observe network traffic (usually at a border location such as near a firewall) and scan for packet traffic that indicates misbehavior. These "network intrusion detection systems" are easy to deploy to protect an enterprise from attack from the outside, but they have the drawback of missing internal behavior that may also be of interest.

APPROACHES TO INTRUSION DETECTION

Not only do different implementations of IDSs work using fundamentally different kinds of data and analysis methods, but they also differ in the types of approaches to intrusion detection that have been incorporated into their design. The correct question here is not "do you want to deploy

an intrusion detection system (IDS)," but rather "which type of IDS do you want to deploy?" The following are the major types of IDSs:

Anomaly Detection Systems

Anomaly Detection Systems are designed to discover anomalous behavior, i.e., behavior that is unexpected and abnormal. At the most elementary level, anomaly detection systems look for use of a computer system during a time of the day or night in which the legitimate user hardly ever uses the computer. Statistical profiles indicating percentiles of measurable behavior and what falls within one standard deviation of the norm, two standard deviations, and so forth are often the basis for determining whether or not a given user action is anomalous. At a more sophisticated level, one might profile variables and processes such as types of usage by each specific user. One user, for example, might access a server mostly to read e-mail; another may balance usage time between e-mail and using spreadsheet-based applications; and a third might mostly write and compile programs. If the first user suddenly starts compiling programs, an anomaly detection system should flag this type of activity as suspicious.

Misuse Detection Systems

The main focus of misuse detection systems is upon symptoms of misuse by authorized users. These symptoms include unauthorized log-ons or bad log-on attempts to systems in addition to abuse of services (e.g., Web-based services, file system mounts, and so on) in which users do not need to authenticate themselves. In the latter case, therefore, good misuse detection systems will identify specific patterns (called "signatures") of anomalous actions. If an anonymous FTP user, for example, repeatedly enters cd .., cd .., cd .. from a command line, there is a good chance that the user is attempting a "dotdot" attack to reach a higher-level directory than FTP access is supposed to allow. It is very unlikely that a legitimate user would repeatedly enter these keystrokes.

Target Monitoring Systems

Target monitoring systems represent a somewhat radical departure from the previously discussed systems in that they do not attempt to discover anomalies or misuse. Instead they report whether certain target objects have been changed; if so, an attack may have occurred. In UNIX systems, for example, attackers often change the /sbin/login program (to cause a pseudo-login to occur in which the password of a user attempting to login is captured and stored in a hidden file) or the /etc/passwd file (which holds names of users, privilege levels, and so on). In Windows NT systems someone may change .DLL (dynamically linked library) files to alter system behavior. Most target monitoring systems use a cryptographic

algorithm to compute a cryptochecksum for each target file. Then if the cryptochecksum is calculated later in time and the new cryptochecksum is different from the previous one, the IDS will report the change. Although this type of IDS superficially does not seem as sophisticated as the previous ones, it has several advantages over anomaly and misuse detection systems:

1. When intruders break into systems, they frequently make changes (sometimes accidentally, sometimes on purpose). Therefore, changed files, executables that are replaced with Trojan Horse versions, and so forth are excellent potential indications that an attack has occurred.
2. Target monitoring systems are not based on statistical norms, signatures, and other indicators that may or may not be valid. These systems are, therefore, not as model-dependent. They are simple and straightforward. Furthermore, they do not really need to be validated because the logic behind them is so obvious.
3. They do not have to be continuously run to be effective. All one has to do is run a target monitoring program at one point in time, then another. Target monitoring systems thus do not generally result in as much performance overhead as do other types of IDSs.

Systems that Perform Wide-Area Correlation of Slow and "Stealth" Probes

Not every attack that occurs is an all-out attack. A fairly typical attack pattern is one in which intruders first probe remote systems and network components such as routers for security-related vulnerabilities, then actually launch attacks later. If attackers were to launch a massive number of probes all at once, the likelihood of noticing the activity would increase dramatically. Many times, therefore, attackers probe one system, then another, then another at deliberately slow time intervals. The result is a substantial reduction in the probability that the probes will be noticed. A fourth type of IDS performs wide-area collection of slow and stealth probes to discover the type of attacks mentioned in this section.

MAJOR ADVANTAGES AND LIMITATION OF INTRUSION DETECTION TECHNOLOGY

Advantages

Intrusion detection is potentially one of the most powerful capabilities that an InfoSec practice can deploy. Much of attackers' ability to perpetrate computer crime and misuse depends on their ability to escape being noticed until it is too late. The implications of the DISA statistics cited earlier are potentially terrifying; in the light of these findings, it might be more

reasonable to ask how an InfoSec practice that claims to observe the principle of "due diligence" could avoid using an IDS enterprise-wide. We strongly assert that any InfoSec practice that does not utilize IDS technology at least to some degree is not practicing due diligence because it will necessarily overlook a large percentage of the incidents that occur. Any practice that remains unaware of incidents does not understand the real risk factor; sadly, it only mimics the behavior of an ostrich with its head in the sand. Simply put, an effective IDS can greatly improve the capability to discover and report security-related incidents.

We also note that the complexity of configuration of most systems and the poor quality of most commercial software effectively guarantees that new flaws will be discovered and widely reported that can be used against most computing environments. Patches and defenses are often not as quickly available as attack tools, and defenses based on monitoring and response are the only way to mitigate such dangers. A failure to use such mechanisms is a failure to adequately provide comprehensive security controls.

In addition to increasing an organization's capability to notice and respond to incidents, intrusion detection systems offer several other major benefits. These include:

1. Cost reduction. Automated capabilities over time generally cost less than humans performing the same function. Once an organization has paid the cost of purchasing and installing one or more IDSs, the cost of an intrusion detection capability can be quite reasonable.
2. Increased detection capability. As mentioned earlier, an effective IDS is able to perform more sophisticated analysis (e.g., by correlating data from a wide range of sources) than are humans. The epitome of the problem of reading and interpreting data through human inspection is reading systems' audit logs. These logs typically produce a volume of data that system administrators seldom have time to inspect, at least in any detail. Remember, too, that attackers often have the initial goal of disabling auditing once they compromise a system's defenses. IDSs do not necessarily rely on audit logs.
3. Deterrent value. Attackers who know intrusion detection capabilities are in place are often more reluctant to continue unauthorized computer-related activity. IDSs thus serve to deter unauthorized activity to some degree.
4. Reporting. An effective IDS incorporates a reporting capability that utilizes standard, easy-to-read and understand formats and database management capabilities.

5. Forensics. A few IDSs incorporate forensics capabilities. Forensics involves the proper handling of evidence that may be used in court. A major goal of forensics is to collect and preserve evidence about computer crime and misuse that will be admissible in a court of law.
6. Failure detection and recovery. Many failures exhibit features similar to misuse or intrusion. Deployment of good IDSs may result in advance notice of these symptoms before they result in full failures. Furthermore, some IDSs can provide audit data about changes, thus allowing failed components to be restored or verified more quickly.

Disadvantages

Intrusion detection is also beset with numerous limitations. Some of the most critical of these drawbacks include:

1. Immaturity. Most (but not all) IDSs available today have significant limitations regarding the quality of functionality they provide. Some are little more than prototypes with a sophisticated user interface. Others purport to compare signatures from a signature library to events that occur in systems and/or networks, but the vendors or developers refuse to allow potential customers to learn how complete and how relevant these libraries are. Equally troubling is the fact that new types of attacks occur all the time; unless someone updates the signature library, detection efficiency will fall. Still other IDSs rely on statistical indicators such as "normal usage patterns" for each user. A clever perpetrator can, however, patiently and continuously engage in activity that does not fall out of the normal range but comes close to doing so. The perpetrator thus can adjust the statistical criteria over time. Someone who normally uses a system between 8 a.m. and 8 p.m. may want to attack the system at midnight. If the perpetrator were to simply attack the system at midnight, alarms might go off because the IDS may not consider midnight usage within the normal range for that user. But if the perpetrator keeps using the system from, say, 11 a.m. to 11 p.m. every day for one week, usage at midnight might no longer be considered statistically deviant.
2. False positives. Another serious limitation of today's IDSs is false positives (Type I errors). A false positive occurs when an IDS signals that an event constitutes a security breach, but that event in reality does not involve such a breach. An example is multiple, failed logins by users who have forgotten their passwords. Most IDS customers today are concerned about false alarms because they are often disruptive and because they sidetrack the people who investigate the false intrusions away from other, legitimately important tasks.

3. Performance decrements. Deploying IDSs results in system and/or network performance hits. The actual amount of decrement depends on the particular IDS; some are very disruptive to performance. Anomaly-based systems are often the most disruptive because of the complexity of matching required.
4. Initial cost. The initial cost of deploying IDSs can be prohibitive. When vendors of IDS products market their products, they often mention only the purchase cost. The cost to deploy these systems may require many hours of consultancy support, resulting in a much higher cost than originally anticipated.
5. Vulnerability to attack. IDSs themselves can be attacked to disable the capabilities they deliver. The most obvious case is when a trusted employee turns off every IDS, engages in a series of illegal actions, then turns every IDS on again. Any attacker can flood a system used by IDS capability with superfluous events to exceed the disk space allocated for the IDS data, thereby causing legitimate data to be overwritten, systems to crash, and a range of other, undesirable outcomes.
6. Applicability. IDSs are designed to uncover intrusions, unauthorized access to systems. Yet a large proportion of the attacks reported during the past year (at the time this chapter was written) were either probes (e.g., use of scanning programs to discover vulnerabilities in systems) or denial-of-service attacks. Suppose that an attacker wants to cause as many systems in an organization's network to crash as possible. Any IDSs in place may not be capable of discovering and reporting many denial-of-service attacks in the first place. Even if they are capable of doing so, knowing that "yes, there was a denial-of-service attack" hardly does any good if the attacked systems are already down! Additionally, many (if not most) of today's IDSs do a far better job of discovering externally initiated attacks than ones that originate from inside. This is unfortunate given that expected loss for insider attacks is far higher than for externally originated attacks.
7. Vulnerability to tampering. IDSs are vulnerable to tampering by unauthorized as well as authorized persons. Many ways to defeat IDSs are widely known within both the InfoSec and perpetrator communities. In a highly entertaining article, Cohen describes 50 of these ways (COHE97).
8. Changing technology. Depending on a particular technology may result in loss of protection as the overall computing infrastructure changes. For instance, network-based intrusion detection is often foiled by switch-based IP networks, ATM-like networks, VPNs, encryption, and alternate routing of messages. All of these technologies are becoming more widely deployed as time goes on.

The advantages and disadvantages of intrusion detection technology are summarized in Exhibit 31.2.

ADVANTAGES	DISADVANTAGES
Cost reduction (at least over time) resulting from automation	Many IDSs do not deliver the functionality that is needed
Increased efficiency in detecting incidents	Unacceptably high false alarm rates
Can deter unauthorized activity	Generally produce performance decrements
Built-in reporting, data management, and other functions	Initial cost may be prohibitive
	May yield superfluous data
Built-in forensics capabilities	IDSs themselves are vulnerable to attack

Exhibit 31.2. Summary of Advantages and Disadvantages of Intrusion Detection Technology

ASSESSING INTRUSION DETECTION REQUIREMENTS

The Relationship of Intrusion Detection to Risk

A large number of organizations go about the process of risk management by periodically performing risk assessments, determining the amount of resources available, then allocating resources according to some method of priority-based risk mitigation strategy, i.e., introducing one or more controls that counter the risk with the greatest potential for negative impact, then implementing one or more measures that address the risk with the second greatest negative impact, and so on until the resources are spent. Regardless of whether or not one agrees with this mode of operation, it tends to guarantee that intrusion detection will be overlooked. In simple terms, intrusion detection does not address any specific risk as directly as measures such as encryption and third-party authentication solutions.

Developing Business-Related Requirements

Developing specific, business-related requirements concerning intrusion detection is anything but an easy process. The difficulty of doing so is, in all likelihood, one of the major detractors in organizations' struggles in dealing with intrusion detection capabilities. Business units, furthermore, may be the most reluctant to utilize intrusion detection technology because of the typical level of resources (personnel and monetary) required and because this technology may superficially seem irrelevant to the needs of fast-paced business units in today's commercial environments.

On the other hand, obtaining buy-in from business units and developing business requirements for intrusion detection at the business unit level is probably not the primary goal anyway. In most organizations if intrusion

detection technology is to be infused successfully, it must be introduced as a central capability. Business requirements and the business rationale for intrusion detection technology are likely to be closely related to the requirements for an organization's audit function. The ultimate goal of intrusion detection technology in business terms is the need to independently evaluate the impact of system and network usage patterns in terms of the organization's financial interests. As such, it is often easiest to put intrusion detection technology in the hands of an organization's audit function.

Decision Criteria

Suppose that your organization decides to introduce intrusion detection technology. After you derive the business requirements that apply to your organization, the next logical step is to determine whether your organization will build a custom IDS or buy a commercial, off-the-shelf version. The latter is generally a much wiser strategy — building a custom IDS generally requires far more time and resources than you might ever imagine. Additionally, maintenance of custom-built IDSs is generally a stumbling block in terms of long-term operations and cost. The exception to the rule is deploying very simple intrusion detection technology. Setting up and deploying "honey pot" servers, for example, is one such strategy. Honey pot servers are alarm servers connected to a local network. Normally nobody uses a honey pot server, but this host is assigned an interesting but bogus name (e.g., patents.corp.com). If anyone logs in or even attempts to login, software in this type of server alerts the administrator, perhaps by having the administrator paged. The major function of honey pot servers is to indicate whether an unauthorized user is "loose on the net" so that one or more individuals can initiate suitable incident response measures. This strategy is not elegant in terms of the intrusion detection capability that it provides, but it is simple and very cost effective. Better yet, an older, reasonably low-ended platform (e.g., a Sparcstation 5) is generally more than sufficient for this type of deployment.

Buying a commercial IDS product is easier when one systematically evaluates the functionality and characteristics of each candidate product against meaningful criteria. We suggest that at a minimum you apply the following criteria:

1. Cost. This includes both short- and long-term costs. As mentioned previously, some products may appear to cost little because their purchase price is low, but life-cycle deployment costs may be intolerable.
2. Functionality. The difference between a system- versus network-based IDS is very important here. Many intrusion detection experts assert that system-based IDSs are better for detecting insider activity, whereas network-based IDSs are better for detecting externally

originated attacks. This consideration is, however, only a beginning point with respect to determining whether or not a product's functionality is suitable. The presence or absence of functions, such as reporting capabilities, data correlation from multiple systems, and near real-time alerting, is also important to consider.

3. Scalability. Each candidate tool should scale not only to business requirements but also to the environments in which it is to be deployed. In general, it is best to assume that whatever product one buys will have to scale upward in time, so obtaining a product that can scale not only to the current environment, but also to more complex environments is frequently a good idea.
4. Degree of automation. The more features of an IDS product that are automated, the less human intervention is necessary.
5. Accuracy. An IDS product should not only identify any *bona fide* intrusion that occurs but should also minimize the false alarm rate.
6. Interoperability. Effective IDSs can interoperate with each other to make data widely available to the various hosts that perform intrusion detection management and database management.
7. Ease of operation. An IDS that is easy to deploy and maintain is more desirable than one that is not.
8. Impact on ongoing operations. An effective IDS causes little disruption in the environment in which it exists.

DEVELOPING AN INTRUSION DETECTION ARCHITECTURE

After requirements are in place and the type of IDS to be used is selected, the next logical phase is to develop an architecture for intrusion detection. In the current context, the term "architecture" is defined as a high-level characterization of how different components within a security practice are organized and how they relate to each focus within that practice. Consider, for example, the components of an InfoSec practice shown in Exhibit 31.3.

To develop an intrusion detection architecture, one should start at the highest level, ensuring that the policies include the appropriate provisions for deploying, managing, and accessing intrusion detection technology. For example, some policy statement should include the provision that no employee or contractor shall access or alter any IDS that is deployed. Another policy statement should specify how much intrusion detection data are to be captured and how they must be archived. It is also important to ensure that an organization's InfoSec policy clearly states what constitutes "unauthorized activity" if the output of IDSs is to have any real meaning.

At the next level down, one might write specific standards appropriate to each type of IDS deployed. For IDSs with signature libraries, for example,

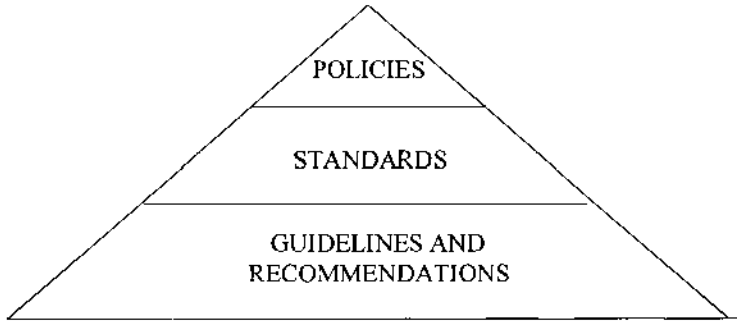

Exhibit 31.3. A Simple Framework for a Security Architecture

it is important to specify how often the libraries should be upgraded. At the lowest level one might include recommendations such as how much disk space to allocate for each particular IDS installation. It is important to realize that an intrusion detection capability does not work well in isolation; it needs to be part of the inner fabric of an organization's culture. As such, developing an intrusion detection architecture is a very important step in successfully deploying intrusion detection technology. Note also that developing such an architecture is not as simple as diagrams such Exhibit 31.3 might imply; it requires carefully analyzing exactly what intrusion detection requires for each component of the architecture and how to embody the solution for each need within that component. Equally important, it requires consensus among organizations that will or may be affected by the rollout of intrusion detection technology in addition to buy-in from senior-level management.

CONCLUSION

We have examined intrusion detection and its potential role in an InfoSec practice, arguing against the "fortress mentality" that results in implementation of security control measures such as password checkers without realizing that no defense measure is 100 percent effective anyway. It is important, therefore, to devote a reasonable portion of an organization's resources to detecting incidents that occur and effectively responding to them. We have taken a look at its advantages and disadvantages, then discussed how one can effectively introduce intrusion detection technology into an organization. Finally, we explained considerations related to deploying IDSs.

Intrusion detection in many ways stands at the same crossroads that firewall technology did nearly a decade ago. The early firewalls were really rather crude and most organizations viewed them as interesting but

impractical. Intrusion detection technology has been available before the first firewall was ever implemented, but the former has always faced more of an uphill battle. The problem can be characterized as due to the mystery and evasiveness that has surrounded IDSs. Firewalls are more straightforward — the simplest firewalls simply block or allow traffic destined for specific hosts. You can be reasonably sure when you buy a firewall product how this product will work. The same has not been true in the intrusion detection arena. Yet at the same time, intrusion detection is rapidly gaining acceptance among major organizations around the world. Although the technology surrounding this area is far less than perfect, it is now sufficiently reliable and sophisticated to warrant its deployment. To ignore and avoid deploying this technology now, in our judgment, constitutes a failure to adopt the types of measures responsible organizations are now putting in place, which in simple terms is a failure to observe "due care" standards.

The good news is that intrusion detection technology is becoming increasingly sophisticated every year. Also encouraging is the fact that performance-related problems associated with IDSs are becoming relatively less important because operating systems and the hardware platforms on which they run are constantly improving with respect to performance characteristics. The research community, additionally, is doing a better job in pioneering the way for the next generation of intrusion detection technology. Some current advances in intrusion detection research include areas such as interoperability of IDSs, automatic reporting, and automated response (in which the IDS takes evasive action when it determines that an attack is in progress).

The bad news is that if your organization does not currently use intrusion detection technology, it is badly behind the intrusion detection "power curve." Consider, furthermore, that an organization that buys, then rolls out a new IDS product is by no means ready to reap the benefits immediately. A definite, steep learning curve for using intrusion detection technology exists. Even if you start deploying this technology now, it takes time to assimilate the mentality of intrusion detection and the technology associated with it into an organization's culture. It is important, therefore, to become familiar with and start using this technology as soon as possible to avoid falling behind even further. The alternative is to continue to function as the proverbial ostrich with its head beneath the sand.

Directory Security

Ken Buszta, CISSP

Many organizations have invested in a wide variety of security technologies and appliances to protect their business assets. Some of these projects have taken their toll on the organization's IT budget in the form of time, money, and the number of personnel required to implement and maintain them. Although each of these projects may be critical to an organization's overall security plan, IT managers and administrators continue to overlook one of the most fundamental and cost-effective security practices available — directory and file permission security. This chapter addresses the dilemma created by this issue, the threats it poses, offers potential solutions, and then discusses several operating system utilities that can aid the practitioner in managing permissions.

Understanding the Dilemma

Today, people desire products that are quick to build and even easier to use, and the information technology world is no different. The public's clamor for products that support such buzzwords as *user friendly* and *feature-enriched* has been heard by a majority of the vendors. We can press one button to power-on a computer, automate signing into an operating system, and have a wide variety of services automatically commence when we start up our computers. In the past, reviews referring to these as ease-of-use features have generally led to increased market share and revenues for these vendors. Although the resulting products have addressed the public's request, vendors have failed to address the business requirements for these products, including:

- *Vendors have failed to understand the growing business IT security model: protect the company's assets.* Vendors have created the operating systems with lax permissions on critical operating files and thereby placed the organization's assets at risk. By configuring the operating system permissions to conform to a stricter permission model, we could reduce the amount of time a practitioner spends in a reactive role and increase the time in proactive roles, such as performance management and implementing new technologies that continue to benefit the organization.
- *Vendors fail to warn consumers of the potential pitfalls created by using the default installation configuration.* Operating system file permissions are associated to user and group memberships and are among the largest pitfalls within the default installation. The default configuration permissions are usually excessive for the average user; and as a result, they increase the potential for unauthorized accesses to the system.
- *Vendors fail to address the average user's lack of computer knowledge.* Many engineers work very diligently to fully understand the operating system documentation that arrives with the software. Even with their academic backgrounds and experience, many struggle and are forced to invest in third-party documentation to understand the complex topics. How can vendors then expect the average user to decipher their documentation and configure their systems correctly?

Threats and Consequences

For experienced security practitioners, we understand it is essential to identify all potential threats to an environment and their possible consequences. When we perform a business impact analysis on data, we must

take into consideration two threats that arise from our file and directory permissions — user account privilege escalation and group membership privilege escalation.

User account privileges refer to the granting of permissions to an individual account. Group membership privileges refer to the granting of permissions to a group of individuals. Improperly granted permissions, whether they are overly restrictive or unnecessarily liberal, pose a threat to the organization. The security practitioner recognizes both of these threats as direct conflicts with the principle of least privilege.

The consequences of these threats can be broken into three areas:

1. *Loss of confidentiality.* Much of our data is obtained and maintained through sensitive channels (i.e., customer relationships, trade secrets, and proprietary methodologies). A disgruntled employee with unnecessarily elevated privileges could easily compromise the system's confidentiality. Such a breach could result in a loss of client data, trust, market share, and profits.
2. *Loss of integrity.* Auditing records, whether they are related to the financial, IT, or production environments, are critical for an organization to prove to its shareholders and various government agencies that it is acting with the level of integrity bestowed upon it. Improper permissions could allow for accidental or deliberate data manipulation, including the deletion of critical files.
3. *Loss of availability.* If permissions are too restrictive, authorized users may not be able to access data and programs in a timely manner. However, if permissions are too lenient, a malicious user may manipulate the data or change the permissions of others, rendering the information unavailable to personnel.

Addressing the Threat

Before we can address the threats associated with file and directory permissions, we must address our file system structure. In this context, we are referring to the method utilized in the creation of partitions. File allocation tables (FAT or FAT32), the Microsoft NT File System (NTFS), and Network File Systems (NFS) are examples of the more commonly used file systems. If practitioners are heavily concerned about protecting their electronic assets, they need to be aware of the capabilities of these file systems. Although we can set permissions in a FAT or FAT32 environment, these permissions can be easily bypassed. On the other hand, both NTFS and NFS allow us to establish the owners of files and directories. This ownership allows us to obtain a tighter control on the files and directories. Therefore, InfoSec best practices recommend establishing and maintaining all critical data on non-FAT partitions.

Once we have addressed our file systems, we can address the permission threat. Consider the following scenario. Your team has been charged with creating the administration scheme for all of KTB Corporation's users and the directory and file permissions. KTB has a centralized InfoSec department that provides support to 10,000 end users. Conservative trends have shown that 25 new end users are added daily, and 20 are removed or modified due to terminations or job transitions. The scheme should take into account heavier periods of activity and be managed accordingly. What would be the best way to approach this dilemma?

As stated earlier, operating systems associate files with users and group memberships. This creates two different paths for the practitioner to manage permissions — by users or by groups. After applying some thought to the requirements, part of your team has developed Plan A to administer the permissions strictly with user accounts. In this solution, the practitioner provides the most scrutiny over the permissions because he or she is delegating permissions on an individual case-by-case basis. The team's process includes determining the privileges needed, determining the resources needed, and then assigning permissions to the appropriate users. The plan estimates that with proper documentation, adding users and assigning appropriate permissions will take approximately five minutes, and a deletion or modification will take ten minutes. The additional time for deletions and modifications can be attributed to the research required to ensure all of the user permissions have been removed or changed. Under this plan, our administrator will need a little over five and a half hours of time each day to complete this primary function. This would allow us to utilize the administrator in other proactive roles, such as implementation projects and metric collection.

Another part of your team has developed Plan B. Under this plan, the administrator will use a group membership approach. The team's process for this approach includes determining the privileges needed, determining the resources needed, examining the default groups to determine if they meet the needs, creating custom groups to address the unmet needs, assigning permissions to the appropriate groups, and then providing

groups with the permissions required to perform their tasks. The team estimates that an administrator will spend approximately five minutes configuring each new user and only two minutes removing or modifying user permissions. The difference in the removal times is attributed to having only to remove the user from a group, as opposed to removing the user from each file or directory. Under Plan B, the administrator will need slightly over four hours to perform these primary duties.

Up until now, both plans could be considered acceptable by management. Remember: there was a statement in the scenario about "heavier periods of activity." What happens if the company goes through a growth spurt? How will this affect the availability of the administrator of each plan? On the other hand, what happens if the economy suffered a downturn and KTB was forced to lay off ten percent, or 2000 members, of its workforce? What type of time would be required to fulfill all of the additional tasking? Under Plan A, the administrator would require over 330 tech hours (or over eight weeks) to complete the tasking, while Plan B would require only 67 hours.

As one can see, individual user permissions might work well in a small environment, but not for a growing or large organization. As the number of users increase, the administration of the permissions becomes more labor intensive and sometimes unmanageable. It is easy for a practitioner to become overwhelmed in this scenario.

However, managing through group memberships has demonstrated several benefits. First, it is scalable. As the organization grows, the administrative tasking grows but remains manageable. The second benefit is ease of use. Once we have invested the time to identify our resources and the permissions required to access those resources, the process becomes templated. When someone is hired into the accounts payable department, we can create the new user and then place the user into the accounts payable group. Because the permissions are assigned to the group and not the individual, the user will inherit the permissions of the group throughout the system. Likewise, should we need to terminate an employee, we simply remove that person from the associated group. (*Note:* The author realizes there will be more account maintenance involved, but it is beyond the scope of this discussion.)

The key to remember in this method is for the practitioner to create groups that are based on either roles or rule sets. Users are then matched against these standards and then placed in the appropriate groups. This method requires some planning on the front end by the practitioner; but over time, it will create a more easily managed program than administering by user. When developing your group management plan, remember to adhere to the following procedure:

- Determine the privileges needed.
- Determine the resources needed.
- Examine the default groups to determine if they meet the needs.
- Create custom groups to address unmet needs.
- Assign users to the appropriate groups.
- Give groups the privileges and access necessary to perform their tasks.

Because each network's design is unique to the organization, careful consideration should be given to the use of custom groups. In 1998, Trusted Systems Services, Inc. (TSSI) addressed this very issue in its Windows NT Security Guidelines study for NSA Research. In this study, TSSI recommends alleviating most of the permissions applied to the public (everyone) group except for Read and Execute. TSSI then suggested the formation of the custom group called Installers that would take on all of these stripped permissions. The purpose of this group is to provide the necessary permissions for technicians who were responsible for the installation of new applications. Although this group would not enjoy the privileges of the administrator's group, it is still an excellent example of supporting the principle of least privilege through group memberships.

Establishing Correct Permissions

When establishing the correct permissions, it is important to understand not only the need to correctly identify the permissions at the beginning of the process but also that the process is an ongoing cycle. Regular audits on the permissions should be performed, including at least once a year by an independent party. This will help address any issues related to collusion and help ensure the integrity of the system.

EXHIBIT 133.1 Windows-Based File Permissions

Special Permissions	Full Control	Modify	Read & Execute	Read	Write
Traverse Folder/Execute File	x	x	x		
List Folder/Read Data	x	x	x	x	
Read Attributes	x	x	x	x	
Read Extended Attributes	x	x	x	x	
Create Files/Write Data	x	x			x
Create Folders/Append Data	x	x			x
Write Attributes	x	x			x
Write Extended Attributes	x	x			x
Delete Subfolders and Files	x				
Delete	x	x			
Read Permissions	x	x	x	x	x
Change Permissions	x				
Take Ownership	x				
Synchronize	x	x	x	x	x

Account maintenance is also a piece of the ongoing cycle. Whether an employee is transferred between departments or is terminated, it is essential for the practitioner to ensure that permissions are redefined for the affected user in a timely manner. Failure to act in such a manner could result in serious damage to the organization.

Permissions Settings

For demonstration purposes of this chapter, we examine the permission settings of two of the more popular operating systems — Microsoft and Linux. The practitioner will notice that these permissions apply to the server as well as the client workstations.

Windows-based permissions are divided into two categories — file and directory. The Window-based file permissions include Full Control, Modify, Read & Execute, Read, and Write. Each of these permissions consists of a logical group of special permissions. Exhibit 133.1 lists each file permission and specifies which special permissions are associated with that permission. Note that groups or users granted Full Control on a folder can delete any files in that folder, regardless of the permissions protecting the file.

The Windows-based folder permissions include Full Control, Modify, Read & Execute, List Folder Contents, Read, and Write. Each of these permissions consists of a logical group of special permissions. Exhibit 133.2 lists each folder permission and specifies which special permissions are associated with it. Although List Folder Contents and Read & Execute appear to have the same special permissions, these permissions are inherited differently. List Folder Contents is inherited by folders but not files, and it should only appear when you view folder permissions. Read & Execute is inherited by both files and folders and is always present when you view file or folder permissions.

For the Linux-based operating systems, the file permissions of Read, Write, and Execute are applicable to both the file and directory structures. However, these permissions may be set on three different levels: User ID, Group ID, or the sticky bit. The sticky bit is largely used on publicly writeable directories to ensure that users do not overwrite each other's files.

When the sticky bit is turned on for a directory, users can have read and/or write permissions for that directory; but they can only remove or rename files that they own. The sticky bit on a file tells the operating system that the file will be executed frequently. Only the administrator (root) is permitted to turn the sticky bit on or off. In addition, the sticky bit applies to anyone who accesses the file.

EXHIBIT 133.2 Windows-Based Folder Permissions

Special Permissions	Full Control	Modify	Read & Execute	List Folder Contents	Read	Write
Traverse Folder/Execute File	x	x	x	x		
List Folder/Read Data	x	x	x	x	x	
Read Attributes	x	x	x	x	x	
Read Extended Attributes	x	x	x	x	x	
Create Files/Write Data	x	x				x
Create Folders/Append Data	x	x				x
Write Attributes	x	x				x
Write Extended Attributes	x	x				x
Delete Subfolders and Files	x					
Delete	x	x				
Read Permissions	x	x	x	x	x	x
Change Permissions	x					
Take Ownership	x					
Synchronize	x	x	x	x	x	x

Permission Utilities

To effectively manage permissions, the practitioner should understand the various tools made available to them by the vendors. Both vendors provide a graphical user interface (GUI) and a command line interface (CL). Although there are several high-profile third-party tools available, we will concentrate on the CL utilities provided by the operating system vendors. Exhibit 133.3 lists the various CL tools within the Windows- and Linux-based operating systems. A brief discussion of each utility follows.

You can use *cacls* to display or modify access control lists (ACLs) of files or folders in a Windows-based environment. This includes granting, revoking, and modifying user access rights. If you already have permissions set for multiple users or groups on a folder or file, be careful using the different variables. An improper variable setting will remove all user permissions except for the user and permissions specified on the command line. It is recommended that the practitioner utilize the edit parameter (/e) whenever using this command line utility.

There are several parameters associated with the *calcs* command, and they can be viewed by simply entering *calcs* at the command prompt. The administrator can then view the permissions set for each of the files within the present directory.

The *chmod* command is used to change the permissions mode of a file or directory.

The *chown* command changes the owner of a file specified by the file parameter to the user specified in the owner parameter. The value of the owner parameter can be a user ID or a log-in name found in the password file. Optionally, a group can also be specified. Only the root user can change the owner of a file. You can change

EXHIBIT 133.3 Permission Management Utilities

Utility	Operating Environment
calcs	Windows
chmod	Linux/UNIX
chown	Linux/UNIX
usermod	Linux/UNIX

the group only if you are a root user or own the file. If you own the file but are not a root user, you can change the group only to a group of which you are a member.

Usermod is used to modify a user's log-in definition on the system. It changes the definition of the specified log-in and makes the appropriate log-in-related system file and file system changes.

The *groupmod* command modifies the definition of the specified group by modifying the appropriate entry in the /etc/ group file.

Specific Directory Permissions

As we consider directory permissions, there are three different types of directories — data directories, operating system directories, and application directories. Although the permission standards may differ among each of these directory types, there are two common permission threads shared among all of them — the system administrator group and the system will maintain inclusive permissions to each of them. (*Note*: The administrator's group does not refer to a particular operating system but to a resource level in general. We could easily substitute *root* for the administrator's title.) Because the administrator is responsible for the network, including the resources and data associated with the network, he must maintain the highest permission levels attainable through the permission structure. The *system* refers to the computer and its requirements for carrying out tasking entered by the user. Failure to provide this level of permission to the system could result in the unit crashing and a potential loss of data. Otherwise, unless explicitly stated, all other parties will maintain no permissions in the following discussions.

The data directories may be divided into home directories and shared directories. Home directories provide a place on the network for end users to store data they create or to perform their tasking. These directories should be configured to ensure adequate privacy and confidentiality from other network services. As such, the individual user assigned to the directory shall maintain full control of the directory. If the organization has defined a need for a dedicated user data manager resource, this individual should also have full control of the directory.

Share directories are placed on the network to allow a group of individuals access to a particular set of data. These directories should not be configured with individual permissions but with group permissions. For example, accounts payable data may be kept in a shared directory. A custom group could be created and assigned the appropriate permissions. The user permissions are slightly different from home directories. Instead of providing the appropriate user with full control, it has been recommended to provide the group with Read, Write, Execute, and Delete. This will only allow the group to manipulate the data within the file; they cannot delete the file itself. Additionally, these permissions should be limited to a single directory and not passed along to the subdirectories.

Security is often an after-thought in the actual application design, especially in the proprietary applications designed in-house. As unfortunate as this is, it is still a common practice; and we must be careful to check the directory permissions of any newly installed application — whether it is developed within the organization or purchased from a third party — because users are often given a full set of permissions in the directory structure. Generally, the application users will not need more than read permissions on these directories, unless a data directory has been created within the application directory structure. If this case exists, the data directory should be treated according to the shared data directory permissions previously discussed. Additionally, the installers group should have the ability to implement changes to the directory structure. This would allow them to apply service patches and upgrades to the application.

The third division is the operating system directories. It is critical for the practitioner to have the proper understanding of the operating system directory and file structure before beginning any installation. Failure to understand the potential vulnerabilities, whether they are in the directory structure or elsewhere, will result in a weak link and an opportunity for the E-criminal.

As stated earlier in the chapter, vendors often create default installations to be user friendly. This provides for the most lenient permissions and the largest vulnerabilities to our systems. To minimize the vulnerability, establish read-only permissions for the average user. There will be situations in which these permissions are insufficient, and they should be dealt with on a case-by-case basis. Personnel who provide desktop and server support may fall into this category. In this case, create a custom group to support the specific activities and assign permissions equivalent to read and add. Additionally, all operating system directories should be owned by the administrator only. This will limit the amount of damage an E-criminal could cause to the system.

Sensitive File Permissions

Until now, we have only looked at the directory permissions. Although this approach addresses many concerns, it is only half of our battle. Several different file types within a directory require special consideration based on their roles. The particular file types are executable/binary compiled, print drivers, scripting files, and help files.

Executable/binary files are dangerous because they direct the system or application to perform certain actions. Examples of these file extensions are DLL, EXE, BAT, and BIN. The average user should be restricted to read and execute permissions. They should not have the ability to modify these files.

Print drivers are often run with a full permission set. Manipulation of these files could allow the installation of a malicious program that runs at the elevated privilege. The average user should be limited to a read and execute permission set.

Improperly set permissions on scripting files, such as Java and ActiveX, could allow for two potential problems. By providing the elevated privileges on these files, the user has the ability to modify these files to place a call to run a malicious program or promote program masquerading. Program masquerading is the act of having one program run under the pretext that it is actually another program. For these reasons, these files should also have a read and execute permission set.

Help files often contain executable code. To prevent program masquerading and other spoofing opportunities, these files should not be writeable.

Monitoring and Alerts

After we have planned and implemented our permission infrastructure, we will need to establish a methodology to monitor and audit the infrastructure. This is key to ensuring that unauthorized changes are identified in a timely manner and to limit the potential damage that can be done to our networks. This process will also take careful planning and administration.

The practitioner could implement a strategy that would encompass all of the permissions, but such a strategy would become time-consuming and ineffective. The more effective approach would be to identify the directories and files that are critical to business operations. Particular attention should be given to sensitive information, executables that run critical business processes, and system-related tools.

While designing the monitoring process, practitioners should be keenly aware of how they will be notified in the event a monitoring alarm is activated and what type of actions will be taken. As a minimum, a log entry should be created for each triggered event. Additionally, a mechanism should be in place to notify the appropriate personnel of these events. The mechanism may be in the form of an e-mail, pager alert, or telephone call. Unfortunately, not all operating systems have these features built in; so the practitioner may need to invest in a third-party product. Depending on the nature of the organization's business, the practitioner may consider outsourcing this role to a managed services partner. These partnerships are designed to quickly identify a problem area for the client and implement a response in a very short period.

Once a response has been mounted to an alert, it is also important for the team to review the events leading up to the alert and attempt to minimize the event's recurrence. One can take three definitive actions because of these reviews:

1. *Review the present standards and make changes accordingly.* If we remember that security is a business enabler and not a disabler, we understand that security must be flexible. Our ideal strategy may need slight modifications to support the business model. Such changes should be documented for all parties to review and approve and to provide a paper trail to help restore the system in the event of a catastrophic failure.
2. *Educate the affected parties.* Often, personnel may make changes to the system without notifying everyone. Of course, those who were not notified are the ones affected by the changes. The practitioner may avoid a repeat of the same event by educating the users on why a particular practice is in place.
3. *Escalate the issue.* Sometimes, neither educating users nor modifying standards is the correct solution. The network may be under siege either from an internal or external source, and it is the practitioner's duty to escalate these issues to upper management and possibly law enforcement officials. For further guidance on handling this type of scenario, one should contact one's legal department and conduct further research on the CERT and SANS Web sites.

Auditing

Auditing will help ensure that file and directory systems are adhering to the organization's accepted standards. Although an organization may perform regular internal audits, it is recommended to have the file and directory structure audited by an external company annually. This process will help validate the internal results and limit any collusion that may be occurring within the organization.

Conclusion

While most businesses are addressing the markets' calls for user-friendly and ease-of-use operating systems, they are overlooking the security needs of most of the corporate infrastructure. This has led to unauthorized accesses to sensitive file structures and, as a result, is placing the organization in a major dilemma. Until we take the time to properly identify file and directory security permissions that best fit our organization's business charter, we cannot begin to feel confident with our overall network security strategy.

Domain 8
Business Continuity Planning

The Business Continuity Planning Domain addresses actions to preserve the business in the face of disruptions to normal business operations, including both natural and man-made events. Information systems and processing continuity are subject to many natural and man-made threats. Organizations must continually plan for potential business disruption, and test the recovery plans for their automated systems. Moreover, these organizations must continue to reengineer the continuity planning process, given the challenges of evolving technologies, including distributed computing and the World Wide Web.

Measures taken to ensure business continuity and disaster recovery have always been a challenge in the IT environment. The current information processing environment is much more complex to manage than those in the past. As systems and networks become more distributed, the control and manageability of those systems travels further away from a central source. In the world of Web applications, much of the control lies outside of the organization owning the resources. Thus, management may well be aware that continuity planning (CP) is important, but does not effectively execute their plans.

The chapters in this domain present a structured approach to contingency planning, including measures to demonstrate its value. Business Continuity Planning, of course, is necessary to ensure that the systems critical to keeping the organization viable are processed at an alternate site in time to avoid an intolerable business impact. The concepts of Business Impact Analysis (BIA) are examined as key tools to assist in the identification of critical applications, systems, and supporting resources.

Reengineering the Business Continuity Planning Process

Carl B. Jackson, CISSP, CBCP

The initial version of this chapter was written for the 1999 edition of the *Information Security Management Handbook*. Since then, E-commerce has seized the spotlight and Web-based technologies are the emerging solution for almost everything. The constant throughout these occurrences is that no matter what the climate, fundamental business processes have changed little. And, as always, the focus of any business impact assessment is to assess the time-critical priority of these business processes. With these more recent realities in mind, this chapter has been updated and is now offered for the reader's consideration.

Continuity Planning: Management Awareness High — Execution Effectiveness Low

The failure of organizations to accurately measure the contributions of the continuity planning (CP) process to their overall success has led to a downward spiraling cycle of the total business continuity program. The recurring downward spin or decomposition includes planning, testing, maintenance, decline → replanning, testing, maintenance, decline → replanning, testing, maintenance, decline, etc.

In the past, *Contingency Planning & Management (CPM)/Ernst & Young Continuity Planning Benchmark* surveys have repeatedly confirmed that continuity planning (CP) is ranked as being either "extremely important" or "very important" to executive management. The most recent *2000–2001 CPM/KPMG Continuity Planning Survey*[1] clearly supports this observation. This study indicates that a growing number of CP professional positions are migrating from the IT infrastructure to corporate or general management positions; however, CP reporting within the IT organization is still the norm. Approximately 40 percent of CP professionals currently report to IT, while around 30 percent report to corporate positions.

Continuity Planning Measurements

While the trends of this survey are encouraging, there is a continuing indication of a disconnect between executive management's perceptions of CP objectives and the manner in which they measure its value. Traditionally, CP effectiveness was measured in terms of a pass/fail grade on a mainframe recovery test, or on the perceived benefits of backup/recovery sites and redundant telecommunications weighed against the expense for these capabilities. The trouble with these types of metrics is that they only measure CP direct costs, or indirect perceptions as to whether a test was effectively executed. These metrics do not indicate whether a test validates the appropriate infrastructure elements or even whether it is thorough enough to test a component until it fails, thereby extending the reach and usefulness of the test scenario.

Thus, one might inquire as to the correct measures to use. Although financial measurements do constitute one measure of the CP process, others measure the CPs contribution to the organization in terms of quality

and effectiveness, which are not strictly weighed in monetary terms. The contributions that a well-run CP process can make to an organization include:

- Sustaining growth and innovation
- Enhancing customer satisfaction
- Providing people needs
- Improving overall mission-critical process quality
- Providing for practical financial metrics

A Receipt for Radical Change: CP Process Improvement

Just prior to the millennium, experts in organizational management efficiency began introducing performance process improvement disciplines. These process improvement disciplines have been slowly adopted across many industries and companies for improvement of general manufacturing and administrative business processes. The basis of these and other improvement efforts was the concept that an organization's processes (Process; see Exhibit 134.1) constituted the organization's fundamental lifeblood and, if made more effective and more efficient, could dramatically decrease errors and increase organizational productivity.

An organization's processes are a series of successive activities; and when they are executed in the aggregate, they constitute the foundation of the organization's mission. These processes are intertwined throughout the organization's infrastructure (individual business units, divisions, plants, etc.) and are tied to the organization's supporting structures (data processing, communications networks, physical facilities, people, etc.).

A key concept of the process improvement and reengineering movement revolves around identification of process enablers and barriers (see Exhibit 134.1). These enablers and barriers take many forms (people, technology, facilities, etc.) and must be understood and taken into consideration when introducing radical change into the organization.

The preceding narration provides the backdrop for the idea of focusing on continuity planning not as a project, but as a continuous process, that must be designed to support the other mission-critical processes of the organization. Therefore, the idea was born of adopting a continuous process approach to CP, along with understanding and addressing the people, technology, facility, etc., enablers and barriers. This constitutes a significant or even radical change in thinking from the manner in which recovery planning has been traditionally viewed and executed.

Radical Changes Mandated

High awareness of management and low CP execution effectiveness, coupled with the lack of consistent and meaningful CP measurements, call for radical changes in the manner in which one executes recovery planning responsibilities. The techniques used to develop mainframe-oriented disaster recovery (DR) plans of the 1980s and 1990s consisted of five to seven distinct stages, depending on whose methodology was being used, that required the recovery planner to:

1. Establish a project team and a supporting infrastructure to develop the plans.
2. Conduct a threat or risk management review to identify likely threat scenarios to be addressed in the recovery plans.
3. Conduct a business impact analysis (BIA) to identify and prioritize time-critical business applications and networks and determine maximum tolerable downtimes.
4. Select an appropriate recovery alternative that effectively addressed the recovery priorities and timeframes mandated by the BIA.
5. Document and implement the recovery plans.
6. Establish and adopt an ongoing testing and maintenance strategy.

Shortcomings of the Traditional Disaster Recovery Planning Approach

The old approach worked well when disaster recovery of "glass-house" mainframe infrastructures was the norm. It even worked fairly well when it came to integrating the evolving distributed client/server systems into the overall recovery planning infrastructure. However, when organizations became concerned with business unit recovery planning, the traditional DR methodology was ineffective in designing and implementing busi-

EXHIBIT 134.1 Definitions

Activities: Activities are things that go on within a process or sub-process. They are usually performed by units of one (one person or one department). An activity is usually documented in an instruction. The instruction should document the tasks that make up the activity.
Benchmarking: Benchmarking is a systematic way to identity, understand, and creatively evolve superior products, services, designs, equipment, processes, and practices to improve the organization's real performance by studying how other organizations are performing the same or similar operations.
Business process improvement: Business process improvement (BPI) is a methodology that is designed to bring about self-function improvements in administrative and support processes using approaches such as FAST, process benchmarking, process redesign, and process reengineering.
Comparative analysis: Comparative analysis (CA) is the act of comparing a set of measurements to another set of measurements for similar items.
Enabler: An enabler is a technical or organizational facility/resource that make it possible to perform a task, activity, or process. Examples of technical enablers are personal computers, copying equipment, decentralized data processing, voice response, etc. Examples of organizational enablers are enhancement, self-management, communications, education, etc.
Fast analysis solution technique: *FAST* is a breakthrough approach that focuses a group's attention on a single process for a one- or two-day meeting to define how the group can improve the process over the next 90 days. Before the end of the meeting, management approves or rejects the proposed improvements.
Future state solution: A combination of corrective actions and changes that can be applied to the item (process) under study to increase its value to its stakeholders.
Information: Information is data that has been analyzed, shared, and understood.
Major processes: A major process is a process that usually involves more than one function within the organization structure, and its operation has a significant impact on the way the organization functions. When a major process is too complex to be flowcharted at the activity level, it is often divided into sub-processes.
Organization: An organization is any group, company, corporation, division, department, plant, or sales office.
Process: A process is a logical, related, sequential (connected) set of activities that takes an input from a supplier, adds value to it, and produces an output to a customer.
Sub-process: A sub-process is a portion of a major process that accomplishes a specific objective in support of the major process.
System: A system is an assembly of components (hardware, software, procedures, human functions, and other resources) united by some form of regulated interaction to form an organized whole. It is a group of related processes that may or may not be connected.
Tasks: Tasks are individual elements or subsets of an activity. Normally, tasks relate to how an item performs a specific assignment.

From Harrington, H.J., Esseling, E.K.C., and Van Nimwegen, H., *Business Process Improvement Workbook,* McGraw-Hill, 1997, 1–20.

ness unit/function recovery plans. Of primary concern when attempting to implement enterprisewide recovery plans was the issue of functional interdependencies. Recovery planners became obsessed with identification of interdependencies between business units and functions, as well as the interdependencies between business units and the technological services supporting time-critical functions within these business units.

Losing Track of the Interdependencies

The ability to keep track of departmental interdependencies for CP purposes was extremely difficult and most methods for accomplishing this were ineffective. Numerous circumstances made consistent tracking of inter-

dependencies difficult to achieve. Circumstances affecting interdependencies revolve around the rapid rates of change that most modern organizations are undergoing. These include reorganization/restructuring, personnel relocation, changes in the competitive environment, and outsourcing. Every time an organizational structure changes, the CPs must change and the interdependencies must be reassessed; and the more rapid the change, the more daunting the CP reshuffling. Because many functional interdependencies could not be tracked, CP integrity was lost and the overall functionality of the CP was impaired. There seemed to be no easy answers to this dilemma.

Interdependencies Are Business Processes

Why are interdependencies of concern? And what, typically, are the interdependencies? The answer is that, to a large degree, these interdependencies are the business processes of the organization and they are of concern because they must function in order to fulfill the organization's mission. Approaching recovery planning challenges with a business process viewpoint can, to a large extent, mitigate the problems associated with losing interdependencies, and also ensure that the focus of recovery planning efforts is on the most crucial components of the organization. Understanding how the organization's time-critical business processes are structured will assist the recovery planner in mapping the processes back to the business units/departments; supporting technological systems, networks, facilities, vital records, people, etc.; and keeping track of the processes during reorganizations or during times of change.

The Process Approach to Continuity Planning

Traditional approaches to mainframe-focused disaster recovery planning emphasized the need to recover the organization's technological and communications platforms. Today, many companies have shifted away from technology recovery and toward continuity of prioritized business processes and the development of specific business process recovery plans. Many large corporations use the process reengineering/improvement disciplines to increase overall organizational productivity. CP itself should also be viewed as such a process. Exhibit 134.2 provides a graphical representation of how the enterprisewide CP process framework should look.

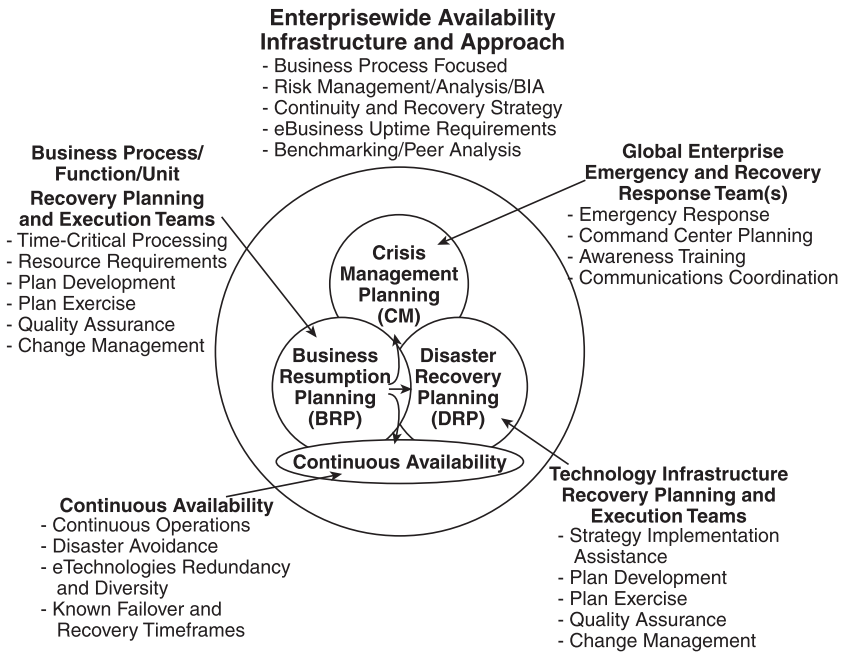

EXHIBIT 134.2 The enterprisewide CP process framework.

This approach to continuity planning consolidates three traditional continuity planning disciplines, as follows:

1. *IT disaster recovery planning (DRP)*. Traditional IT DRP addresses the continuity planning needs of the organizations' IT infrastructures, including centralized and decentralized IT capabilities and includes both voice and data communications network support services.
2. *Business operations resumption planning (BRP)*. Traditional BRP addresses the continuity of an organization's business operations (e.g., accounting, purchasing, etc.) should they lose access to their supporting resources (e.g., IT, communications network, facilities, external agent relationships, etc.).
3. *Crisis management planning (CMP)*. CMP focuses on assisting the client organization develop an effective and efficient enterprisewide emergency/disaster response capability. This response capability includes forming appropriate management teams and training their members in reacting to serious company emergency situations (e.g., hurricane, earthquake, flood, fire, serious hacker or virus damage, etc.). CMP also encompasses response to life-safety issues for personnel during a crisis or response to disaster.
4. *Continuous availability (CA)*. In contrast to the other CP components as explained above, the recovery time objective (RTO) for recovery of infrastructure support resources in a 24×7 environment has diminished to *zero* time. That is, the client organization cannot afford to lose operational capabilities for even a very short period of time without significant financial (revenue loss, extra expense) or operational (customer service, loss of confidence) impact. The CA service focuses on maintaining the highest uptime of support infrastructures to 99 percent and higher.

Moving to a CP Process Improvement Environment

Route Map Profile and High-Level CP Process Approach

A practical, high-level approach to CP process improvement is demonstrated by breaking down the CP process into individual sub-process components as shown in Exhibit 134.3.

The six major components of the continuity planning business process are described below.

1. *Current State Assessment/Ongoing Assessment.* Understanding the approach to enterprisewide continuity planning as illustrated in Exhibit 134.3, one can measure the "health" of the continuity planning process. During this process, existing continuity planning business sub-processes are assessed to gauge their overall effectiveness. It is sometimes useful to employ gap analysis techniques to understand current state, desired future state, and then understand the people, process, and technology barriers and enablers that stand between the current state and the future state. An approach to co-development of current state/future state visioning sessions is illustrated in Exhibit 134.4.
   The current state assessment process also involves identifying and determining how the organization "values" the CP process and measures its success (often overlooked and often leading to the failure of the CP process). Also during this process, an organization's business processes are examined to determine the impact of loss or interruption of service on the overall business through performance of a business impact assessment (BIA). The goal of the BIA is to prioritize business processes and assign the recovery time objective (RTO) for their recovery, as well as for the recovery of their support resources. An important outcome of this activity is the mapping of time-critical processes to their support resources (e.g., IT applications, networks, facilities, communities of interest, etc.).
2. *Process Risk and Impact Baseline.* During this process, potential risks and vulnerabilities are assessed, and strategies and programs are developed to mitigate or eliminate those risks. The stand-alone risk management review (RMR) commonly looks at the security of physical, environmental, and information capabilities of the organization. In general, the RMR should identify or discuss the following areas:

   - Potential threats
   - Physical and environmental security
   - Information security
   - Rrecoverability of time-critical support functions
   - Single-points-of-failure

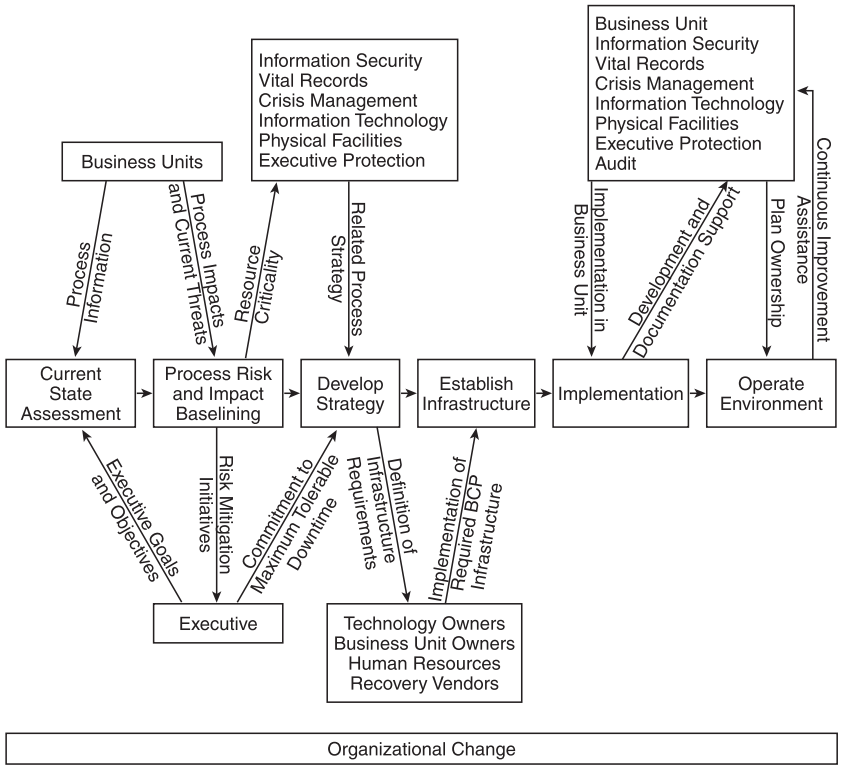

EXHIBIT 134.3 A practical, high-level approach to CP process improvement.

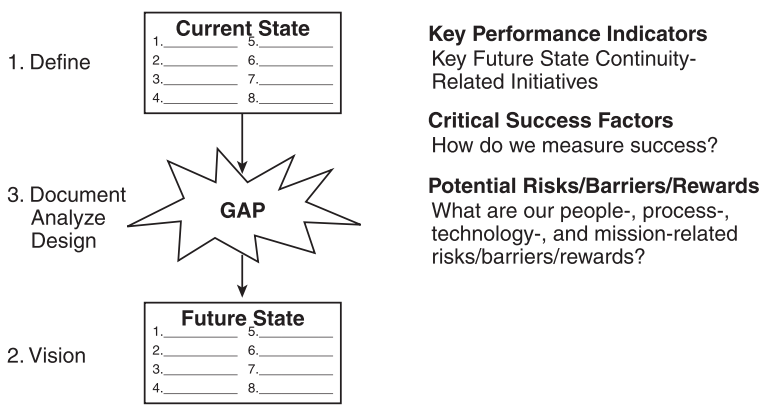

EXHIBIT 134.4 Current state/future state visioning overview.

- Problem and change management
- Business interruption and extra expense insurance
- An offsite storage program, etc.

3. *Strategy Development.* This process involves facilitating a workshop or series of workshops designed to identify and document the most appropriate recovery alternative to CP challenges (e.g., determining if a hotsite is needed for IT continuity purposes, determining if additional communications circuits should

be installed in a networking environment, determining if additional workspace is needed in a business operations environment, etc.). Using the information derived from the risk assessments above, design long-term testing, maintenance, awareness, training, and measurement strategies.

4. *Continuity Plan Infrastructure*. During plan development, all policies, guidelines, continuity measures, and continuity plans are formally documented. Structure the CP environment to identify plan owners and project management teams, and to ensure the successful development of the plan. In addition, tie the continuity plans to the overall IT continuity plan and crisis management infrastructure.
5. *Implementation.* During this phase, the initial versions of the continuity or crisis management plans are implemented across the enterprise environment. Also during this phase, long-term testing, maintenance, awareness, training, and measurement strategies are implemented.
6. *Operate Environment.* This phase involves the constant review and maintenance of the continuity and crisis management plans. In addition, this phase may entail maintenance of the ongoing viability of the overall continuity and crisis management business processes.

How Does One Get There? The Concept of the CP Value Journey

The CP value journey is a helpful mechanism for co-development of CP expectations by the organization's top management group and those responsible for recovery planning. To achieve a successful and measurable recovery planning process, the following checkpoints along the CP value journey should be considered and agreed upon. The checkpoints include:

- *Defining success*. Define what a successful CP implementation will look like. What is the future state?
- *Aligning the CP with business strategy*. Challenge objectives to ensure that the CP effort has a business-centric focus.
- *Charting an improvement strategy*. Benchmark where the organization and the organization's peers are, the organization's goals based on their present position as compared to their peers, and which critical initiatives will help the organization achieve its goals.
- *Becoming an accelerator*. Accelerate the implementation of the organization's CP strategies and processes. In today's environment, speed is a critical success factor for most companies.
- *Creating a winning team*. Build an internal/external team that can help lead the company through CP assessment, development, and implementation.
- *Assessing business needs*. Assess time-critical business process dependence on the supporting infrastructure.
- *Documenting the plans*. Develop continuity plans that focus on ensuring that time-critical business processes will be available.
- *Enabling the people*. Implement mechanisms that help enable rapid reaction and recovery in times of emergency, such as training programs, a clear organizational structure, and a detailed leadership and management plan.
- *Completing the organization's CP strategy*. Position the organization to complete the operational and personnel related milestones necessary to ensure success.
- *Delivering value*. Focus on achieving the organization's goals while simultaneously envisioning the future and considering organizational change.
- *Renewing/recreating*. Challenge the new CP process structure and organizational management to continue to adapt and meet the challenges of demonstrate availability and recoverability.

The Value Journey Facilitates Meaningful Dialogue

This value journey technique for raising the awareness level of management helps to both facilitate meaningful discussions about the CP process and ensure that the resulting CP strategies truly add value. As discussed later, this value-added concept will also provide additional metrics by which the success of the overall CP process can be measured.

The Need for Organizational Change Management

In addition to the approaches of CP process improvement and the CP value journey mentioned above, the need to introduce people-oriented organizational change management (OCM) concepts is an important component in implementing a successful CP process.

H. James Harrington et al., in their book *Business Process Improvement Workbook*,[2] point out that applying process improvement approaches can often cause trouble unless the organization manages the change process. They state that, "Approaches like reengineering only succeed if we challenge and change our paradigms and our organization's culture. It is a fallacy to think that you can change the processes without changing the behavior patterns or the people who are responsible for operating these processes."[3]

Organizational change management concepts, including the identification of people enablers and barriers and the design of appropriate implementation plans that change behavior patterns, play an important role in shifting the CP project approach to one of CP process improvement. The authors also point out that, "There are a number of tools and techniques that are effective in managing the change process, such as pain management, change mapping, and synergy. The important thing is that every BPI (Business Process Improvement) program must have a very comprehensive change management plan built into it, and this plan must be effectively implemented."[4]

Therefore, it is incumbent on the recovery planner to ensure that, as the concept of the CP process evolves within the organization, appropriate OCM techniques are considered and included as an integral component of the overall deployment effort.

How Is Success Measured? Balanced Scorecard Concept[5]

A complement to the CP process improvement approach is the establishment of meaningful measures or metrics that the organization can use to weigh the success of the overall CP process. Traditional measures include:

- How much money is spent on hotsites?
- How many people are devoted to CP activities?
- Was the hotsite test a success?

Instead, the focus should be on measuring the CP process contribution to achieving the overall goals of the organization. This focus helps to:

- Identify agreed-upon CP development milestones.
- Establish a baseline for execution.
- Validate CP process delivery.
- Establish a foundation for management satisfaction to successfully manage expectations.

The CP balanced scorecard includes a definition of the:

- Value statement
- Value proposition
- Metrics/assumptions on reduction of CP risk
- Implementation protocols
- Validation methods

Exhibits 134.5 and 134.6 illustrate the balanced scorecard concept and show examples of the types of metrics that can be developed to measure the success of the implemented CP process. Included in this balanced scorecard approach are the new metrics upon which the CP process will be measured.

Following this balanced scorecard approach, the organization should define what the future state of the CP process should look like (see the preceding CP value journey discussion). This future state definition should be co-developed by the organization's top management and those responsible for development of the CP process infrastructure. Exhibit 134.4 illustrates the current state/future state visioning overview, a technique that can also be used for developing expectations for the balanced scorecard. Once the future state is defined, the CP process development group can outline the CP process implementation critical success factors in the areas of:

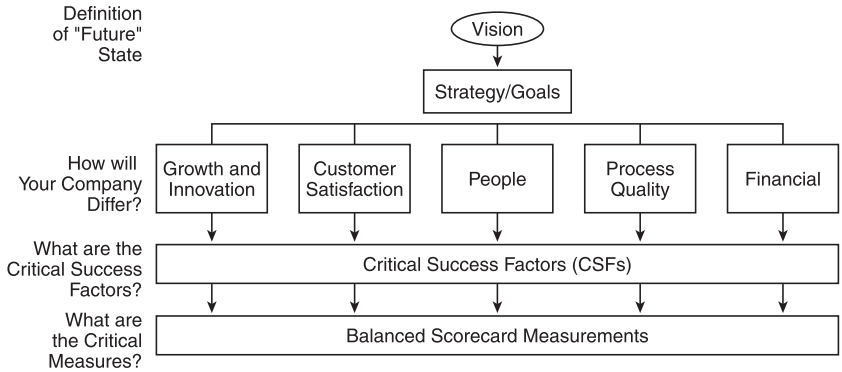

EXHIBIT 134.5 Balanced scorecard concept.

EXHIBIT 134.6 Continuity Process Scorecard

Question: How should the organization benefit from implementation of the following continutity process components in terms of people, processes, technologies, and mission/profits?

Continuity Planning Process Components	People	Processes	Technologies	Mission/Profits
Process methodology				
Documented DRPs				
Documented BRPs				
Documented crisis management plans				
Documented emergency response procedures				
Documented network recovery plan				
Contingency organization walk-throughs				
Employee awareness program				
Recovery alternative costs				
Continuous availability infrastructure				
Ongoing testing programs				
etc.				

- Growth and innovation
- Customer satisfaction
- People
- Process quality
- Financial state

These measures must be uniquely developed based on the specific organization's culture and environment.

What about Continuity Planning for Web-Based Applications?

Evolving with the birth of the Web and Web-based businesses is the requirement for 24×7 uptime. Traditional recovery time objectives have disappeared for certain business processes and support resources that support the organizations' Web-based infrastructure. Unfortunately, simply preparing Web-based applications for sustained 24×7 uptime is not the only answer. There is no question that application availability issues must be addressed, but it is also important that the reliability and availability of other Web-based infrastructure components (such as computer hardware, Web-based networks, database file systems, Web servers, file and print servers, as well as preparing for the physical, environmental, and information security concerns relative to each of these [see RMR above]) also be undertaken. The terminology for preparing the entirety of this

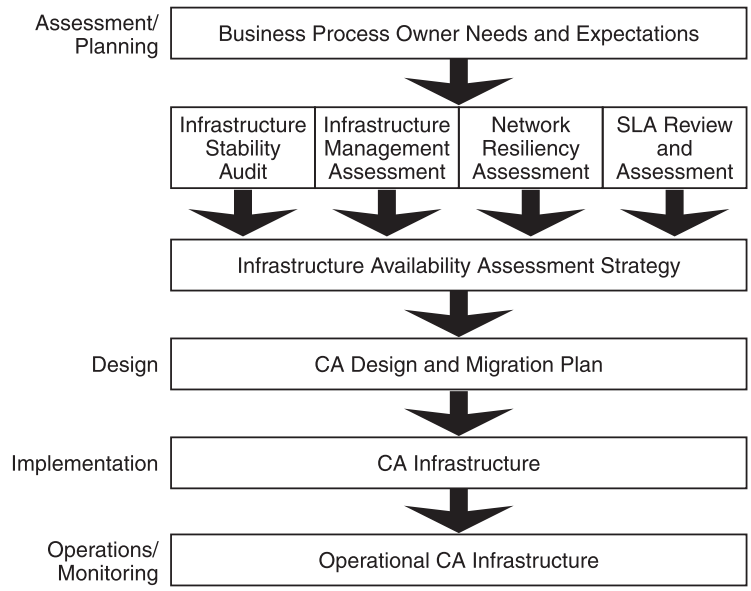

EXHIBIT 134.7 Continuous availability methodological approach.

infrastructure to remain available through major and minor disruptions is usually referred to as continuous or high availability.

Continuous availability (CA) is not simply bought; it is planned for and implemented in phases. The key to a reliable and available Web-based infrastructure is to ensure that each of the components of the infrastructure have a high-degree of resiliency and robustness. To substantiate this statement, *Gartner Research* reports "Replication of databases, hardware servers, Web servers, application servers, and integration brokers/suites helps increase availability of the application services. The best results, however, are achieved when, in addition to the reliance on the system's infrastructure, the design of the application itself incorporates considerations for continuous availability. Users looking to achieve continuous availability for their Web applications should not rely on any one tool but should include the availability considerations systematically at every step of their application projects."[7]

Implementing a continuous availability methodological approach is the key to an organized and methodical way to achieve 24×7 or near 24×7 availability. Begin this process by understanding business process needs and expectations, and the vulnerabilities and risks of the network infrastructure (e.g., Internet, intranet, extranet, etc.), including undertaking single-points-of-failure analysis. As part of considering implementation of continuous availability, the organization should examine the resiliency of its network infrastructure and the components thereof, including the capability of its infrastructure management systems to handle network faults, network configuration and change, the ability to monitor network availability, and the ability of individual network components to handle capacity requirements. See Exhibit 134.7 for an example pictorial representation of this methodology.

The CA methodological approach is a systematic way to consider and move forward in achieving a Web-based environment. A very high-level overview of this methodology is as follows.

- *Assessment/planning*. During this phase, the enterprise should endeavor to understand the current state of business process owner expectations/requirements and the components of the technological infrastructure that support Web-based business processes. Utilizing both interview techniques (people to people) and existing system and network automated diagnoses tools will assist in understanding availability status and concerns.
- *Design*. Given the results of the current state assessment, design the continuous availability strategy and implementation/migration plans. This will include developing a Web-based infrastructure classification system to be used to classify the governance processes used for granting access to and use of support for Web-based resources.

- *Implementation*. Migrate existing infrastructures to the Web-based environment according to design specifications as determined during the design phase.
- *Operations/monitoring*. Establish operational monitoring techniques and processes for the ongoing administration of the Web-based infrastructure.

Along these lines, in their book *Blueprints for High Availability: Designing Resilient Distributed Systems*,[8] Marcus and Stern recommend several fundamental rules for maximizing system availability (paraphrased):

- *Spend money…but not blindly*. Because quality costs money, investing in an appropriate degree of resiliency is necessary.
- *Assume nothing*. Nothing comes bundled when it comes to continuous availability. End-to-end system availability requires up-front planning and cannot simply be bought and dropped in place.
- *Remove single-points-of-failure*. If a single link in the chain breaks, regardless of how strong the other links are, the system is down. Identify and mitigate single-points-of-failure.
- *Maintain tight security*. Provide for the physical, environmental, and information security of Web-based infrastructure components.
- *Consolidate servers*. Consolidate many small servers' functionality onto larger servers and less numerous servers to facilitate operations and reduce complexity.
- *Automate common tasks*. Automate the commonly performed systems tasks. Anything that can be done to reduce operational complexity will assist in maintaining high availability.
- *Document everything*. Do not discount the importance of system documentation. Documentation provides audit trails and instructions to present and future systems operators on the fundamental operational intricacies of the systems in question.
- *Establish service level agreements (SLAs)*. It is most appropriate to define enterprise and service provider expectations ahead of time. SLAs should address system availability levels, hours of service, locations, priorities, and escalation policies.
- *Plan ahead*. Plan for emergencies and crises, including multiple failures in advance of actual events.
- *Test everything*. Test all new applications, system software, and hardware modifications in a production-like environment prior to going live.
- *Maintain separate environments*. Provide for separation of systems, when possible. This separation might include separate environments for the following functions: production, production mirror, quality assurance, development, laboratory, and disaster recovery/business continuity site.
- *Invest in failure isolation*. Plan — to the degree possible — to isolate problems so that if or when they occur, they cannot boil over and affect other infrastructure components.
- *Examine the history of the system*. Understanding system history will assist in understanding what actions are necessary to move the system to a higher level of resiliency in the future.
- *Build for growth*. A given in the modern computer era is that system resource reliability increases over time. As enterprise reliance on system resources grow, the systems must grow. Therefore, adding systems resources to existing reliable system architectures requires preplanning and concern for workload distribution and application leveling.
- *Choose mature software*. It should go without saying that mature software that supports a Web-based environment is preferred over untested solutions.
- *Select reliable and serviceable hardware*. As with software, selecting hardware components that have demonstrated high mean times between failures is preferable in a Web-based environment.
- *Reuse configurations*. If the enterprise has stable system configurations, reuse or replicate them as much as possible throughout the environment. The advantages of this approach include ease of support, pretested configurations, a high degree of confidence for new rollouts, bulk purchasing possible, spare parts availability, and less to learn for those responsible for implementing and operating the Web-based infrastructure.
- *Exploit external resources*. Take advantage of other organizations that are implementing and operating Web-based environments. It is possible to learn from others' experiences.
- *One problem, one solution*. Understand, identify, and utilize the tools necessary to maintain the infrastructure. Tools should fit the job; so obtain them and use them as they were designed to be used.

- *KISS: keep it simple….* Simplicity is the key to planning, developing, implementing, and operating a Web-based infrastructure. Endeavor to minimize Web-based infrastructure points of control and contention, as well as the introduction of variables.

Marcus and Stern's book[8] is an excellent reference for preparing for and implementing highly available systems.

Reengineering the continuity planning process involves not only reinvigorating continuity planning processes, but also ensuring that Web-based enterprise needs and expectations are identified and met through the implementation of continuous availability disciplines.

Summary

The failure of organizations to measure the success of their CP implementations has led to an endless cycle of plan development and decline. The primary reason for this is that a meaningful set of CP measurements has not been adopted to fit the organization's future-state goals. Because these measurements are lacking, expectations of both top management and those responsible for CP often go unfulfilled. Statistics gathered in the *Contingency Planning & Management/KPMG Continuity Planning Survey* support this assertion. Based on this, a radical change in the manner in which organizations undertake CP implementation is necessary. This change should include adopting and utilizing the business process improvement (BPI) approach for CP. This BPI approach has been implemented successfully at many Fortune 1000 companies over the past 20 years. Defining CP as a process, applying the concepts of the CP value journey, expanding CP measurements utilizing the CP balanced scorecard, and exercising the organizational change management (OCM) concepts will facilitate a radically different approach to CP. Finally, because Web-based business processes require 24×7 uptime, implementation of continuous availability disciplines are necessary to ensure that the CP process is as fully developed as it should be.

The Role of Continuity Planning in the Enterprise Risk Management Structure

Carl Jackson, CISSP, CBCP

Driving Continuity Planning to the Next Level

Traditional approaches to IT-centric disaster planning emphasized the need to recover the organization's technological and communications platforms. Today, many organizations have shifted away from focusing strictly on technology recovery and more toward continuity of prioritized business processes and the development of specific business process recovery plans. In addition, continuity planners are also beginning to articulate the value of a fully functioning and ongoing continuity planning (CP) business process to the enterprise, and not just settling for BCP as usual. In fact, many organizations are expanding the CP business process beyond traditional boundaries to combine and support a larger organizational component, i.e., enterprise risk management (ERM) functionality.

The purpose of this chapter is to discuss the role of continuity planning business processes in supporting an enterprise view of risk management and to highlight how the ERM and CP organizational components, working in harmony, can provide measurable value to the enterprise, people, technologies, processes, and mission. The chapter also focuses briefly on additional continuity process improvement techniques.

If not already considered a part of the organization's overall enterprise risk management program, why should business continuity planning professionals seriously pursue aligning their continuity planning programs with ERM initiatives? The answer follows.

The Lack of Meaningful Metrics

Lack of suitable business objectives-based metrics has forever plagued the CP profession. As CP professionals, we have for the most part failed to sufficiently define and articulate a high-quality set of metrics by which we would have management gauge the success of CP business processes. So often, we allow ourselves to be measured either by way of fiscal measurements (i.e., cost of hot-site contracts, cost of software, cost of head count, etc., all in comparison to some ill-defined percentage of the annual IT budget), or in terms of successful or nonsuccessful CP tests, or in the absence of unfavorable audit comments.

On the topic of measurement, the most recent Contingency Planning & Management/KPMG 2002 Business Continuity Planning Survey,[1] (http://www.contingencyplanning.com/) had some interesting insights. When asked how their organization measured the performance of their BCP program, survey respondents answered as shown in Exhibit 136.1.

EXHIBIT 136.1 How Does an Organization Measure the Performance of Its BCP Program?

	Percent
Service-level monitoring	26
Results of BCP testing	54
Audit findings	40
Performance reviews	30
Benchmarking/comparison to industry norms	14

This annual BCP survey makes it clear that rather than measure CP program effectiveness based on value-added contributions to enterprise value drivers, management continues to base CP performance on the results of tests or on adverse audit comments.

Shareholder Expectations

Should shareholders hold an executive manager responsible for overall enterprise performance? Or should management be held accountable for the success or failure of individual board of director votes, or one or two tactical decisions in support of strategic goals? Overall enterprise performance against revenue, profit, and marketplace goals is the usual answer given to these questions. Tactical decisions made to achieve those goals sometimes are successful and sometimes they are not, but it is the overall effect that is important.

Rather than being measured on quantitative financial measures only, why should the CP profession not consider developing both quantitative *and* qualitative metrics that are based on the value drivers and business objectives of the enterprise? We need to be phrasing CP business process requirements and value contributions in terms with which executive management can readily identify. Consider the issues from the executive management perspective. They are interested in ensuring that they can support shareholder value and clearly articulate this value in terms of business process contributions to organizational objectives. As we recognize this, we need to begin restructuring how the CP processes are measured. Many organizations have redefined or are in the process of redefining CP as part of an overarching ERM structure. The risks that CP processes are designed to address are just a few of the many risks that organizations must face. Consolidation of risk-focused programs or organizational components, like information security, risk management, legal, insurance, etc., makes sense; and in most cases capitalizes on economies of scale.

Given this trend, consider the contribution an enterprise risk management program should make to an organization.

The Role of Enterprise Risk Management

The Institute of Internal Auditors (IIA), in its publication, *Enterprise Risk Management: Trends and Emerging Practices*,[2] describes the important characteristics of a definition for ERM as:

- Inclusion of risks from all sources (financial, operational, strategic, etc.) and exploitation of the "natural hedges" and "portfolio effects" from treating these risks in the collective
- Coordination of risk management strategies that span:
  - — Risk assessment (including identification, analysis, measurement, and prioritization)
  - — Risk mitigation (including control processes)
  - — Risk financing (including internal funding and external transfer such as insurance and hedging)
  - — Risk monitoring (including internal and external reporting and feedback into risk assessment, continuing the loop)
- Focus on the impact to the organization's overall financial and strategic objectives

According to the IIA, the true definition of ERM is "dealing with uncertainty" and is defined by them as "a rigorous and coordinated approach to assessing and responding to all risks that affect the achievement of an organization's strategic and financial objectives. This includes both upside and downside risks."

It is the phrase "coordinated approach to assessing and responding to all risks" that is driving many continuity planning and risk management professionals to consider proactively bundling their efforts under the banner of ERM.

Trends

What are the trends that are driving the move to include traditional continuity planning disciplines within the ERM arena? Following are several examples of the trends that clearly illustrate that there are much broader risk issues to be considered, with CP being just another mitigating or controlling mechanism.

- *Technology risk:* To support mission-critical business processes, today's business systems are complex, tightly coupled, and heavily dependent on infrastructure. The infrastructure has a very high degree of interconnectivity in areas such as telecommunications, power generation and distribution, transportation, medical care, national defense, and other critical government services. Disruptions or disasters cause ripple effects within the infrastructure with failures inevitable.
- *Terrorism risk:* Terrorists have employed low-tech weapons to inflict massive physical or psychological damage (box cutters, anthrax-laden envelopes). Technologies and tools that have the ability to inflict massive damage are getting cheaper and easier to obtain every day, and are being used by competitors, customers, employees, litigation teams, etc. Examples include:
- *Cyber-activism:* The Electronic Disturbance Theater and Floodnet, which conducts virtual protests by flooding a particular Web site in protest
- *Cyber-terrorism:* NATO computers hit with e-mail bombs and denial-of-service attacks during the 1999 Kosovo conflict.
- *Legal and regulatory risk:* There is a large and aggressive expansion of legal and regulatory initiatives, including the Sarbanes–Oxley Act (accounting, internal control review, executive verification, ethics and whistleblower protection), HIPAA (privacy, information security, physical security, business continuity), Customs-Trade Partnership Against Terrorism (process control, physical security, personnel security), and the Department of Homeland Security initiatives, including consolidation of agencies with various risk responsibilities.
- *Recent experience:* Recent events including those proclaimed in headlines and taking place in such luminary companies as Enron, Arthur Andersen, WorldCom, Adelphia, HealthSouth, and GE have shaken the grounds of corporate governance. These experiences reveal and amplify underlying trends impacting the need for an enterprise approach to risk management.

Response

Most importantly, the continuity planner should start by understanding the organization's value drivers, those that influence management goals and answer the questions as to how the organization actually works. Value drivers are the forces that influence organizational behavior, how the management team makes business decisions, and where it spends its time, budgets, and other resources. Value drivers are the particular parameters that management expects to impact its environment. Value drivers are highly interdependent. Understanding and communicating value drivers and the relationship between them are critical to the success of the business to enable management objectives and prioritize investments.

In organizations that have survived through events such as September 11, 2001, the War on Terrorism, Wall Street roller coasters, world economics, and the like, there is a realization that ERM is broader than just dealing with insurance coverage. The enterprise risk framework is similar to the route map pictured in Exhibit 136.2. Explanations of the key components of this framework are as follows:

Business Drivers

Business drivers are the key elements or levers that create value for stakeholders, and particularly shareholders. Particular emphasis should be made on an organization's ability to generate excess cash, and the effective use of that cash. Business drivers vary by industry; however, they will generally line up in four categories:

1. *Manage growth:* Increasing revenue or improving the top line is achieved in many ways, such as expanding into new markets, overseas expansion, extending existing product lines, developing new product areas, and customer segments.

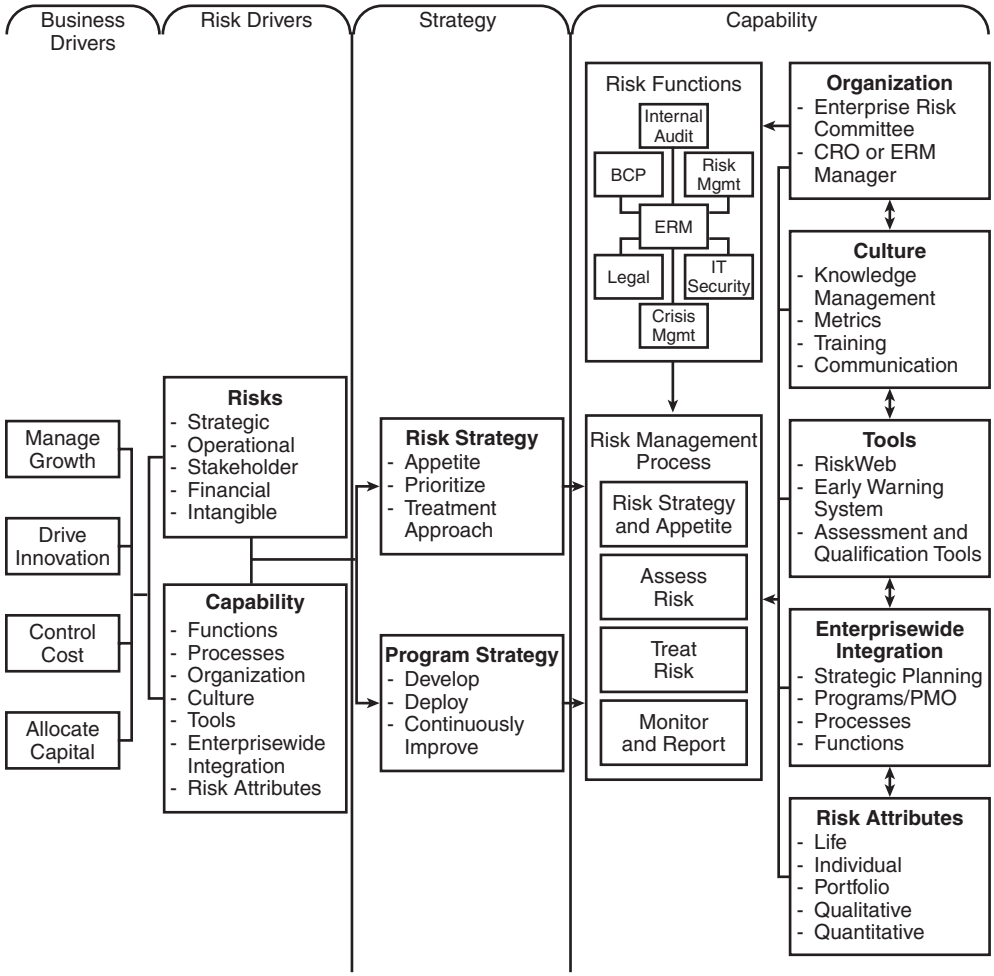

EXHIBIT 136.2 Enterprise risk management framework.

2. *Drive innovation:* The ability to create new products and markets through product innovativeness, product development, etc. New products and markets often give the creator a competitive advantage, leading to pricing power in the market, which allows the company to generate financial returns in excess of its competition.
3. *Control costs*: Effectively managing cost increases the competitive positioning of the business and the amount of cash left over.
4. *Allocate capital:* Capital should be effectively allocated to those business units, initiatives, markets, and products that will have the highest return for the least risk. These are the primary business drivers; they are what the organization does and the standards by which it expects to be measured.

Risk Drivers

Both the types of risk and the capability of the organization to manage those risks should be considered.

- *Risk types*: The development of a risk classification or categorization system has many benefits for an organization. The classification system creates a common nomenclature that facilitates discussions about risk issues within the organization. The system also facilitates the development of information systems that gather, track, and analyze information about various risks, including the ability to correlate cause

and effect, identify interdependencies, and track budgeting and loss experience information. Although many risk categorization methods exist, Exhibit 136.3 provides examples of risk types and categories.

- *Risk capability:* The ability of the organization to absorb and manage various risks, including how well the various risk management-related groups work together, what the risk process is within the enterprise, what organizational cultural elements should be considered, etc. The key areas of the risk capability will be discussed in greater detail later.

Risk Strategy

The strategy development section focuses management attention on both risk strategy and program strategy.

- *Risk appetite:* Of importance in the risk strategy is the definition of appetite for risk. Risk appetite levels need to be set for various types of impacts. Each risk level should have a corresponding response that then is cascaded throughout the organization.
- *Prioritization*: Based on the risk level, the inventory of risks should be prioritized and considered for the treatment approach.
- *Treatment approach*: Although most continuity planners focus on reducing risk through contingency planning, many alternatives exist and should be thoroughly considered.
  - — *Accept risk:* Management decides to continue operations as-is with a consensus to accept the inherent risks.
  - — *Transfer risk:* Management decides to transfer the risk, for example, from one business unit to another or from one business area to a third party (i.e., insurer).
  - — *Eliminate risk:* Management decides to eliminate risk through the dissolution of a key business unit or operating area.
  - — *Acquire risk:* Management decides that the organization has a core competency managing this risk, and seeks to acquire additional risk of this type.
  - — *Reduce risk:* Management decides to reduce current risks through improvement in controls and processes.
  - — *Share risk:* Management attempts to share risk through partnerships, outsourcing, or other risk-sharing approaches.

Program Strategy

Business continuity planning programs, like all other risk management programs, require strategic planning and active management of the program. This includes developing a strategic plan and implementation work plans, as well as obtaining management support, including required resources (people, time, and funding) necessary to implement the plan.

EXHIBIT 136.3 Risk Types and Categories

Strategic	Operational	Stakeholder	Financial	Intangible
Macro trends	Business interruption	Customers	Transaction fraud	Brand/reputation
Competitor	Privacy	Line employees	Credit	Knowledge
Economic	Marketing	Management	Cash management	Intellectual property
Resource allocations	Processes	Suppliers	Taxes	Information systems
Program/project	Physical assets	Government	Regulatory compliance	Information for decision making
Organization structure	Technology infrastructure	Partners	Insurance	
Strategic planning	Legal	Community	Accounting	
Governance	Human resources			
Brand/reputation				
Ethics				
Crisis				
Partnerships/JV				

Capabilities

The risk management capability speaks to the ability of the organization to effectively identify and manage risk. Following is a list of some of the key elements that make up the risk management capability:

- *Risk Functions*: Various risk management functions must participate, exchange information and processes, and cooperate on risk mitigation activities to fully implement an ERM capability. Some of these risk management functions might include:
  - Business continuity planning
  - Internal audit
  - Insurance
  - Crisis management
  - Privacy
  - Physical security
  - Legal
  - Information security
  - Credit risk management

Defining Risk Management Processes

Effective risk management processes can be used across a wide range of risk management activities, including:

- Risk strategy and appetite
  - Define risk strategy and program
  - Define risk appetite
  - Determine treatment approach
  - Establish risk policies, procedures, and standards
- Assess risk
  - Identify and understand value and risk drivers
  - Categorize risk within the business risk framework
  - Identify methods to measure risk
  - Measure risk
  - Assemble risk profile and compare to risk appetite and capability
- Treat risk
  - Identify appropriate risk treatment methods
  - Implement risk treatment methods
  - Measure and assess residual risk
- Monitor and report
  - Continuously monitor risks
  - Continuously monitor risk management program and capabilities
  - Report on risks and effectiveness of risk management program and capabilities

Organization

A Chief Risk Officer (CRO), an enterprise risk manager, or even an enterprise risk committee may manage the enterprise risk management activities. Their duties would typically include:

- Provide risk management program leadership, strategy, and implementation direction.
- Develop risk classification and measurement systems.
- Develop and implement escalation metrics and triggers (events, incidents, crisis, operations, etc.).
- Develop and monitor early warning systems based on escalation metrics and triggers.
- Develop and deliver organizationwide risk management training.

- Coordinate risk management activities; some functions may report to the CRO, others will be coordinated.

Culture

Creating and maintaining an effective risk management culture is very difficult. Special consideration should be given to the following areas:

- *Knowledge management:* Institutional knowledge about risks, how they are managed, and experiences by other business units should be effectively captured and shared with relevant peers and risk managers.
- *Metrics:* The accurate and timely collection of metrics is critical to the success of the risk management program. Effort should be made to connect the risk management programs to the Balanced Scorecard, EVA, or other business management and metrics systems.
  - The Balanced Scorecard is a management system (not only a measurement system) that enables organizations to clarify their vision and strategy and translate them into action. It provides feedback around both the internal business processes and external outcomes to continuously improve strategic performance and results. When fully deployed, the Balanced Scorecard transforms strategic planning from an academic exercise into the reality of organizational measurement processes.[3]
  - EVA (Economic Value Added) is net operating profit minus an appropriate charge for the opportunity cost of all capital invested in an enterprise. As such, EVA is an estimate of true "economic" profit, or the amount by which earnings exceed or fall short of the required minimum rate of return that shareholders and lenders could get by investing in other securities of comparable risk. Stern Stewart developed EVA to help managers incorporate two basic principles of finance into their decision making. The first is that the primary financial objective of any company should be to maximize the wealth of its shareholders. The second is that the value of a company depends on the extent to which investors expect future profits to exceed or fall short of the cost of capital.[4]
- *Training:* Effective training programs are necessary to ensure that risk management programs are effectively integrated into the regular business processes. For example, strategic planners will need constant reinforcement in risk assessment processes.
- *Communication:* Frequent and consistent communications around the purpose, success, and cost of the risk management program are a necessity to maintain management support and to continually garner necessary participation of managers and line personnel in the ongoing risk management program.
- *Tools:* Appropriate tools should be evaluated or developed to enhance the effectiveness of the risk management capability. Many commercial tools are available and their utility across a range of risk management activities should be considered. Quality information about risks is generally difficult to obtain and care should be exercised to ensure that information gathered by one risk function can be effectively shared with other programs. For example, tools used to conduct the business impact assessment should facilitate the sharing of risk data with the insurance program.
- *Enterprisewide Integration:* The ERM and BCP programs should effectively collaborate across the enterprise and should have a direct connection to the strategic planning process, as well as the critical projects, initiatives, business units, functions, etc. Broad, comprehensive integration of risk management programs across the organization generally lead to more effective and efficient programs.

Risk Attributes

Risk attributes relate to the ability or sophistication of the organization to understand the characteristics of specific risks, including their life cycle, how they act individually or in a portfolio, and other qualitative or quantitative characteristics.

- *Life Cycle:* Has the risk been understood throughout its life cycle and have risk management plans been implemented before the risk occurs, during the risk occurrence, and after the risk? This obviously requires close coordination between the risk manager and the continuity planner.
- *Individual and Portfolio:* The most sophisticated organizations will look at each risk individually, as well as in aggregate or in portfolio. Viewing risks in a portfolio can help identify risks that are natural hedges

against themselves, and risks that amplify each other. Knowledge of how risks interact as a portfolio can increase the ability of the organization to effectively manage the risks at the most reasonable cost.

- *Qualitative and Quantitative:* Most organizations will progress from being able to qualitatively assess risks to being able to quantify risks. In general, the more quantifiable the information about the risk, the more treatment options available to the organization.

The Role of Continuity Planning

From the enterprise view, business continuity planning is an integral element of the risk functionality as mentioned earlier. The main message is that the control functions should be organized and exercised in a planned manner for the good of the enterprise.

A well-constructed and implemented enterprisewide approach to continuity planning enables an organization to deal effectively with a major business disruption. Continuity planning is a process that minimizes the impact on an organization's time-critical business processes given significant disruptive events such as power outages, natural disasters, accidents, acts of sabotage, or other such occurrences. The CP process is intended to help management develop cost-effective approaches to ensuring continuity during and after an interruption of time-critical processes, supporting systems, and resources. An effective planning structure will address the information required and steps involved in recovering and maintaining time-critical business processes — the lifeblood of an organization. Continuity planning services should be designed to assist in the development, implementation, and maintenance of effective continuity plans focused on the unique needs of the organization.

The CP process also includes assessing and improving the overall Crisis Management Planning (CMP) infrastructure of the organization. CMP focuses on assisting the organization to develop an effective and efficient enterprisewide emergency and disaster response capability. This response capability includes forming appropriate management teams and training team members in reacting to serious company emergency situations (i.e., hurricane, earthquake, flood, fire, serious hacker or virus damage, etc.).

The continuity planning approach consolidates three traditional continuity-planning disciplines as follows:

1. IT disaster recovery planning (DRP). Traditional disaster recovery planning addresses the restoration planning needs of the organization's IT infrastructures, including centralized and decentralized IT capabilities, and includes both voice and data communications network support services.
2. Business continuity planning (BCP). Traditional BCP addresses continuity of an organization's business operations (i.e., Accounting, Procurement, HR, etc.) should they lose access to their supporting resources (i.e., IT, communications network, facilities, external agent relationships, etc.).
3. Crisis management planning (CMP). CMP focuses on assisting the organization to develop an effective and efficient enterprisewide emergency and disaster response capability. This response capability includes forming appropriate management teams and training their members in reacting to serious company emergency situations (i.e., hurricane, earthquake, flood, fire, serious hacker or virus damage, etc.) to at least minimize but avoid (hopefully) a disaster. CMP also encompasses response to life-safety issues for personnel during a crisis or response to disaster. Nowhere is the need for effective risk management capabilities more evident than at a time of managing a crisis. In light of the recent headline incidents of corporate meltdowns, global terrorism, and a rapidly changing business environment, boards of directors and senior management must now take the time to reassess their organizations' crisis and enterprise risk management (ERM) capabilities.

The key components of the continuity planning development methodology are discussed next.

Assessment Phase

- *Business impact assessment (BIA):* During this process, an organization's business objectives and processes are examined to determine the impact of loss or interruption of service on the overall business. The goal of the BIA is to prioritize business processes and assign the recovery time objective (RTO) for their recovery and the recovery of their support resources. An important outcome of this activity is the mapping of time-critical processes to their support resources (i.e., IT applications, networks, facilities, third parties, etc.).

- *CP process current state assessment:* This process involves analyzing the organization's environment to gauge the health and vitality of the continuity planning process. This process also involves identifying or determining how the organization values the CP process and measures its success (an often-overlooked process and one that frequently leads to the failure of the CP process).
- *Risk management review (RMR):* During this process, potential risks and vulnerabilities are assessed and strategies and programs are developed to mitigate or eliminate those risks. Using traditional qualitative risk assessment approaches that focus on the security of physical, environmental, and information capabilities of the organization can support this process. In general, the RMR should identify or discuss seven basic areas:

  1. Potential threats
  2. Physical security
  3. Recoverability of time-critical processes and support resources
  4. Single points of failure
  5. Problem and change management
  6. Business interruption and extra-expense insurance
  7. A critical system off-site storage program

Design Phase

- *Leading practices/benchmarking services:* This optional component encompasses reviewing the performance of industry and peer benchmarking studies to determine leading practices, which can then be used to help establish the most appropriate Future State Vision for the organization's CP infrastructure.
- *Recovery strategy visioning:* This interactive, facilitated process includes developing an appropriate and measurable CP process. Major organization stakeholders can use this technique to develop the best possible overall CP process by encouraging input and buy-in.
- *Recovery strategy development:* This practice involves facilitating a workshop or series of workshops designed to determine and document the most appropriate recovery alternative to CP challenges (i.e., determining whether a hot site is needed for IT continuity purposes; whether additional communications circuits should be installed in a networking environment; whether additional workspace is needed in a business operations environment, etc.) using the information derived from the business impact assessments. From these facilitated workshops, the CP development team works with the organization teams to create a business case documenting the optimal recovery alternative solutions.
- *Continuity plan development:* During plan development, the recovery team members are selected, assigned, and formally documented. The detailed activities and tasks associated with the recovery of time-critical processes (or IT infrastructure components, etc.) are detailed and assigned to recovery team members. All the inventory information needed by the recovery team members is also collected and documented, including data, software, telecommunications, people, space, documentation, offsite workspace, equipment, etc.
- *CP testing, maintenance, training, and measurement:* During this process, the CP development team works with the organization management to design appropriate CP testing, maintenance, training, and measurement strategies and guidelines.

Implement Phase

- *Plan testing:* During plan testing, the CP development team works with business unit leaders to simulate potential disasters and test continuity plans for effectiveness. Any necessary adjustments and modifications are incorporated into the plan.
- *CP process implementation:* During this phase, the development team will work with the organization to deploy the continuity plans that have been developed, and to implement long-term testing, maintenance, training, and measurement strategies, as determined in the Design Phase.
- *Continuity and crisis management plan implementation:* During this phase, the initial versions of the continuity and crisis management plans are implemented across the enterprise environment.

Measure Phase

The continuity plan and process review and maintenance phase involves the regular review and maintenance of the continuity and crisis management plans.

Other Techniques for Improving CP Efficiencies

In combination with the introduction of ERM disciplines in improving the CP function, traditional CP Process Improvement, Organizational Change Management, and Balanced Scorecard techniques can also be used to assist in improving the efficiencies of continuity planning business processes.

CP Process Improvement

Harrington et al., in *Business Process Improvement Workbook*,[5] point out that applying process improvement approaches can often cause trouble unless the organization manages the change process. They state that

> …approaches like reengineering only succeed if we challenge and change our paradigms and our organization's culture. It is a fallacy to think that we can change the processes without changing the behavior patterns or the people who are responsible for operating these processes.

The Need for Organizational Change Management

The plans may be ready for the company, but the company may not be ready for the plans. Organizational change management concepts, including the identification of people enablers and barriers, and the design of appropriate implementation plans that change behavior patterns, play an important role in shifting the CP project approach to one of CP process improvement.

> There are a number of tools and techniques that are effective in managing the change process, such as pain management, change mapping, and synergy. The important thing is that every BPI program must have a very comprehensive change management plan built into it, and this plan must be effectively implemented.[5]

How Can We Measure Success? The Balanced Scorecard Concept

A complement to the CP Process Improvement approach is the establishment of meaningful measures or metrics that the organization can use to weigh the success of the overall CP process. This concept was mentioned briefly when discussing development of metrics that fit the culture of the organization. Traditional CP measures have included:

- How much money is spent on hot sites?
- How many people are devoted to CP activities?
- How many adverse audit comments have been brought to management's attention?

Instead, the focus should be on measuring the CP process contribution to achieving the overall goals of the organization, as mentioned in the ERM discussion. This focus helps us to:

- Identify agreed-upon CP development milestones
- Establish a baseline for execution
- Validate CP process delivery
- Establish a foundation for management satisfaction to successfully manage expectations

The *CP Balanced Scorecard* includes a definition of the:

- Value Statement
- Value Proposition
- Metrics and assumptions on reduction of CP risk
- Implementation Protocols
- Validation Methods

Following this Balanced Scorecard[6] approach, and aligning development of the scorecard with the ERM business and risk drivers mentioned earlier, the organization could define what the future-state of the CP process should look like. This future-state definition should be co-developed by the organization's top management and those responsible for development of the CP process infrastructure. Current State/Future State Visioning is a technique that can also be used for developing expectations for the Balanced Scorecard. Once the future-state vision is defined, the CP process development group can outline the CP process implementation critical success factors in the areas of:

- Growth and innovation
- Customer satisfaction
- People
- Process quality
- Financial state

These measures must be uniquely developed based on the specific organization's culture and environment.

Next Steps

What can the CP professional do within his organization to begin considering the feasibility of shifting the continuity planning processes under the ERM umbrella? One suggestion might be to identify the Enterprise Risk Committee or other suitable risk management organizational components within the company and initiate discussions relative to some of the issues raised in this chapter. In addition, depending on the industry group your organization is in, there may well be industry leading practices or examples of other organizations that have undertaken this course of action. You may well be able to profit from the experiences of others. There are professional societies such as the Risk and Insurance Managers Society, Inc. (http://www.rims.org/) and the Institute of Internal Auditors (http://www.theiia.org) where additional information can be obtained on this subject.

Summary

The failure of organizations to measure the success of their CP implementations has led to what seems like an endless cycle of plan development and decline. The chief reason for this cycle is that a meaningful set of CP measurements that complement the organization's business drivers have not been adopted. Because these measurements are lacking, expectations, reasonable or otherwise, of both executive management and those responsible for CP often go unfulfilled. Statistics gathered in the Contingency Planning and Management/KPMG Continuity Planning Survey support this assertion.

A true understanding of business objectives and their value-added contributions to overall business goals is a powerful motivator for achieving success on the part of the CP manager. There are many value drivers of strategic (competitive forces, value chains, key capabilities, dealing with future value, business objectives, strategies and processes, performance measures, etc.), financial (profits, revenue growth, capital management, sales growth, margin, cash tax rate, working capital, cost of capital, planning period and industry-specific subcomponents, etc.), and operational value (customer or client satisfaction, quality, cost of goods, etc.) that the CP professional should focus on, not only during the development of successful continuity planning strategies, but also when establishing performance measurements.

This chapter has introduced the role of continuity planning business processes in supporting an enterprise view of risk management, and to highlight how, working in harmony, the ERM and CP functions can provide measurable value to the enterprise, people, technologies, processes, and mission. It is incumbent upon continuity planning managers and enterprise risk managers to search for a way to merge efforts to create a more effective and efficient risk management structure within the enterprise.

Acknowledgment

Special thanks go to Mark Carey, President, DelCreo, Inc., for his valuable contributions to this chapter.

Business Continuity in the Distributed Environment

Steven P. Craig

This chapter describes the process of business recovery planning with an emphasis on the considerations for LANs and the components that comprise the LAN. The considerations of this chapter can be applied to companies of any size with a recovery scope from operational to catastrophic events.

INTRODUCTION

Today's organizations, in their efforts to reduce costs, are streamlining layers of management while implementing more complex matrices of control and reporting. Distributed systems have facilitated the reshaping of these organizations by moving the control of information closer to its source, the end user. In this transition, however, secure management of that information has been placed at risk. Information Technology Departments must protect the traditional system environment within the computer room plus develop policies, standards, and guidelines for the security and the protection of the company's information base. Further, the information technology staff must communicate these standards to all users to enforce a strong baseline of controls.

In these distributed environments, information technology personnel are often asked to develop system recovery plans outside the context of an overall business recovery scheme. Recoverability of systems, however, should be viewed as only one part of business recovery. Information Systems, in and of themselves, are not the lifeblood of a company; inventory, assets, processes, and people are all essential factors that must be considered in the business continuation design. The success of business continuity planning rests on a company's ability to integrate systems recovery in the greater overall planning effort.

BUSINESS RECOVERY PLANNING — THE PROCESS

Distinctive areas must be addressed when formulating a company's business disaster recovery plan that follow the stages of the scientific process, namely; the statement of the problem, development of an hypothesis, and testing of the hypothesis. Most importantly, as with any scientifically developed process, the Disaster Recovery Planning Process development is iterative! The testing phase of this process identifies whether or not the plan will work in practice, not just in theory. It is imperative that the plan and its assumptions be tested, tested, and re-tested. The important distinction about disaster recovery planning, and the importance of its viability, is what is at stake — namely the survivability of the business!

The phases of a viable disaster recovery plan process are

- Awareness and Discovery
- Risk Assessment
- Mitigation
- Preparation
- Testing
- Response and Recovery

Some of these phases may be combined, depending on the size of the company and the extent of exposure to risk. However, these phases are distinct and discussed more in length in the following sections.

Awareness and Discovery

Awareness begins when a recovery planning team can identify both possible threats and plausible threats to business operations. The more pressing issue for an organization in terms of business recovery planning is that of plausible threats. These threats must be evaluated by recovery planners and their planning efforts, in turn, will depend on these criteria:

1. The business of the company.
2. The area of the country in which the company is located.
3. The company's existing security measures.
4. The level of adherence to existing policies and procedures.
5. Management's commitment to existing policies and procedures.

Awareness is also education! Part of the awareness process consists of instructing all employees on what exposures exist for the company and themselves; what measures have been taken to minimize those exposures; and what their individual roles are in complying with those measures.

Pertaining to systems and information: what exposures are there; what information is vital to the organization; and, what information is proprietary and confidential to the business? Also with respect to systems,

another question that needs to be addressed is, when is an interruption considered to be catastrophic as opposed to operational? Again, this needs to be answered on a company-by-company basis. In an educational environment the systems being down for two to three days may not be considered catastrophic, however, in a process control environment (e.g. chemicals or electronics) a few minutes of down time might be considered catastrophic.

Discovery is determining the extent of the exposure and the extent of recovery planning and of the security measures that should be taken. Based on the response to the awareness question, what is plausible; there are more questions to be asked: what specific operations would be impacted by the exposures; what measures are in place or could be put in place to minimize those exposures; and, what measures could be taken to remove the exposure?

Risk Assessment

Risk assessment is a decision process that weighs the cost of implementing preventative measures against the risk of loss from not taking any action. There are qualitative and quantitative approaches to risk analysis of which there are full text references written on the subject. Typically for the systems environment, in terms of outright loss, two major cost factors arise. The first is the loss from not conducting business due to system down time. The second is the replacement cost of the equipment. The unavailability of systems for an extended period of time is the easiest intuitive sell, as it is readily understandable by just about everyone in today's organizations as to how much they rely on systems.

The cost to replace systems and information, however, is often not well understood, at least not from a catastrophic loss point of view. In many instances, major organizations, when queried on insurance coverage for systems, come up with some surprising results. There will typically be coverage for mainframes and mid-range systems, as well as coverage for the software for these environments, but when it comes to the workstations or the network servers they are deemed as not worth enough to insure. Another gaping hole is the lack of coverage for the information itself. The major replacement cost for a company is the recreation of its information base.

Further, the personal computer (PC), no matter how it is configured or what it is hooked up to or how extensive the network, is still perceived to be a stand alone unit from the risk assessment point of view. Even though many companies have retired their mainframes and fully embraced an extensive client/server architecture to fully manage their businesses, and fully comprehend the impact of the loss of its use, they erroneously look at

the replacement cost of the unit rather than the distributed system as the basis of risk.

Risk Assessment is the control point of the recovery planning process. The amount of exposure a company believes it has, or is willing to accept, determines how much additional effort the company will put forth on this process. Quite simply, a company with no plan is taking on the full risk of exposure, assuming that nothing, at least nothing severe, will ever happen to them. Companies that have developed plans have decided on the extent of risk assumption in two ways: (1) they have identified their "worst case scenario"; (2) they have made decisions based on how much they will expend in offsetting that scenario through mitigation, contingency plans, and training. Risk Assessment is the phase required to gel a company's management perspective, which in turn supports the goal to develop and maintain a company-wide contingency plan.

Mitigation

Mitigation has two primary objectives: lessen the exposures and minimize possible loss. History teaches us several lessons in this area. You can be sure that companies in Chicago now think twice about installing data centers in the basement of buildings after the underground floods of 1992. Bracing of key computer equipment and of office furniture has become popular in California due to the potential injuries to personnel and the threat of loss of assets from earthquakes. And, forward thinking companies in the South and Southern Atlantic states are installing systems far from the exterior of the buildings and windows because of the potential damage due to hurricanes.

Once again, from a more operational perspective, you can read story after story in the trade journals about back-up schemes gone awry, if there was a back-up performed at all! Although it is a simple concept, to make a back up copy of key data and systems, it is a difficult one to enforce in a distributed systems environment. To wit, as systems have been distributed and the end-user has been empowered, the regimen of daily or periodic back ups has diminished. The end-user has been empowered with the tools but not given the responsibility that goes along with the use of those tools. I recently went into a company, one of the leaders in the optical disk drive market, and found that it did perform daily backups to optical disk (using its own product) of its accounting and manufacturing systems; but they never rotated the media and never thought to take it off site! Any event impacting the hardware (e.g., fire, theft, earthquake) would have also destroyed the "only backup" and the means of business recovery for this premier company.

Preparation

This phase of your disaster planning process delineates what must be done in addition to the mitigation taken, should an event occur. Based on the perception of what could happen; who will take what actions? Are alternates identified for key staff members that may have been injured as a result of the event? Can the building be occupied, if not, where will temporary operations be set up? What supplies, company records, etc., will be required to operate from a temporary facility? What computer support will be required at the temporary location? Will a hot site be used for systems and telecommunications? What vendors and services providers need to be contacted; and further, do you have access to their off-hours phone numbers, emergency numbers, or home phone numbers? These are all questions that need to be addressed, contingencies established, and the plans documented as an integral part of your disaster preparedness process.

Testing

As mentioned above, the testing phase proves out the viability of your planning efforts. If there are omissions in your plan, or invalid assumptions, or inadequately postulated solutions... this is where you want to find these things out! Not at the time of an actual event! Additionally, organizations do not remain static; the elements of change within an organization and its environment dictate a reasonable frequency of testing. This is the phase of your plan you must afford to reiterate until you are comfortable with the results and that your plans will work in time of crisis. Section 3.0 covers testing more in-depth and proposes a testing strategy made available by the use of distributed systems.

Response and Recovery

Most of us carry auto insurance, home insurance, professional liability insurance and life insurance, yet we hope we'll never have to use it or rely on it. Well, this is the phase of your contingency plan you hope you never have to use! This part of your plan details what individuals will take on specific roles as part of predetermined teams, trained to address the tasks of: emergency response, assessment of damage, clean-up, restoration, alternate site start-up, emergency operations center duties and whatever else managing through your crisis might demand.

Every phase of the planning process, prior to this phase, is based on normalcy. The planning effort is based on what is perceived to be plausible. Responses are envisioned to cover those perceptions, and are done so under rational conditions. Remember that people are an integral part of the response and recovery effort. Dealing with a catastrophic crisis is not a normal part of everyday life or of someone's work load.

You can expect very different reactions from individuals, you may think you knew well, under severe stress. A simple example, you may have experienced yourself, is being trapped in an elevator for several minutes. Within a couple of minutes, individual's personalities, anxieties, and fears start to surface. Some will begin to panic, others will start taking control of the situation. Here again, testing the plan may afford you some insight as to how your team members will react. Ideally you will be able to stage some tests that will involve "role playing" so as to give your team members a sense of what they may be exposed to and the conditions they will have to work under.

DEPARTMENTAL PLANNING

Time and time again I will be asked to help a company develop its business resumption plan, only to be asked to focus just on the systems and ignore everything else; for the most obvious reason — cost. As it turns out, if a company receives an action item as a result of an audit, it is typically a part of an EDP audit and thus only targeted at the systems of a company. In turn, the company focuses only on the audit compliance, thus viewing disaster recovery as an expense, rather than the view of being an investment in business continuity.

Having a plan which addresses data integrity and systems survivability is a good start, but there is a lot more to consider. Depending on the nature of the business, telecommunications availability, as an example, may be much more important than systems availability. In a manufacturing environment, if the building and equipment were to be damaged, getting the systems up and running would not necessarily be the most important priority.

A company's Business Continuation Plan is, in fact, a compilation of its departmental plans. It is essential that each department identify its own processes and subsequent priorities of those processes. Overall company-wide operating and recovery priorities are then established by the company's management based on the input supplied by the departments. Information Technology, as a service department to all other departments, is subsequently in a much better position to plan recovery capacity and required system availability based on their inputs, priorities, and departmental recovery schedules.

INFORMATION TECHNOLOGY'S ROLE

Information Technology should not be responsible for creating the individual departmental plans for the rest of the company, but it can and indeed needs to take a leadership role in the departmental plan development. Information Technology has generally been the department that has the best appreciation and understanding of information flow throughout

the organization. It is therefore in the best position to identify and assess the following areas.

Inter-Departmental Dependencies

Many times in reviewing a company's overall plan and its departmental plans and their subsequent priorities, conflicts in the priorities will arise. This occurs because the departments tend to develop their plans on their own without the other departments in mind. One department may down play the generation of certain information, knowing it has little importance to its own operations, but it might be a vitally important input to the operation of another department. Information Technology can typically identify these priority discrepancies simply by being able to review each of the other department's plans.

External Dependencies

During the discovery process, recovery planners should determine with what outside services end-user departments are linked. End-user departments often tend to think of external services as being outside the scope of their recovery planning efforts, despite the fact that dedicated or unique hardware and software are required to use the outside services. At a minimum, make sure the departmental plans include the emergency contact numbers for the services and any company account codes that would permit linkage to the service from a recovery location. Also inquire as what provisions the outside service provider may have to assist your company in its recovery efforts.

Outsourced Operations

A 1990s trend in corporate strategic directions has been the outsourcing of entire department operations. The idea is to focus the company's resources on what it does best, and outsource the functions that it believed other companies could better handle as part of their expertise and focus. The idea sounds good in theory, but in practice this has been a mixed bag of tricks. The bottom line of this strategic direction was that it would add to the bottom line. Based on what is being published on the subject, the savings may only be a short-term result, and in fact be very costly in the long run. From a contingency planning perspective, what happens if the idea does not work; how does a company rebuild an Information Systems Department from scratch?

With respect to recovery planning, this is a key area that requires involvement at the earliest stages possible, including the review of contract wording and stipulations. This is an area in which the contractor has to be an integral partner, with as much ownership and jointly owned risk as the acquiring company. In many disasters, the Information Systems staffs

are the first responders for business recovery; will the contractor be as willing to take on this role? The recovery planner needs to validate that the on-site outsourced contractors are as well trained on response and recovery as the other internal departments. The area of systems is so integral to the recovery capability of the other departments that is it imperative that the outsourced information systems personnel be well versed in the recovery needs and response priorities of all of the departments they are there to support.

Collectively, the outsourcer may have considerably more resources available to it than the customer; however, it must be agreed to contractually that the contractor will bring its resources to bear in the event of the customer's catastrophe. Normally these outsourced arrangements start off with the greatest of intentions, but once things get under way and the conditions of systems, documentation, and operations are established — anything outside the scope of the contract is doable, but with incremental cost. Costs were what was intended to be cut when the outsourcing direction was decided upon, upping these costs will be a tough sell. So the recovery planner has to be involved early in the development of any such outsourcing contract and be sure to protect the company's contingency planning interests.

Internal and External Exposures

Stand-alone systems acquired by departments for a special purpose are often not linked to a company's networks. Consequently, they are often overlooked in terms of data security practices.

For example, a mortgage company funded all of its loans via wire transfer from one of three standalone systems. This service was one of the key operations of the company. Each system was equipped with a modem and a uniquely serialized encryption card for access to the wire service. As you might guess, these systems were not maintained by Information Technology; there were no data or system back-ups maintained by the end-user department; and, each system was tied to a distinct phone line. Any mishap involving those three systems could have potentially put this department several days, if not weeks, in arrears in funding its loans. A replacement encryption card and linkage establishment would have taken as much as a month under catastrophic conditions to re-establish.

As a result of this discovery, a secondary site was identified and a standby encryption card, an associated alternate phone line and a disaster recovery action plan were filed with the wire service. This one finding and its resolve more than justified the expense of the entire planning effort.

Another external exposure was identified for the same company during the discovery process dealing with power and the requirements of its UPS

capabilities. The line of questioning was on the sufficiency of battery back up capacity and whether an external generator should be considered as well for longer term power interruption. An assumption had been made that even in the event of an area wide disaster that power would probably be restored within 24 hours. The company had 8 hours of battery capacity which would suffice for the main operational shift of the company. At first I was in agreement with them, knowing that the county's power utility company had a program of restoring power on a priority basis for the larger employers of the county. When I mentioned this observation to them, I was corrected! They were in a special district and actually acquired their power from the city; and as a business would have power restored only after all the emergency services and city agencies were restored. The restoration period was unknown! The assumption of power restoration within 24 hours was revised and an external generator was added to the uninterruptable power supply system.

Systems themselves should not be the only type of exposure looked for. In a recent client discovery walk-through, a protracted construction project was underway. The existing computer room (on the eighth floor of a twenty story high rise) was being remodeled to house the company's latest generation of computers and telecommunications equipment. The room had originally been designed with standalone air conditioners, a UPS system, secured entry and a raised floor. Sprinklers had been eliminated from the room to avoid potential water damage and a Halon fire suppression system had been installed.

As a result of the construction, the computer equipment was temporarily moved to the adjoining computer technician's room. As you might guess, the technician's room had none of the protections that had been developed for the computer room. However, while there were short-term exposures (for length of the construction period) this was a known calculated risk. The actual exposure discovered was the computer room itself. During construction, the Halon fire suppression system and alarms had been turned off, as well as the stand alone air conditioning systems within. In addition a considerable amount of packing material had been accumulated within the room, so much so that it was stacked from floor to ceiling. The room was hot, from the lack of air conditioning. This was a fire waiting to happen. A fire needs fuel, oxygen, and heat _ all three readily existed in the room. If a fire were to start there were no active fire suppression capabilities within the room and with the alarms being turned off, it would have been well under way before the other building detection systems would have been alerted. A fire located here would have easily knocked out the central computing capability and telecommunications for the entire corporation as well as potentially destroying several floors of this corporate tower. Transition periods can be the times of greatest vulnerability for any

company, as existing detection and protection systems are temporarily shut down. The recovery planner needs to know that the planning process is reiterative, if the assumptions of the plan change, a review of all of the process steps is in order.

Apprise Management of the Risk

It is entirely management's decision on how much risk they are willing to take or deem what risks are unacceptable. However, as Information Technology identifies the various risks, it is their responsibility to make management aware of those risks. This holds true across the board on all security issues, be they system survivability issues (disaster recovery) or confidentiality or system integrity issues.

A company having its key system client files breached from the outside or a sales representative's laptop stolen with those key client files contained within, can be potentially more devastating to a company's operations than a prolonged power outage.

Apprise Management of Mitigation Cost

I find a tremendous amount of frustration in Information Technology departments these days, as departments have been "right-sized" and yet have to manage more complex systems than ever before. Many of the things that you will uncover will have such an obvious risk that obtaining approval for your mitigation campaigns should be relatively easy to obtain. Other system related topics are more intangible or in some cases deemed as being a "nuisance" are admittedly a tougher sell.

To cope with today's organizational demands and yet still feel "good" about the job it is performing, the Information Technology personnel responsible for this planning effort has to adapt to the changing times, anticipate the risks, and present to management the mitigation options and their associated costs; knowing that management will make a decision with the company's best interest in mind.

Policies

The best approach to begin an implementation of a system or data safeguard strategy is to first define and get approval from management on the policy or standard operating procedure that requires the safeguard be established. In assisting a community college in putting together a disaster recovery plan for its central computing operations, we discovered numerous departments had isolated themselves from the networks supported by the Information Technology group. The reason for this departure was the belief that the servers were always crashing, which was a cause for concern some three years ago, but no longer true. Yet to date, these

departments including Accounting, were processing everything locally on their hard drives with no back-ups whatsoever! This practice, now three years old, needed to be dispelled, as a disaster such as a fire in the Accounting Department would severely disrupt if not cause a cessation of the college's operations altogether. One of the other satellite campuses of the district, went entirely its own route and set up its own network with no ties to the central computing facility, and you guessed it, absolutely no back-ups at all!

We subsequently went back to the fundamentals; distribute the responsibility for data integrity along with the distributed system capability. A college policy statement on data integrity was made to the effect:

The recoverability and correctness of digitized data, which resides on college owned computer systems and media, is the responsibility of the individual user. The ultimate responsibility of ensuring the data integrity for each departmental workstation rests with the department/division administrator.

Information Technology will provide the guidelines for data back-ups. Adherence to these guidelines by the users of the college owned workstations is mandatory.

Establish Recovery Capability

Based on the inputs from the departments of the company and the company's overall priorities, Information Technology is challenged with designing an intermediate system configuration that is adequately sized to permit the company's recovery, immediately following the event. This configuration whether it be local, at an alternate company site, or a hot site needs to initially sustain the highest priority applications, yet be adaptable to expand to address other priorities; depending on how long it make take to re-occupy the company's facilities and fully restore all operations back to normal. You'll need to consider, for example, that the key Client/Server Applications may be critical to company operations whereas office automation tools may not.

Restore Full Operational Access

Information Technology's plan also needs to address the move back from an alternate site and what resources will be required to restore and resume full operations. Depending on the size of the enterprise and the disaster being planned for, this could include hundreds to thousands of end-user workstations. At a minimum, this step will be as complex as a move of your company to a new location.

PLANNING FOR THE DISTRIBUTED ENVIRONMENT

First and foremost, what are your marching orders? What is the extent to which your plan is to cover? Is it just the servers? Is it just the computers directly maintained by the Information Technology Department? Or is it the entire enterprise's systems and data that your are responsible for? Determining the extent of recovery is your first step, i.e., defining the scope of the project. The project scope, the overall company priorities, and the project funding will bracket the options you have in moving forward. But what follows in the next sections are some of the basics no matter what your budget. As you read through them, you'll find many of these ideas are founded in sound operational management, as they should be.

Protecting the LAN

There are two primary reasons why computer rooms are built: one, to provide special environmental conditions; and two, for control. Environmental conditions include: air conditioning, fire rated walls, dry sprinkler systems, special fire abatement systems (Halon, FM-200), raised flooring, cable chase-ways, equipment racking, equipment bracing, power conditioning, and continuous power (UPS systems), etc. "Control" includes a variety of factors, namely: access, external security, and internal security. All these aspects of protection (mitigation steps taken to offset the risk of fire, theft, malicious tampering, etc.,) were built-in benefits of the computer room. Yet if one walks around company facilities today, they will find servers and all sorts of network equipment on desk tops in open areas, on carts with wheels, in communication closets that are unlocked or with no conditioned power — yes, they're truly distributed and open! What's on those servers or accessible through those servers… just about anything and everything important to the company.

Internal Environmental Factors. A computer room is a viable security option, though there are some subtleties to designing one specifically for a client/server environment. If the equipment is to be all rack mounted, racking can be suspended from the ceiling, which still yields clearance from the floor avoiding possible water damage. Notably, the cooling aspects of a raised floor design, plus its ability to hide a morass of cabling are no longer needed in a distributed environment.

Conditioned power requirements have inadvertently modified computer room designs as well. If an existing computer room has a shunt trip by the exit but standalone battery backup units are placed on servers, planners must review their computer room emergency shutdown procedures. The idea of the shunt trip was to "kill all power" in the room, so that if operational personnel had to leave in a hurry, they would be able to come back later and reset systems in a controlled sequence. However, when

there are individual battery back-up units that sustain equipment in the room, the equipment connected to them will continue to run, even after the shunt is thrown, until the batteries run out!

Rewiring the room for all wall-circuits to run off the master UPS, in proper sequence with the shunt trip, is one way to resolve this conflict. However if the computer room houses mainframe, mid-range, and client/server equipment a different strategy might be required. Many of the client/server systems are designed to "begin" an orderly shut down once the cut over to battery power has been detected. This is not the case with all mid-range and mainframe systems.

There are instances when it would be better to allow an orderly shut down to occur, a short term power outage for example. While other times an instant shut off of all power would be required, as in the case of a fire or an earthquake.

The dilemma rests with the different requirements of the system platforms; the solution lies in the wiring of the room. One option is to physically separate the equipment into different rooms and wire each room according to the requirements of the equipment it contains. Another solution is a two-stage shunt approach: a red shunt would immediately shut off all power, as was always intended; a yellow shunt would cut all power except from the UPS, allowing the servers to initiate an orderly shut down on their own.

Room placement within the facility is also a consideration as pointed out earlier. If designing a room from scratch, identify an area with structural integrity, avoid windows, and eliminate overhead plumbing.

Alternate fire suppression systems are still a good protection strategy for all the expensive electronics and the operational, on-site tape back-ups within a room. If these types of systems are beyond your budget, consider multiple computer rooms (companies with a multiple building campus environment or multiple locations can readily adapt this as a recovery strategy). Equip the rooms with sprinklers; and keep some tarpaulins handy to throw over the equipment to protect the equipment from incidental water damage (a broken sprinkler pipe for example). A data safe may also be a worthwhile investment for the back-up media maintained on-site. However, if you go through the expense of using a safe, train your personnel to keep it closed! Eight out of ten site visits where a data safe is used, I'll find the door ajar (purely as a convenience). The safe only provides the protection to your media when it is sealed. If the standard practice is to keep it closed, then the personnel won't have to second guess, under the influence of adrenaline, whether or not they shut it as they evacuated the computer room.

If your company occupies several floors within a building and you maintain communication equipment (servers, hubs, modems, etc.) within the

closets; then treat them as a miniature computer room as well. Keep the doors to the closets locked and equip the closet with power conditioning and adequate ventilation.

Physical Security. The other aspect of a secured computer room was "control." Control (both internal and external to the company) of access to the equipment, cabling, and back-up media. Servers out in the open are prime targets for a range of mishaps from "innocent" tampering to outright theft. A thief, in stealing a server, not only gets away with an expensive piece of equipment but a potentially great amount of information; which, if the thief realizes it, may be several times more valuable and marketable than the equipment.

I mentioned earlier a college satellite campus that had no back-ups of the information contained within its network. I had explained to that campus administration, which by the way kept their servers out in the open of their administration office area that was in a temporary trailer, that a simple theft (equipment with a street value of $2000) would challenge their viability of continuing to operate as a college. All their student records, transcripts, course catalogs, instructor directories, financial aid records and more were maintained on their servers. With no back-ups to rely on and their primary source of information evaporated they would be faced with literally thousands of hours to re-construct their information bases.

Property Management. Knowing what and where the organization's computer assets (hardware, software, and information) are, at any moment in time, is critical to your recovery efforts. This may sound blatantly obvious, but remember we're no longer talking about the assets just within the computer room. Information Technology needs to be aware of: every workstation used throughout the organization, whether it is connected to a network or not (this includes portables); what its specific configuration is; what software resides on it; and, what job function it supports. This is readily doable, if all hardware/software acquisitions and installations are run through your department; and , the company's policies and procedures support your control (meaning that all departments and all personnel willingly adhere to the policies and procedures), and your property management inventory is properly maintained. Size is a factor here. If you manage an organization with a single server and fifty workstations, you may not deem this too large a task; however, if you support several servers and several hundred workstations, then you'll appreciate the amount of effort this can entail.

Data Integrity. Information is the one aspect of a company's systems that cannot be replaced, if lost or destroyed, simply by ordering another copy or another component. You can have insurance, "hot-site" agreements or

quick replacement arrangements for hardware and global license agreements for software, but your data integrity process is entirely up to you! You, as the Information Technology Specialist and the Disaster Recovery Planner are the individual that needs to insure the company's information will be recoverable when needed. It all goes back to the risk of loss as to how extensive a data integrity program you need to devise; from policies, to frequency of back-ups, to storage locations, to retention schedules, to the periodic verification that the back-ups are being done correctly. If you are just starting your planning process, this should be the first area you focus your mitigation efforts on. None of the other strategies you'll implement will count if there is no possible recovery of the data.

Network Recovery Strategies

As Information Technology your prime objective with respect to systems contingency planning is system survivability. This means that you have provisions in place, albeit limited capacity, to continue to support the company's system needs for priority processing through the first few hours immediately following the disaster.

Fault Tolerance vs. Redundancy. To a degree what we're striving for is fault tolerance of the company's critical systems. Fault tolerance, means that no single point of failure will stop the system. This is many times built in as part of the operational component design of the system. Examples include: mirroring of disks, use of RAID systems, shadowed servers, and UPS's to multiple T1's for wide area communications. Redundancy, duplication of key components, is the basis of fault tolerance. Where fault tolerance can not be built in, a quick replacement or repair program needs to be devised. Moving to an alternate site, either one of your company's, or a facility that is under contract for emergency support, i.e., a hot site, is a quick replacement strategy.

Alternate Sites and System Sizing. Once the priorities of a company are fully understood, sizing the amount of system capacity required to support those priorities, in the first few hours, through the first few days and weeks after a disaster can be accomplished. If you plan for you own recovery site, using another company location, or establish a contract with a "hot-site" service provider, you will want to adequately size the immediate recovery capacity. This is extremely important, as most hot-site service providers will not allow you to modify your requirements once you've declared a disaster.

The good news with respect to distributed systems, is that the hot-site service providers offer you options for recovery: from using their recovery center; to bringing self-contained vans to your facility, equipped with your required server configuration; to shipping you replacement equipment for what was lost, assuming your facility is still operable.

Adequate Backups with Secure Off-site Storage. This process must be based on established company policies that identify vital information and detail how its integrity will be managed. The work flow of the company and the volatility of its information base will dictate the frequency of back-ups. At a minimum, backup should occur daily for servers; and, weekly or monthly for key files of individual workstations.

Workstation based information continues to be one of the greatest vulnerabilities for most companies. There is so much vital information stored locally on these workstations with little or no backup. If individuals have taken the precaution of creating backups, they are typically stored right next to the workstations, leaving the company exposed to any type of catastrophic disaster. The recovery planner must insist that the company proactively address this issue through policy and through providing the means for effective workstation backups.

Planners must decide when and how often to take back-ups off-site. Depending on a company's budget, off-site could be the building next door, a bank safety deposit box, the network administrator's house, the branch office across town, or a secure media vault at a storage facility maintained by a company that's in the business of "off-site" media storage. Once the company meets the objective of separating the backup copy of vital data from its source, it must address the accessibility of the off-site copy.

The security of the company's information is also of vital concern. Security has several facets: if at a branch office, where do they safeguard the copy; if at the network administrator's house where is it kept; and what about the exposure to the media during transit? There are off-site storage companies that intentionally used unmarked, nondescript vehicles to transport your company's backup tapes to and from storage. This makes a lot of sense as your information is valuable and in your attempt to secure it you don't want to be advertising who you are using and where your storing your complete system backups.

Several products have come to market (1998) which will assist the LAN Administrator with these backup issues. Several of the products offer highly compressed, encrypted backups of workstations and other servers. The compression techniques require very little in the way of bandwidth, so they even work very effectively in remote backups of laptops using the Internet. The concept of vaulting, running mirrored data centers in separate locations, has been implemented by larger corporations who traditionally had the means to invest in the communications capabilities and the system redundancy. This type of capability is now made possible through these new tools. It is possible today to either work with off-site storage vendors to remotely backup at their facility or if the company has multiple locations,

to readily implement vaulting at the client/server level. Either way recovery options are facilitated via dial-up access to key recovery systems and data.

Adequate LAN Administration. Keeping track of everything the company owns, with respect to its hardware, software, and information bases is fundamental to your company's recovery effort. The best aid in this area is a solid audit application that is periodically run on all workstations. This assists you in maintaining an accurate inventory across the enterprise as well as providing you a tool for monitoring software acquisitions and hardware configuration modifications. The inventory may be extremely beneficial for insurance loss purposes. It also provides you with accurate records for license compliance and application revision maintenance.

Personnel. The all too often overlooked area of systems recovery planning is the system's personnel. Will there be adequate system personnel resources to handle the complexities of response and recovery. What if a key individual is impacted by the same catastrophic event that destroys the systems? This event could cause a single point of failure.

An option available to the planner is to an "emergency staffing contract." A qualified systems engineer hired to assist on a key project that you never seems to get completed (e.g., the network system documentation) may be a cost-effective security measure. Once that project is completed to satisfaction, the company can consider structuring a contractual arrangement that, for example, retains the engineer for one to three days a month to continue to work on documentation and other special projects. The contract could also stipulate coverage for staff vacations and sick days and should guarantee the engineer will be available on an as needed basis should the company experience an emergency. The advantage of this concept, is that you maintain an effective resource that is well trained and versed on your company's systems should you need to rely on them during an emergency; you have coverage for the company during employee's personal leaves; and, you have your systems documented!

TESTING

The timeless adage with regards to a business's success being "location, location, location," is adapted here. The pro forma success of a business's recovery plan will be most influenced by the extent of the "testing, testing, testing" of its plan! Testing and training are the reiterative and necessary components of the planning process that keep the plan up-to-date and maintain the viability of recovery.

Tests can be conducted in a variety of ways; from desk checking, reading through the plan and thinking though the outcome, to full parallel system testing, setting up operations at a hot site or alternate location and have

the users run operations remotely. The full parallel system test does generally prove out that the hot site equipment and remote linkages work but doesn't necessarily test the feasibility of the user-department's plans, as it is a system test. Full parallel testing is also generally staged with a limited amount of time which adds the pressure of "getting it done" and "passing" because of the time restriction.

Advantages of the Distributed Environment for Testing

Distributed client/server systems because of their size and modularity permit a readily available, modifiable, and affordable system set up for testing. They allow for a testing concept that I coin, "cycle testing."

For those of you with a manufacturing background, this draws a direct parallel to cycle counting; a process whereby inventory is categorized by value and counted several times a year rather than a one time physical inventory. With cycle counting, inventory is counted all year long, with portions of the inventory being selected to be counted either on a random basis or on a pre-selected basis. Inventory is further classified into categories, such that the more expensive or critical inventory items are counted more frequently, and the less expensive items less frequently. The end result is the same as taking a one time physical inventory, in that by the end of a calendar year, all the inventory has been counted. However, the cycle counting method has several advantages: (1) Operations do not have to be completely shut down, while the inventory is being taken; (2) Counts are not done under the pressure of "getting it done" which can result in more accurate counts; (3) Errors in inventories are discovered and corrected as a part of the continuous process.

The parallels to cycle testing are straightforward. Response and recovery plan tests can be staged with small manageable groups, so as not to be disruptive to company operations. Tests can be staged by a small team of facilitators and observers, on a continual basis. Tests can be staged and debriefings held with out the pressure of "getting it done"; allowing the participants the time to fully understand their role and critically evaluate their ability to respond to the test scenarios and make necessary corrections to the plan. Any inconsistencies or omissions in a department's plan can be discovered and resolved directly amongst the working participants.

Just as the more critical inventory items can be accounted for on a more frequent basis, so can the crucial components required for business recovery, i.e., systems and telecommunications. With the wide spread use of LANs and client/server systems throughout companies today, the Information Systems department is afforded more opportunity to work with the other departments in testing their plans and… getting it right!

SUMMARY

Developing a business recovery plan is not a one time, static task. It is a process that requires the commitment and cooperation of the entire company. In order to perpetuate the process, Business Recovery Planning must be a company stipulated policy as well as a company sponsored goal. The organizations that adopt this company culture oriented posture are the ones whose plans are actively maintained and tested, and whose employees are well trained and poised to proactively respond to a crisis. The primary objective of developing a Business Resumption Plan is the survivability of the business.

An organization's Business Resumption Plan is, in fact, an orchestrated collection of its Departmental Response and Recovery Plans. Information Technology's plan is also a departmental plan, however, in addressing the overall coordination of the departmental plans, Information Technology is typically in the best position to facilitate the other departments' development of their plans. With respect to the continuing trend of distributed processing permeating throughout organizations, Information Technology can be of particular help in identifying the organization's inter-departmental information dependencies and external dependencies for information access and exchange.

There are some basic protective security measures that should be fundamental to Information Technology's plan, no matter what the scope of disasters being planned for. From operational mishaps, to industrial espionage, to area-wide disasters, you'll want to make sure the Information Technology plan addresses:

1. an adequate back-up methodology with off-site storage;
2. sufficient physical security mechanisms for the servers and key network components;
3. sufficient logical security measures for the organization's information assets, and
4. adequate LAN/WAN administration, including up-to-date inventories of equipment and software.

Lastly, in support of an organization's goal to have its Business Resumption Planning process in place to facilitate its quick response to a crisis, the plan must be sufficiently and reiteratively tested and the key team members sufficiently trained. When testing is routinely built into the planning process, it becomes the feedback step that keeps: the plan current; the response and recovery strategies properly aligned; and, the responsible team members postured to respond. Once a plan is established, testing is the key process step that keeps the plan viable. Plan viability equates to business survivability!

The Changing Face of Continuity Planning

Carl Jackson, CISSP, CBCP

To one degree or another, the information security professional has always had responsibility for ensuring the availability and continuity of enterprise information. While still the case, specialization within the availability discipline has resulted in the growth of the continuity planning (CP) profession and the evolution into full-time continuity planners by many former information security specialists. Aside from the growth and reliance upon E-business by most major worldwide companies, the events of September 11, 2001, and even the Enron meltdown have served to heighten awareness for increased planning and advanced arrangements for ensuring availability. The reality is that continuity planning has a changing face, and is simply no longer *recovery planning as usual*. This chapter focuses on some of the factors to be considered by continuity planning professionals who must advance their skills and approaches to keep up with swiftly evolving current events.

REVOLUTION

Heraclitus once wrote, "There is nothing permanent except change." The continuity planning profession has evolved from the time when disaster recovery planning (DRP) for mainframe data centers was the primary objective. Following the September 11 attacks and the subsequent calls for escalating homeland security in the United States, the pace of change for the CP profession has increased dramatically from just a few months prior to the attacks. In looking back, some of us who have been around awhile may reminisce for the good ole' days when identification of critical applications was the order of the day. These applications could be easily plucked from a production environment to be plopped down in a hot site somewhere, all in the name of preventing denial of access to information assets. In retrospect, things were so simple then — applications stood alone, hard-wired coax connectivity was limited and limiting, centralized change control ruled, physical security for automated spaces solved a multitude of

sins, and there were less than half a dozen vendors out there that could provide assistance. Ah, those were the days!

The kind of folks who performed disaster recovery tasks in those times were fairly technical and were usually associated with the computer operations side of the house. They tended to understand applications and disk space and the like, and usually began their disaster recovery planning projects by defining, or again redefining, critical applications. Of course, the opinion of the computer operations staff about what constituted a critical application and that of the business process owner many times turned out to be two different things.

Of late, especially since September 11, we have seen the industry shift from a focus strictly on computer operations and communications recovery planning to one where business functionality and processes are considered the start and endpoint for proper enterprisewide availability. This is the point where many continuity planners began to lose their technical focus to concentrate on understanding business process flow and functional interdependencies so that they could map them back to supporting resources that included IT and communications technologies. Some of us simply lost our technological edge, due to the time it took to understand business processes and interdependencies, but we became good at understanding business value-chain interrelationships, organizational change management, and process improvement/reengineering.

Exhibit 42-1 depicts the evolution of industry thinking relative to the passage from technical recovery to business process recovery. It also reflects the inclination by continuity planners to again focus on technologies for support of Internet-based business initiatives.

As organizations move operations onto the Web, they must ensure the reliability and availability of Web-based processes and technologies. This includes the assurance that trading partners, vendors, customers, and employees have the ability to access critical B2B (business-to-business) and B2C (business-to-customer) resources. This has been identified in recent security surveys (sources include Gartner Research, IDC, and Infonetics) that suggest the worldwide marketplace for Internet security solutions will reach somewhere around $20 billion by 2004. Included within the scope of the security solutions marketplace are myriad products that facilitate detection, avoidance, mitigation of, and recovery from adverse events.

THE LESSONS OF SEPTEMBER 11

For the past decade or so, continuity planners have been shifting the emphasis to business process planning as the starting point for any meaningful continuity planning exercise. The pace has accelerated within the

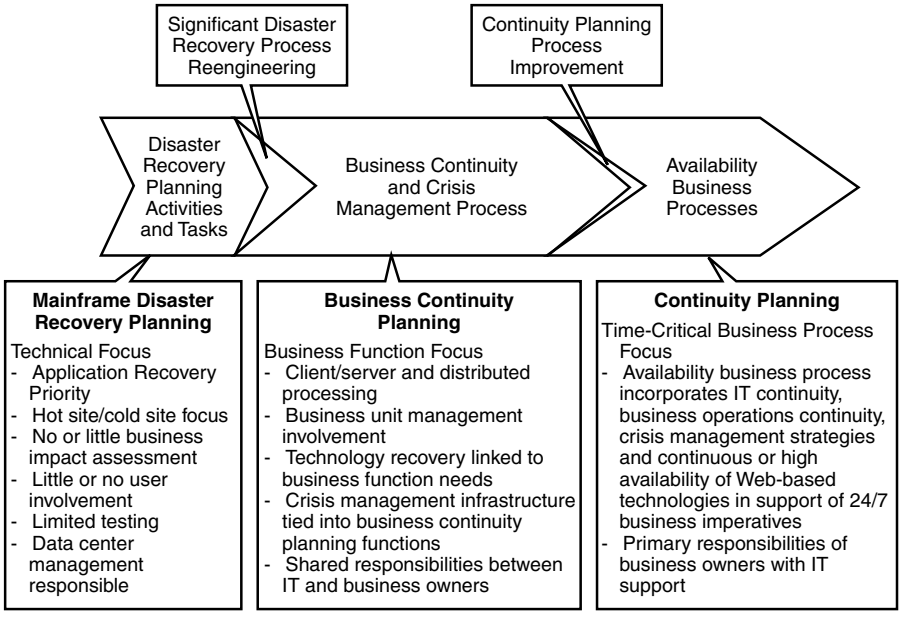

Exhibit 42-1. Evolution from technical recovery to business process recovery.

past five years, with E-business considerations driving shorter and shorter recovery time windows. But something happened following the September 11 attacks in the United States that appeared to redouble the speed of shifting focus for many of us.

We have all lived through much since the attacks of September 11. Our horror turned to shock and then grief for those souls lost on that day, and continues in military and related activities the world continues to undertake in response to these atrocities. As continuity planning professionals, we have a very unique view of events such as these because our careers so closely relate to mitigation and recovery from disruptions and disasters.

Call to Arms

The September 11 attacks raised the awareness level for the need for appropriate recovery planning in the United States and indeed the rest of the world. The U.S. Attorney General's call for companies to revisit their security programs in light of the terrorist attacks on U.S. properties should also serve to put executive management on notice — as if they needed any more incentives — that it may be time to rethink investments in their security and continuity planning programs.

There are no signs that the potential for disruptions caused by terrorist activities will be over anytime soon. In fact, it was recently made public

that the U.S. Government has activated its own continuity plans by establishing off-site operations for all three branches of government at secret locations outside of the Washington, D.C. area. These contingency plans were originally prepared during the Eisenhower administration in anticipation of nuclear attack during the Cold War, but they were thankfully never needed — until now. It is more than interesting to think that these long-prepared contingency plans had to be activated some 50 years later! I wonder if the folks who suggested that these plans be developed in the first place had to worry about cost justification or return on investment?

A Look at the Aftermath

The extent of the damage to the WTC complex alone was staggering. Even six months following the attacks, companies displaced by them continue to struggle. *The Wall Street Journal* reported on March 15, 2002, that of the many large companies impacted by September 11, numerous ones remain either undecided about moving back or have decided not to move back into the same area (see Exhibit 42-2). The graphic illustrates the destroyed and damaged buildings and lists some of the large companies located there.

This event displaced well over 10,000 employees of the hundreds of companies involved. It is estimated that in excess of 11 million square feet of space have been impacted.

There were many lessons learned from these tragic events. There are two areas that stick most in my mind as significant. First, it was the bravery of the people in reacting to the event initially and within a short period of time following the events; and second, it was the people who had to execute under duress on the many recovery teams that reacted to help their organizations survive. It was the people who made it all happen, not just the hot sites or the extra telecommunications circuits. That lesson, above all, must be remembered and used as a building block of future leading practices.

The Call for Homeland Security

From the mailroom to the executive boardroom, calls abound for increased preparations of your organization's responsibility in ensuring homeland security. Following September 11, continuity planners must be able to judge the risk of similar incidents within their own business environments. This includes ensuring that continuity planning considerations are built in to the company's policies for dealing with homeland security. Planners cannot neglect homeland security issues for their own organization, but they must also now be aware of the preparations of public- and private-sector partner organizations. Once understood, planners must interleave these external preparations with their own continuity and crisis management planning actions. In addition, continuity planners may want to

RED ALERT

The Bush administration unveiled a color-coded, five-level warning system for potential terrorist attacks. In the future, Attorney General Ashcroft will issue higher states of alerts for regions, industries, and businesses that may be the specific targets of terrorists.

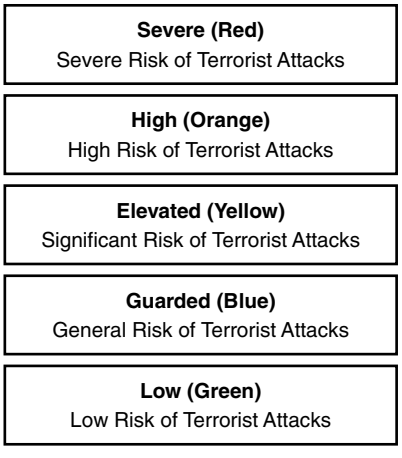

Exhibit 42-3. Alert system offered by the Office of Homeland Security. (Source: Office of Homeland Security.)

consider adoption, for crisis management purposes, of an alert system similar to the one offered by the Office of Homeland Security (see Exhibit 42-3).

The Importance of Education, Training, and Awareness

The results of the 2000/2001 CPM/KPMG Business Continuity Study Benchmark Report show that dismal attention has been paid by many companies to training, education, and awareness. When asked, "Do employees get sufficient disaster recovery/business continuity planning training?", of those answering the survey, 75 percent responded with *no* for the year 1999; and 69.5 percent said *no* for the year 2000. Unfortunately, I doubt that these percentages have improved to any significant degree, even since September 11.

People Must Be the Focus

People are important! Whether it is a life safety issue, or their participation in the recovery after the event, it is people who are most impacted by the disruption; and it is people who will have to recover following the disruption. All one has to do is look at case studies of the companies that had to recover following the attacks on the World Trade Center. For instance, in one sad case, all of the people who had participated in the most recent hot site test perished in the attack.

Planners simply should not allow haphazard education, training, and awareness programs to continue. These programs must be designed to teach the people how to protect themselves and the organization and to periodically refresh the message. *The single largest lesson that must be learned from September 11 is that the people must be the focus of all crisis management and continuity planning activities — not technology.* There is absolutely no question that technologies and their recovery requirements are vital, but technologies and processes are things that can be reconstructed or replaced. People cannot, as demonstrated by the loss of approximately 3000 souls on September 11.

What about Executive Protection and Succession Plans?

Not typically considered as part of the continuity planning responsibility, the events of September 11 call attention to the need for organizational management to revisit dated executive protection and succession plans and to test enterprise crisis management plans by challenging old assumptions based upon pre-September 11 thinking.

Business Process Continuity versus IT DRP

Another lesson learned was that, while many companies impacted by the events were able to recover automated operations, the vast majority of them were seriously disabled from a business process/operations standpoint. Their inability to physically transport people and supplies — given aircraft groundings — to off-site locations suitable for recovering business processes and supporting infrastructures (i.e., mail room operations, client/server configurations, purchasing, HR, back-office operations, etc.) illustrated that the practice of only preparing for IT recovery had resulted in a serious shortfall of preparations.

Security and Threats Shifting

There were many, many more companies seriously impacted than those located directly in the WTC buildings. Businesses all over the country, and indeed the world, that had critical dependencies upon the WTC-based companies were also injured by the event. Subsequent severe travel restrictions and the resulting economic downturn affected countless other organizations. Our highly interconnected world is much different than our world of just a few short non-Internet years ago. There are no islands in the global economy; and because the United States is the largest economic engine in that financial system, and because each U.S. company plays a role in that engine, it seems really rather shortsighted for major companies to not be making availability-related investments. Our risks have changed and shifted focus in addition to the ones mentioned above.

Others include:

- *Nuclear power plant security.* Recent media reports indicate that the U.S. Nuclear Regulatory Commission is unsure how many foreign nationals or security guards are employed at nuclear reactors and does not require adequate background checks of nuclear reactor employees that would uncover terrorist ties. There are 21 U.S. nuclear reactors located within five miles of an airport, 96 percent of which were not designed to withstand the crash of a small airplane.
- *Airport security.* It was recently reported (Fox News, March 25, 2002) that, according to a confidential February 19, 2002, Transportation Department memo, the department ran tests of security at 32 airports around the country that continued to be found lacking.
- *Border security.* There is focused attention on the increased security needs and staffing levels of border security staff along both the Canadian and Mexican borders to the United States, and President Bush is calling for consolidation of the INS and Customs Department.
- *Food and water supply security.* In connection with concerns over bioterrorism, Homeland Security is calling for consolidation of rival U.S. agencies responsible for food and water safety.
- *Internet security.* The U.S. Government is attempting to persuade industry to better protect the Internet from threats of cyber-crime and cyber-terrorism.
- *Travel security.* Key personnel residences and travel to unstable international destinations must be monitored and controlled appropriately.

Reassess Risk

As enterprise risk is assessed, through either traditional risk analysis/assessment mechanisms or through business impact assessments, understanding potential impacts from these expanded threats is essential and prudent. We must consider the impact of functionality loss that may occur either inside or outside our walls. These types of potential impacts include the direct ones, like those listed above, and those impacts that might disrupt an external entity that our organization relies upon — a supply-chain partner, key vendor, outsourcer, parent or subsidiary company, etc. Now is the time to go back and seriously consider the last time your organization performed a comprehensive risk assessment/business impact assessment, and think about updating it. Organizations change over time and should be reevaluated frequently.

THE LESSONS OF ENRON

Speaking of reliance on key external relationships, the Enron situation and its repercussions among the supply-chain partners, outsourcers, vendors, and supplier relationships continue to ripple through several industry

groups. Understanding your organization's reliance upon primary supply-chain partners and assorted others is crucial in helping you anticipate the breadth and scope of continuity and crisis management planning efforts — if for no other reason than for you to say that these issues were considered during preparations and not merely ignored. Granted, there is no question that, given the global level of the Enron-related events, it would have been challenging for those with internal continuity planning responsibilities to anticipate the extent of the impacts and to appropriately prepare for all contingencies. But in hindsight, it will be incumbent upon those who have responsibility for preparing continuity and crisis management plans to be at least aware of the potential of such events and be prepared to demonstrate some degree of due diligence.

COMPUTER FORENSIC TEAMS

The composition of crisis management and continuity planning teams is changing as well. Virus infestations, denial-of-service attacks, spoofing, spamming, content control, and other analogous threats have called for the inclusion of computer forensic disciplines into development of continuity planning infrastructures. Forensic preparations include understanding the procedures necessary to identify, mitigate, isolate, investigate, and prosecute following such events. It is necessary to incorporate enterprise forensic teams, legal resources, and public relations into continuity planning and crisis management response teams.

THE INTERNET AND ENTERPRISE CONTINUOUS AVAILABILITY

With growing Internet business process reliance on supporting technologies as the motivating force, continuity planners must once again become conversant and comfortable with working in a technical environment — or at least comfortable enough to ensure that the right technical or infrastructure personnel are involved in the process. The terminology currently used to describe this Internet resource availability focal point is *continuous* or *high availability*.

Continuous availability (CA) is a building-block approach to constructing resilient and robust technological infrastructures that support high-availability requirements. In preparing your organization for high availability, focusing on *automated applications* is only a part of the problem. On this topic Gartner Research writes:

> Replication of databases, hardware servers, Web servers, application servers, and integration brokers/suites help increase availability of the application services. The best results, however, are achieved when, in addition to the reliance on the system's infrastructure, the design of the application itself incorporates considerations for continuous availability. Users looking to achieve continuous availability

for their Web applications should not rely on any one tool but should include the availability considerations systematically at every step of their application projects.

— Gartner Group RAS Services
COM-12-1325, 29 September 2000

Implementing CA is easier said than done. The key to achieving 24/7 or near-24/7 availability begins with the process of determining business process owner needs, vulnerabilities, and risks to the network infrastructure (e.g., Internet, intranet, extranet, etc.). As part of considering implementation of continuous availability, continuity planners should understand:

- The resiliency of network infrastructures as well as the components thereof
- The capability of their infrastructure management systems to handle network faults
- The network configuration and change control practices
- The ability to monitor network availability
- Infrastructure single points of failure
- The ability of individual network components to handle capacity requirements, among others

Among the challenges facing continuity planners in CA are:

- Ensuring that time-critical business processes are identified within the context of the organization's Web-based initiatives
- Making significant investments in terms of infrastructure hardware, software, management processes, and consulting
- Obtaining buy-in from organizational management in the development, migration, and testing of CA processes
- Keeping continuous availability processes in line with enterprise expectations for their organization's continuity and crisis management plans
- Ensuring CA processes are subjected to realistic testing to assure their viability in an emergency

FULL-SCOPE CONTINUITY PLANNING BUSINESS PROCESS

The evolution from preparing disaster recovery plans for mainframe data centers to performing full-scope continuity planning and, of late, to planning for the continuous operations of Web-based infrastructure begs the question of process improvement. Reengineering or improving continuity planning involves not only reinvigorating continuity planning processes but also ensuring that Web-based enterprise needs and expectations are identified and met through implementation of continuous availability disciplines. Today, the continuity planning professional must

possess the necessary skill set and expertise to be able to effectively manage a full-scope continuity planning environment that includes:

- *IT continuity planning.* This skill set addresses the recovery planning needs of the organization's IT infrastructures, including centralized and decentralized IT capabilities, and includes both voice and data communications network support services. This process includes:
  - Understanding the viability and effectiveness of off-site data backup capabilities and arrangements
  - Executing the most efficient and cost-effective recovery alternative, depending upon recovery time objectives of the IT infrastructure and the time-critical business processes it supports
  - Development and implementation of a customized IT continuity planning infrastructure supported by appropriately documented IT continuity plans for each primary component of the IT infrastructure
  - Execution of IT continuity planning testing, maintenance, awareness, training, and education programs to ensure long-term viability of the plans, and development of appropriate metrics that can be used to measure the value-added contribution of the IT infrastructure continuity plans to the enterprise people, process, technologies, and mission
- *Business operations planning.* This skill set addresses recovery of an organization's business operations (i.e., accounting, purchasing, etc.) should they lose access to their supporting resources (i.e., IT, communications network, facilities, external agent relationships, etc.). This process includes:
  - Understanding the external relationships with key vendors, suppliers, supply-chain partners, outsourcers, etc.
  - Executing the most efficient and cost-effective recovery alternative, depending upon recovery time objectives of the business operations units and the time-critical business processes they support
  - Development and implementation of a customized business operations continuity plan supported by appropriately documented business operations continuity plans for each primary component of the business units
  - Execution of business operations continuity plan testing, maintenance, awareness, training, and education programs to ensure long-term viability of the plans
  - Development of appropriate metrics that can be used to measure the value-added contribution of the business operations continuity plans to the enterprise people, processes, technologies, and mission
- *Crisis management planning.* This skill set addresses development of an effective and efficient enterprisewide emergency/disaster response capability. This response capability includes forming appropriate

management teams and training their members in reacting to serious company emergency situations (i.e., hurricane, earthquake, flood, fire, serious hacker or virus damage, etc.). Key considerations for crisis management planning include identification of emergency operations locations for key management personnel to use in times of emergency. Also of importance is the structuring of crisis management planning components to fit the size and number of locations of the organization (many small plans may well be better than one large plan). As the September 11 attacks fade somewhat from recent memory, let us not forget that people responding to people helped save the day; and we must not ever overlook the importance of time spent on training, awareness, and education for those folks who will have responsibilities related to continuity following a disruption or disaster. As with IT and business operations plans, testing, maintenance, and development of appropriate measurement mechanisms is also important for long-term viability of the crisis management planning infrastructure.

- *Continuous availability.* This skill set acknowledges that the *recovery time objective* (RTO) for recovery of infrastructure support resources in a 24/7 environment has shrunk to *zero* time. That is to say that the organization cannot afford to lose operational capabilities for even a very short period of time without significant financial (revenue loss, extra expense) or operational (customer service, loss of confidence) disruptions. CA focuses on maintaining the highest possible uptime of Web-based support infrastructures, of 98 percent and higher.
- *The importance of testing.* Once developed and implemented, the individual components of the continuity plan business process must be tested. What is more important is that the people who must participate in the recovery of the organization must be trained and made aware of their roles and responsibilities. Failure of companies to do this properly was probably the largest lesson learned from the September 11 attacks. Continuity planning is all about people!
- *Education, training, and awareness.* Renewed focus on practical personnel education, training, and awareness programs is called for now. Forming alliances with other business units within your organization with responsibility for awareness and training, as well as utilizing continuity planning and crisis management tests and simulations, will help raise the overall level of awareness. Repetition is the key to ensuring that, as personnel turnover occurs, there will always be a suitable level of understanding among remaining staff.
- *The need to measure results.* The reality is that many executive management groups have difficulty getting to the bottom of the value-add question. What degree of value does continuity planning add to the enterprise people, processes, technology, and mission? Great question. Many senior managers do not seem to be able to get beyond the *financial justification* barrier. There is no question that justification of investment

in continuity plan business processes based upon financial criteria is important, but it is not usually the financial metrics that drive recovery windows. These metrics must be both quantitative and qualitative. It is the *customer service and customer confidence* issues that drive short recovery time frames, which are typically the most expensive. Financial justifications typically only provide support for them.

Implementation of an appropriate measurement system is crucial to success. Companies must measure not only the financial metrics but also how the continuity planning business process adds value to the organization's people, processes, technologies, and mission. These metrics must be both quantitative and qualitative. Focusing on financial measures alone is a lopsided mistake!

CONCLUSION

The growth of the Internet and E-business, corporate upheavals, and the tragedy of September 11 and subsequent events have all contributed to the changing face of continuity planning. We are truly living in a different world today, and it is incumbent upon the continuity planner to change to fit the new reality.

Continuity planning is a *business process*, not an event or merely a plan to recover. Included in this business process are highly interactive continuity planning components that exist to support time-critical business processes and to sustain one another. The major components include planning for:

- IT and communications (commonly referred to as disaster recovery planning)
- Business operations (commonly referred to as business continuity planning)
- Overall company crisis management
- And, finally, for those companies involved in E-business — continuous availability programs

In the final analysis, it is incumbent upon continuity planning professionals to stay constantly attuned to the changing needs of our constituents, no matter the mission or processes of the enterprise. The information security and continuity planning professional must possess the necessary skill set and expertise to effectively manage a full-scope continuity planning environment. Understanding the evolution and future focus of continuity planning as it supports our information security responsibilities will be key to future successes. As Jack Welch has said, "Change before you have to."

ABOUT THE AUTHOR

Carl Jackson, CISSP, CBCP, brings more than 25 years of experience in the areas of business continuity planning, information security, and IT internal control reviews and audits. As the vice president, continuity planning, for QinetiQ-Trusted Information Management Corporation, he is responsible for the continued development and oversight of QinetiQ-TIM (U.S.) methodologies and tools in the enterprisewide business continuity planning arena, including network and E-business availability and recovery.

Restoration Component of Business Continuity Planning

John Dorf, ARM and Martin Johnson, CISSP

Everyone understands the importance of developing a business continuity plan (BCP) to ensure the timely recovery of mission-critical business processes following a damaging event. There are two objectives, however, and often, the second objective is overlooked return to normal operations as soon as possible. The reason for the urgency to return to normal operations is that backup and work-around procedures are certainly not "business as usual." Backup capabilities, whether due to the loss of primary premises or primary data, probably only include those business activities that are critical to getting by. The longer a company must operate in this mode, the more difficult the catch-up will be. There are several steps that can be taken in advance to prepare for the timely, efficient return to normalization. The purpose of this chapter is to discuss the steps and resources to ensure total recovery. In addition, it is important to understand how to handle damaged equipment and media in order to minimize the loss associated with a disaster.

Restoration includes the following:

1. Handling damaged equipment and media in order to minimize the loss
2. Salvaging hard copy and electronic media
3. Performing damage assessment and the resulting disposition of damaged facilities and equipment
4. Determining and procuring appropriate property insurance
5. Identifying internal and external resources to perform restoration activities
6. Developing, maintaining, and testing your restoration plan

This chapter will help you understand the issues related to each of these items and be a resource for developing the necessary information for inclusion in your BCP program.

The more time that passes before the salvation of hardcopy and electronic media, the greater the chance that the data or archival records will be permanently lost. However, if you rush to handle, move, dry, etc., media and do not do so in the correct manner, you may worsen the situation. Therefore, to ensure minimizing the damage you must act quickly and correctly to recover data and restore documents. This also applies to the facilities and infrastructure damage.

Having telephone numbers for restoration companies is not enough. The primary reason is in the event of a regional problem like flooding, ice storms, etc., you will have to wait for those companies that have advance commitments from other companies.

Another important issue associated with restoration is insurance. It is imperative you understand what is covered by your insurance policy and what approval procedures must be completed before any restoration work is performed. There are many stories about how insurance companies challenged claims because of disagreements concerning coverage or restoration procedures. Challenges from insurance carriers can hold up restoration for extended periods of time. Following are two examples showing the importance and magnitude of effort involved with restoration after a disaster.

> The 1993 World Trade Center bombing illustrates the potential magnitude of a clean-up effort. Over a 16-day period, 2700 workers hired by a restoration contractor, working round the clock in three shifts, cleaned over 880,000 square feet of space in the twin towers and other interconnected facilities. Ninety percent of the floors in the 110-story towers had light amounts of soot, while 10 percent suffered heavier damage.
>
> In 1995, Contra Costa County, California, suffered almost $15 million in arson-related fire damage to four county courthouses over a three-week period. In all, 124,000 files had to be freeze-dried and restored at an estimated cost of $50 per document.

A good restoration program will not guarantee you will not have a problem with your insurance carrier. The following is an example of how a disagreement between an insured and insurer can delay restoration of your business:

> In 1991, a 19-hour fire at One Meridian Plaza in Philadelphia destroyed eight of the 38 floors in the building. It took 6 years of legal maneuvering to settle the claim between the building owners and the insurers. Each party disagreed with the other over the extent of the restoration. For most of the 6 years, the parties' difference amounted to almost $100 million. The owners believed that the floors above the 19th floor had to be torn down because the steel beams supporting the structure had moved 4 inches and could not be certified as safe. The insurance company disagreed and argued that the building could be repaired without tearing down the floors. The owner and insurer also disagreed over the extent of environmental cleanup caused by the fire. Eventually, the matter was settled out of court for an undisclosed sum.

Understanding the Issues

For all damaged or destroyed property a company must understand when it needs to try to restore the property, and when the property can just be replaced. A critical issue concerning restoration is really the handling of documents and electronic media. Handling of the physical damage is more easily accomplished and more straightforward. The handling of vital records, however, is more difficult. The vital records may only be needed if an original contract is challenged, or is needed from a corporate entity standpoint. How a company deals with this exposure is not an easy determination. Some companies build facilities that are protected from most hazards to critical documents and data. The issue concerning having both a protected environment and duplication becomes a business issue; how much insurance is enough? Therefore, any time a company only has a single copy of vital documents and data, it must develop a strategy of what it would do if those records are damaged. This is a dilemma for many companies where duplicate copies cannot be maintained. Insurance companies have millions of pages of archived contracts and other legal documents that may not be feasibly copied. Other industries such as financial services handle equity certificates and other legal tender that perhaps cannot be copied as a normal course of business.

A company should develop a restoration plan in conjunction with performing a vital records review. In this way, the restoration of business-critical items can be assessed along with the alternatives of providing replication. Insurance coverage must be evaluated and coordinated with the restoration plan and other components of business continuity planning.

How to Select Restoration Service Providers

It is not difficult to find a service provider to clean up the rubble following a flood or fire. It is much more difficult to find a service provider that knows how to dry the soaked documents to best ensure their usability. It also takes a lot of expertise to handle fire-damaged documents and magnetic media to restore information.

The normal care for selecting any critical supply chain partner should be used. For a restoration company, however, you don't have the ability to ask for a pilot program. There are many sources of information to identify restoration companies, including local, state, and federal agencies. In addition, the Internet is an excellent source for both planning information, and resources.

Your own insurance carrier is also a good source of service provider information. Additionally, many insurance carriers have a partnership with recovery firms so that a firm is authorized to do certain work and

deal directly with the insurance carrier to ensure there are no misunderstandings about the work to be performed.

Where Does Insurance Coverage Fit into Your Restoration Program?

The subjects of restoration and insurance are closely intertwined as, in most cases, property insurers are expected to pay for the majority of the cost of any restoration. The settlement of a property insurance claim can be a complex, time-consuming, and vexing issue, even for a seasoned insurance professional. The insured often do not understand their coverage and routinely overestimate the amount of the loss or assume that a claim is covered when it is not. Insurers and their representatives may communicate poorly with the insured as to the nature of the coverage, the information required to adjust the claim, and the timetable to be expected. Both sides need to cooperate and communicate clearly so that reasonable expectations are established quickly and conflicts can be resolved in a timely manner.

The discussion on insurance includes a brief overview of standard commercial property insurance policies and common problems during the claim settlements process.

Property Insurance Overview

Property insurance can be purchased with many options, which serve to tailor the standard policy language to the specific needs of the policyholder. Therefore, it is important that business owners take the time to review their needs with their insurance agent, broker, or advisor, so that the resulting insurance purchase reflects those needs before a loss occurs. This will help avoid future misunderstandings with the insurance company in the event of a claim.

Property insurance can be purchased on either a Named Perils or All Risk form. The All Risk form covers all causes of loss that are not specifically excluded in the policy and provides broader protection to the insured than a Named Perils form. Under a Named Perils form, the insured bears the responsibility of proving that damage to the property was caused by one of the enumerated causes of loss. Use of the All Risk form shifts the burden of proof onto the insurer to prove that a particular loss was not covered by the policy. Insurers avoid the use of the phrase "All Risk" and use the phrase "Special Form" to describe this same coverage.

The property policy valuation clause is a second area of frequent misunderstanding by policyholders. That is, if a loss occurs, on what basis will the policyholder be compensated for the loss or damage to the property? Insurers offer two basic valuation choices: actual cash value (ACV) or replacement cost coverage. ACV is defined as the cost to repair or replace the lost or damaged property with property of like kind and quality less physical depreciation. For example, suppose that a commercial refrigerator purchased five years ago and expected to have a useful working life of ten years is burned up in a fire. Assuming that the refrigerator had been well maintained up to the time of the loss, the insurance company adjuster might offer to settle the claim for 50 percent of the cost today of a new refrigerator of similar design, quality, and capacity. It should be noted that the lost or damaged property will be valued as of the date of the loss and not on the basis of the original cost.

Replacement cost valuation means that the policyholder will be compensated on the basis of new for old. That is, the policyholder is entitled to compensation on the basis of the cost to repair or replace the lost or damaged property with property of like kind and quality with no deduction for physical depreciation. As noted above, the determination of the replacement cost of the damaged or lost property takes place as of the actual date of loss.

Regardless of whether ACV or replacement cost valuation is chosen, the policyholder needs to make sure that the amount of insurance purchased accurately reflects the current replacement cost value of the insured property. This is necessary to avoid a coinsurance penalty being applied that could reduce any loss adjustment.

If replacement cost coverage is chosen, then in the event of loss or damage to the covered property, the insured must actually repair or replace the lost or damaged property. Otherwise, the insurance company is usually only required to reimburse the insured on an ACV basis.

Finally, the insurance company will never pay more than the applicable amount of insurance that has been purchased by the policyholder. This last provision underscores the need for business owners to adequately assess the replacement cost value of their property at the time the policy is placed.

We have not included an in-depth discussion of the topics of Business Interruption or Extra Expense insurance in our discussion of property insurance because it is beyond the scope of this chapter. These coverages

go hand in hand with adequate property insurance coverage. Business interruption coverage pays for lost earnings and continuing expenses during the period of time the business is shut down. Extra expense coverage pays for the additional costs to maintain business during the shut-down period. The absence or insufficiency of either of these coverages can jeopardize the survival of the business that is jeopardized because of a lack of financial resources during the restoration period. Detailed records of all expenditures to maintain the operations of the business (extra expense) should be kept and included in the claim. The business interruption portion of the claim will be based on the lost earnings of the business as compared with periods preceding the loss.

In addition to standard property insurance coverage, business owners should discuss with their insurance advisors the need for additional insurance coverage in the following areas:

- Boiler and machinery
- Valuable papers
- Accounts receivable
- Electronic data processing (EDP)

Property insurance policies exclude coverage for damage caused by:

- Explosion of steam boilers, steam pipes, steam engines, or steam turbines
- Artificially generated electric current, including electric arcing, that affects electrical devices, appliances, or wire
- Mechanical breakdown, including rupture or bursting caused by centrifugal force

Such damage may be covered under boiler and machinery insurance policies. Boiler and machinery policies have many characteristics similar to property policies. In the event of a loss, these insurers often provide assistance in the repair or replacement of the damaged equipment. They also provide statutorily required inspection services.

Valuable papers coverage under a standard commercial property insurance policy is limited to $2500. Valuable papers coverage may be important for businesses where the destruction of documents would cause the business to suffer a monetary loss or to expend large sums in reconstructing the documents. The limit of insurance under a standard property policy can be increased to meet a desired need. The ISO (Insurance Services Office) valuable papers form defines valuable papers and records as “inscribed, printed, or written documents, manuscripts, or records.” Money and securities, data processing programs, media, and converted data are not covered. Coverage for loss or destruction to money and securities can be found in Crime Insurance policies. Data processing programs, media, and data can be covered under EDP policies. Care needs to be exercised in estimating the cost of reconstructing documents so that adequate limits of insurance can be purchased.

If Accounts Receivable records are damaged by an insured cause of loss, this type of coverage will pay the business owner amounts due from customers that he is unable to collect as a result of the damage to his records, collection expenses in excess of normal collection costs, and other reasonable expenses incurred to reestablish records of accounts receivable. This coverage can be purchased as an endorsement to a commercial property insurance policy. Again, care must be exercised in setting an adequate amount of insurance.

Electronic data processing (EDP) coverage is a must for organizations that rely heavily on data processing or electronic means of information storage. EDP coverage can provide All Risk coverage for equipment and data, software and media, including the perils of electrical and magnetic injury, mechanical breakdown, and temperature and humidity changes, which are important to computer operations. In addition, the coverage can include the cost of reproducing lost data, which is not available under a standard commercial property insurance policy.

Property Insurance Claims Settlement Process

Exhibit 137.1 provides a broad overview of the claim settlement process. The exhibit underscores the importance of complete and well-organized documentation and open communication during the claim settlement process. These two factors are major reasons why claims settlements are delayed or even end up in litigation. The items shown in this table are important steps to include in your restoration plan.

The claims settlement process is adversarial by its nature. The insured party is intent on maximizing its potential recovery under its insurance policy, while the insurance company is trying to minimize its exposure

EXHIBIT 137.1 Overview of the Claim Settlement Process

- Report the event to the property insurance company immediately. Depending on the specific items damaged and the nature of the damage, it may be appropriate to notify the boiler and machinery insurer as well.
- Prevent further damage to covered property.
- Obtain property repair/replacement estimates or appraisals and prepare and document the claim. If business interruption and/or extra expense are going to be claimed, extensive additional documentation may be needed. (If a business interruption loss exceeds $1 million, the insured should consider hiring accountants experienced in documenting such claims.)
- Submit documentation to the insurance company adjuster and cooperate with the adjuster in his investigation and adjustment of the claim.
- Request authorization to proceed with repairs or the purchase of major items.
- If appropriate, request a partial payment of the claim from the insurance company.
- Negotiate the final claim settlement with the insurance company adjuster.
- Submit a sworn proof of loss to the insurance company.
- Receive claim settlement.

to the insured's claim. This does not mean that the claim settlement process must be nasty or unpleasant. The parties should work together in good faith in arriving at a reasonable settlement of a claim. The insurance carrier will be less likely to raise substantive issues if it believes that the insured is not trying to take advantage of the situation. Likewise, if the insurer establishes reasonable ground rules at the beginning of the process, it should expect the insured to be forthcoming with the information requested in a timely manner. Although it is usually in the insured's best interests to provide complete and well-organized documentation, the insured should not overwhelm the insurance company and should only provide the documentation necessary to substantiate the amounts requested, keeping ancillary documentation available in the event that the insurance carrier requests additional information.

The insurance adjuster is an individual assigned by the insurance company to handle a claim on its behalf. The adjuster may be an employee of the insurance company or may work for an independent firm hired by the insurance company. Adjusters will be the key contact between the insurer and the insured. Their responsibilities include determining the cause of a loss, the nature and scope of damage to the property, whether the policy covers the damages claimed, to what extent property should be repaired or replaced and the corresponding cost, and finally the amount that the insurance carrier is willing to pay in settlement of the claim. The adjuster also acts as a quarterback in determining whether other specialists need to become involved.

Depending on the size and complexity of the claim, the insurance carrier may selectively involve accountants, lawyers, and other specialists in the claim settlement process. These specialists are working on behalf of the insurance carrier and not the insured. Although the insured should not be unduly alarmed if the insurance company employs such specialists, the insured may be well advised to consider employing his own specialists to work on his behalf in calculating the claim in order to be on a more equal footing with the insurance company.

The agent or broker who placed the insurance can provide guidance and assistance to the insured in handling the claim. This should be expected, because the broker or agent has received compensation to arrange the insurance. Smaller brokers sometimes lack the capability to be of much assistance in a claim situation.

The responsibilities of the policyholder in the event of a loss are spelled out in most insurance policies. They include prompt notification of the insurer, protecting the covered property from further damage, providing detailed inventories of the damaged and undamaged property, allowing the insurance company to inspect the damaged property, take samples, and examine the pertinent records of the company, providing a sworn proof of loss, cooperating with the insurer in the investigation and settlement of the claim, and submitting to examination under oath concerning any matter relating to the insurance or the claim.

Willis Corroon, a large multinational insurance broker, recommends that the following steps be taken immediately following a loss:

- Make sure that the loss area is safe to enter.
- Report the claim to the agent and to the insurer.
- Restore fire protection.
- Take immediate action to minimize the loss.
- Protect undamaged property from loss.

- Take photographs of the damage.
- Identify temporary measures needed to resume operations and maintain safety and security, and the costs of those measures.
- Consult with engineering, operations, and maintenance personnel as well as outside contractors for an initial estimate of the scope and cost of repairs.
- Make plans for repairing the damage.

What Is Included in a Restoration Plan?

After a disaster such as a fire or hurricane, the natural inclination is to assume that documents, computer records, equipment and machinery, and high-tech computers and other data processing equipment that appear to be unusable or severely damaged should be scrapped and replaced. However, before anything is done, experts should be brought in to assess the damage and determine short- and long-term courses of action. The short-term course of action is intended to stabilize the situation at the disaster location so as to prevent further damage from occurring. The long-term strategy is to determine which items can be salvaged and repaired and which should be replaced.

Although notification to the insurance company should be one of the first steps taken after a disaster has occurred, do not wait for the insurance adjuster to show up before implementing stabilization procedures. It is a common insurance policy requirement that the insured take steps to prevent additional damage from occurring after a disaster. Such post-loss disaster mitigation should be part of a comprehensive business continuity plan. If no plan exists, then common sense should prevail.

Your restoration plan should include the following:

- Ensure life safety at the disaster location.
- Reactivate fire protection and other alarm/life safety systems.
- Establish security at the site to keep out intruders, members of the public, the press, as well as employees who should not be allowed in the disaster area unless they are directly involved in damage assessment or mitigation efforts.
- Cover damaged roofs, doors, windows, and other parts of the structure.
- Arrange for emergency heat, dehumidification, or water extraction.
- Separate damaged components that may interfere with restoration, but do not dispose of these components because restoration experts and the insurance adjuster will want to inspect them.
- Take photographs or videotape of the disaster site as well as damaged and undamaged property.
- Bring in experts in document/records restoration and qualified technical personnel to work on computer and communications equipment and systems, machinery and furniture, wall and floor coverings, and structural elements.
- Maintain a log of all steps taken after a disaster, noting time, location, what has been done, who did it, as well as work orders and invoices of all expenditures relating to the disaster.

After the disaster site has been secured and stabilized and the extent of damage assessed, contracts should be negotiated with qualified restoration contractors. The insurance company adjuster may be able to recommend qualified contractors. The adjuster should be consulted before any contracts are awarded.

The extent of the restoration possibly depends on the type of property damaged, the nature of the damage, and the extent and speed of post-disaster damage minimization. Another factor is the level of expertise brought in to assess and recommend restoration strategies as well as the quality of the restoration contractors brought in to do the work.

Following are some generalized comments on the restoration of paper documents, magnetic media (computer disks and tape), and electronic equipment and machinery.

Water damage is one of the most prevalent forms of damage to paper-based documents. Restoration efforts need to begin immediately if documents are to be saved. Water should be pumped out of the area as quickly as possible. The area also needs to be vented to allow air to circulate. Cool temperatures will help preserve water-soaked documents until actual restoration work can begin. Bringing in a freezer unit such as a refrigerated trailer (capable of being held at 0 degrees F) to store the documents will help slow down mold damage. Before

freezing, documents should be cleaned and handled with extreme care. Documents should be kept in blocks (i.e., not pulled apart) as this will prevent additional deterioration. Documents that are not thoroughly soaked can be dried using dehumidification. Freeze-drying water-soaked documents will produce good results. Sterilization and application of a fungicidal buffer will help prevent further mold damage. Dehumidification and freeze-drying can take from one to two weeks to be completed.

Damaged computer tapes and diskettes need to be restored within 72 to 96 hours of a disaster to be effective. Water-damaged diskettes can be opened and dried using isopropyl alcohol and put into new jackets. Then the information is transferred onto new disks. Tapes can be freeze-dried or machine-dried using specialized machinery. The data on the tapes is then transferred to new media. Soot- and smoked-damaged diskettes need to be cleaned by hand, and then data transfer can take place.

Equipment and machines need to be evaluated on a case-by-case basis. There are specialist firms that can evaluate and recommend repair/restoration strategies for equipment. These firms may also do the repairs, or they may recommend shipping the damaged equipment to the manufacturer or utilize other shops to do the restoration. In general, insurance companies will not authorize replacement of damaged equipment with new or refurbished equipment unless the cost to repair the item exceeds 50 percent of its replacement cost. Smoke, soot, and other contaminants can be removed from equipment and replacement parts when damaged parts cannot be adequately cleaned. Occasionally, the original manufacturer may balk at substantially repairing damaged equipment, claiming that the repair will prove inadequate or will void the manufacturer's warranty. They are usually interested in selling new equipment. In such cases, insurance companies may be able to purchase replacement warranties (to replace the original manufacturer's warranty) from a warranty replacement company to satisfy the insured. The replacement warranty will be for the period of time remaining on the original manufacturer's warranty.

What Are the Costs for a Restoration Program?

The costs associated with restoration are more "at time of disaster" costs and would be covered by insurance. Having a thorough restoration strategy and plan will help to scope the insurance needed, and may even save money for those who are over-insured due to the lack of knowledge.

The primary cost of a program are the people resources necessary to develop and maintain the capability.

An approach to matching insurance needs with the potential cost to restore data and infrastructure is to start with your insurance carrier. Determine the types of restoration covered with different policies and then compare the coverage with restoration company estimates. Costs are usually based on square feet, type of media, etc.

Restoration of critical equipment is usually procured through the source of the equipment. This may include staged replacement parts or quick-ship components. Sometimes there is an incremental charge to maintenance fees to guarantee expedited service or replacement.

Ensuring Provider Can and Will Perform at Time of Disaster

Restoration is a service not dissimilar to maintenance for critical IT and facility operations. In the event of an emergency, any delay can cause a significant financial impact. You should view restoration in this same light. Therefore, expend the same diligence you would to selecting a service provider for ensuring business continuation, to selecting one for ensuring timely business resumption.

Testing Your Restoration Plan

Once a restoration plan has been implemented, it should be tested as part of a company's BCP program. The purpose of testing will be to validate that the plan:

1. Meets the business needs in terms of timeframe
2. Reduces the exposure to the loss of documents and data to an acceptable level
3. Remains in compliance with insurance requirements
4. Is current and the level of detail is sufficient to ensure a timely, efficient recovery

Testing is a primary means of keeping the restoration plan current. Regular tests with varying scope and objectives prevent the program from becoming too routine. As with any testing program, you start out simple and build on successes. Initially, it may involve contacting your service providers and verifying the following:

- You would be able to reach them at any hour, on any day
- They should be able to respond within the expected timeframes

Other tests may involve your restoration team members' awareness of the plan, ability to perform the tasks, and coordination with other "recovery and return to normal" activities.

In some cases, a company's need for restoration services actually diminishes. As IT solutions become more robust and the need for nonstop processing increases, more and more companies employ remote, replicated data. In this case, if the primary copy of data is lost, a second, equally current copy is available. Therefore, if a company had services for the restorations of electronic media, it may not be necessary.

Restoration Plan without a BCP Plan

Even if your company does not have a BCP program, it is still prudent to have ready resources to provide restoration services if needed. A company that does not understand the need for a BCP program will not allocate resources to develop a restoration strategy. A fallback would be to coordinate with your insurance carrier an understanding the critical nature of your vital records and single points of processing failure in order to procure the appropriate resources to get the job done.

Conclusion

A restoration strategy is one that can be implemented relatively easily and at minimal cost. Have your insurance carrier explain the types of hazards and restoration techniques, and if in a bind, work with the approved service partners.

Because time is of the essence when it comes to recovering damaged vital records and sensitive equipment, a BCP team should be assigned specific restoration responsibilities. Restoration should be a close second when it comes to recovering your business following a disaster.

Getting Support for Your Restoration Program

The most difficult task in developing a restoration capability and plan is to get internal manpower resources approved to help with the work. There may be some reluctance to go to management and suggest there is a need to prepare for the potential damage to critical property after management has spent money supposedly to eliminate the risk.

Everyone has seen news reports of damage due to floods, fires, and explosions. What most people do not know is that there is significant technology available to recover the critical data from damaged vital records. In addition, there are service providers who will guarantee replacement equipment within preestablished timeframes for a fixed subscription fee.

The important task is for the owner of critical business data and processing equipment to educate himself and his management that preplanning can significantly reduce the impact from potential loss of data.

Next Steps to Planning for Restoration

Below is an outline of steps to be performed to design and implement a restoration strategy to further protect a company's informational and physical assets.

I. Assess the needs
   A. What insurance coverage currently exists for the recovery and restoration of vital records following an event?
   B. What are the coverage options available for restoration of archival data and documents, as well as data needed to fully recover business processing?
   C. What are the business risks in terms of single copies of vital records?

D. What are the business risks associated with the loss of equipment and facilities?

II. Develop a restoration strategy
   A. Identify alternatives to either eliminate single points of failure or reduce the impact of lost or damaged property.
   B. Perform a cost/benefit analysis of viable alternatives.
   C. Obtain approval and funding for appropriate alternatives.
   D. Implement the preventive and restoration strategies.

III. Develop a restoration plan and ongoing quality assurance
   A. Incorporate restoration into the existing BCP program.
   B. Assign restoration roles and responsibilities.
   C. Coordinate restoration with the risk management department and other BCP efforts.
   D. Develop ongoing plan maintenance tasks and schedules.
   E. Perform periodic tests of restoration capability.

Business Resumption Planning and Disaster Recovery: A Case History

Kevin Henry, CISA, CISSP

Business resumption and disaster recovery planning is probably the part of information security that is easiest to overlook and postpone. Perhaps that is because few people actually enjoy preparing a business resumption plan. Like insurance, it is something one hopes is never needed; and because it is an inexact science at best, one is rarely sure that it has been completed correctly. More often, however, no one intentionally delays business resumption planning; it just does not happen — because of other job pressures, deadlines, and more seemingly urgent demands on one's time.

It is estimated that fewer than 50 percent of all firms have a reliable, complete, and current business resumption and disaster recovery plan in place.[1] For that reason, many firms are looking at two initiatives to address the lack of viable business resumption plans. The first is establishing a risk manager position within the corporation, a position with the primary responsibility of coordinating the development of business resumption and disaster recovery plans. The second initiative is to build business resumption and disaster recovery plan funding and timelines into every project. This is intended to force the development of plans prior to the project wrapping up and the team members dispersing. The effectiveness of these initiatives will ultimately depend on the leadership of senior management to enforce the mandate of the risk managers and require the completion of these tasks prior to project closure.

Because no organization ever wants to experience either a partial or full interruption of business operations, there is a silver lining in every cloud. The experience of having handled — and survived — a disaster can have a long-term benefit to a company. This chapter examines an actual case history of a computer system failure and the events that contributed to this becoming a disaster. In this particular instance, the business plan was implemented and, as it always seems to be, it was not a complete solution; however, it allowed a measure of the business process to continue to operate.

A business resumption plan is designed to provide an alternate method of continuing business operations in the event that the "normal" processes have been disrupted. A business resumption plan must address all types of scenarios that could disrupt the business process. These can be computer failures, but they are often other internal or external incidents that prevent an operation from continuing its usual practices. Some of these other disruptions may be environmental, such as fire (even if in a nearby structure) or flood, or they may be other external issues such as labor disruptions, gas leaks, or power failures. One notable computer system failure was caused by a watermain break some distance from the data processing site. When the water supply to the air conditioning unit was stopped, the air conditioning unit shut down and the data center overheated within a very short time.

One primary purpose of a business resumption plan and disaster recovery plan is to reduce the likelihood of a disaster occurring. This is a natural by-product of the initial stages of a properly developed business

resumption plan. As the business resumption team begins to examine the area that it is developing a plan for, that team will create an awareness of the risks a system or corporation is exposed to. This will also locate and identify the weaknesses that could lead to an operational failure. These weaknesses might be found in a system, a process, hardware, software, lack of training, personnel issues that have not been addressed, or some form of environmental or external threat. Following that, the purpose of the plan is to set up a framework for the business process to be able to resume its usual operations in an alternate manner. The implementation speed of a business resumption plan is primarily dependent on the importance of the system. A critical system (such as 911, hospitals, or air traffic control) must have a plan that can be operational within seconds or minutes, while a less-critical system may be able to slowly come up to speed, over a period of days or even weeks.

An excellent example of a successful business resumption scenario was the ability of United Airlines to continue its operations despite a fire that shut down its operational control center for three weeks in 1999. Despite controlling 2500 flights a day from that site, United was able to resume processing at its backup site in less than one hour, with the result that only one flight had to be canceled and a handful of other flights experienced minor delays. Fortuitously, this backup site was just in the final stages of acceptance testing as part of the development of a new business resumption plan.

Once a disaster has struck, the primary intent of the business groups is to resume operations with as little operational impact on critical systems as possible. Simultaneously, the disaster recovery plan implementation is beginning. The first goal of the disaster recovery plan is to prevent further damage. This means, first and foremost, ensuring personal safety. Then the disaster recovery plan splits into three areas: cleanup of the damaged site (salvage and repair), supporting the alternate business operations, and transition back to normal process.

The ultimate goal of the business resumption and disaster recovery plan is achieved when business operations are able to resume their normal or predisaster state. Failure to be able to maintain or resume operations in a timely manner results in a devastating statistic of nearly 50 percent total business failure.

To be effective, a business resumption and disaster recovery plan must be fully documented. Every responsibility and task, all software and hardware, communications links, and security requirements must be written out and available immediately when required. It is not sufficient to rely on personnel with a wealth of experience or understanding of the operations to be available for consultation in the middle of the disaster. When properly documented, any two people reading the document will reach the same conclusions and take the same actions. When this can be proven to be the case, then one can be assured that the documentation is thorough and clear.

A Case History

This case history is an actual sequence of events experienced by Serv-co (a fictitious name). There is a tremendous amount of information to be learned from this disaster — both to see the sequence of events that led up to and contributed to the disaster itself, and the lessons learned through the handling of the disaster.

Serv-co had a payments processing system (see Exhibit 138.1) that handled all of the incoming payments to the company — mailed checks, Internet payments, and payments handled by agents of Serv-co, including local banks and independent agents and representatives. The payment processing system handled in excess of 25,000 payments daily. The incoming payments were handled at three separate workstations (see Exhibit 138.1). The workstation operators would enter the payment amount and account number into the workstation. Once a thousand payments had been entered, the file was closed and transmitted to a central server. Attached to the file were control totals to assist in verification of file integrity and error detection. Once a day, the area manager would log on to the server and group all of the day's transaction files into one large file. Once some preliminary balancing had been done, the manager would establish a communications link to the legacy mainframe system that handled all customer account management and invoicing. The manager would transmit the cumulative file to the legacy system. Once received by the mainframe system, batch processes would be run that posted all of the payment activity to the individual customer accounts.

Unfortunately, one day the payment processing system failed.

The failure of the payment processing system happened, as most failures seem to do, on a Friday afternoon in mid-summer when most people's minds are already at the beach. The area manager called the support vendor and reported a strange error code that had been encountered when she tried to transfer the day's payments summary file to the mainframe system.

Being late on a Friday, it was agreed that the support company, referred to as Maint Group, would come out to Serv-co's location first thing Monday morning to investigate and correct the problem. This was not

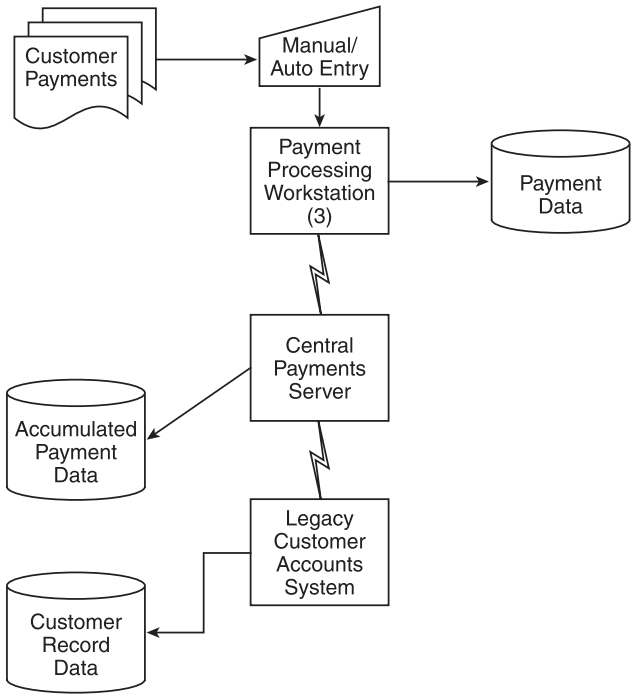

EXHIBIT 138.1 Payments system layout.

considered a serious problem. In the past, it had happened that minor system failures or file errors and imbalances would delay the posting of customer payments to their accounts by a day or two.

With his usually cheerful greeting, Maint Group's technician arrived early Monday morning to repair the problem. It should be noted that Maint Group was not the original vendor of the equipment; Maint Group had assumed the maintenance contract when the original vendor failed and went out of business. Within moments, the helpful grin of the technician faded as he realized that despite his years of experience with this equipment, he had never encountered this error condition. At this point, the value of a large vendor with a network of offices and a second-tier support group became apparent. Although this was not a common error, the technician was able to obtain assistance through contact with another branch (see Exhibit 138.2).

The error turned out to be a hard drive disk failure requiring the replacement of the hard drive. Here the first major deficiencies of the Serv-co payment processing system became clear. When Serv-co had purchased the system, instead of purchasing a server-class machine, the system server only included one hard drive and one power supply. Because of this, Serv-co's own Information Systems Standards Group had refused to accept the maintenance and oversight of the system.

EXHIBIT 138.2 Vendor Selection

When making a new purchase of hardware or software, or making the decision about in-house support or outsourced maintenance agreements, the choice of vendor is critical. Many times, the number of firms to choose from may be limited, especially when proprietary products are involved. However, where possible, a company or agency should ensure that it retains sufficient skills in-house to be able to perform or oversee basic updates and tasks. This is a safeguard against vendor failure or vendor labor disruption. Also, the choice of a large vendor may be more expensive than a local, smaller vendor. The larger vendor may have more technical and equipment support available for that price, whereas the smaller vendor may be able to provide faster or a more-personal level of service. Ensure that the choice of vendor includes a review of whether the vendor has adequate support systems in place to deal with abstract or custom problems and has ready access to spare components; although there may be a higher cost for such support, it can be critical in a disaster scenario.

Since the original purchase, the Payment Processing group had also moved to a new location. This meant a move of their workstations and server to a new facility. The equipment was located in a secure room; however, no provisions had been made for a proper power supply (UPS), nor were the proper environmental conditions provided for the equipment. This included mounting the server itself on a shelf over a desk. In addition, no secure and organized storage facility was provided for the backup tapes. The Payments Processing workgroup had several employees who had a keen interest in computers and were enthusiastic about looking after the equipment; however, without proper training and knowledge, they were unable to identify some of the basic deficiencies in the setup of the system.

As with many corporations, Serv-co had undergone some major restructuring a few years earlier. As part of this, several of the employees who were most knowledgeable about the system were released from Serv-co as part of a downsizing initiative. Because there was little or no documentation for the system, much of the practical knowledge of the system departed with these individuals (see Exhibit 138.3).

Back to the case history. The technician now had to find a new hard drive for the server. Because the equipment was now more than 12 years old, it was obsolete and piece parts were becoming increasingly difficult to find. In fact, Maint Group had sent a note to Serv-co two years earlier, indicating that the hard drive for this system was manufacturer discontinued and had exceeded its life expectancy. Maint Group recommended immediate replacement of the equipment. As a part of this notice, Maint Group also indicated that because of these limitations, it would only be able to continue to support the equipment on a "best effort" basis.

The technician was able to locate a hard drive in another city and arrangements were made to courier the hard drive to Serv-co for delivery first thing the next morning (Tuesday).

Tuesday morning the package arrived; the drive it contained was not the same one indicated by the label on the outside of the package. (Obviously, whenever a critical delivery of this type is required, the sender should take the necessary steps to verify the contents of the delivery.)

At this point, Serv-co had begun the transition from a minor inconvenience to a major disaster. Every day that passed caused an increase in the number of customers who have made payments to Serv-co and they received bills that did not reflect those payments. Moreover, these bills assessed the customers with an invalid late payment charge. This began to cause increased workload for the Customer Service Representatives and lead to poor customer relations and possibly even unwelcome media attention. By the end of this disaster, more than 15,000 customers had been affected.

Maint Group located two more hard drives in other parts of the country and arranged to have both sent to Serv-co for delivery the next morning. However, Wednesday morning arrived with no deliveries. Because of a labor disruption at the airline, the packages had been bumped off their flights and consequently did not arrive.

Thursday morning a replacement hard drive arrived and, with a great sense of relief, the technician began to install it. Once installed, the technician asked the local manager for the copies of the system backups so that he could begin to load the operating system onto the new drive. The manager reached across the shelf and passed the technician a stack of old tape cartridges. For several years since the downsizing of the "computer support" person for the group, the manager had faithfully been taking daily backups and storing them on these tapes. What she did not realize was that all she was backing up were the daily transaction files, not the operating system. Serv-co had no viable backup copy of its operating system.

The Maint Group technician called his technical support personnel and was told that a generic copy of the operating system was available, but that it would not contain any customization that had been built into the

EXHIBIT 138.3 Documentation

Documentation is perhaps the most critical resource in a disaster situation. When properly prepared, documentation allows all personnel involved to understand their tasks and responsibilities and how those tasks fit into the other activities surrounding the disaster. Ideally, documentation should be written in a clear, standard format so that no time or effort is lost trying to understand the flow of the documents. This means that any two people who read the documents will come to the same conclusion and undertake the same actions.

Documentation must be written for all processes and tasks surrounding a system, especially the routine or mundane daily tasks. Often, it is these tasks that no one knows how to do, or forgets, when the "expert" is sick or on vacation.

operating system by the original vendor (who, as one remembers, had since gone out of business). This generic copy was installed but it was not useable in its current state. Maint Group immediately began the task of writing patches to the operating system to meet the requirements of the Serv-co application. These patches were promised to be ready by the following Tuesday.

At this point, the customer impact had become critical and Serv-co began to examine its business continuity program. As a proper program should, it reflected the critical time factors that applied to this group. Management had accepted that payments processing was not as critical as some other services provided by Serv-co and rightfully had designed the plan to allow for a few days' delay before business process resumption. The business resumption plan prescribed a manual work-around of entering the payments into financial spreadsheets. These spreadsheets would then be FTP'd to the legacy mainframe systems and the batch processes adapted to read the new files. This was a tremendously labor-intensive operation, and a call went out to the various departments within Serv-co to provide personnel to work over the long holiday weekend to input these payments.

Because of the manual effort involved, more personnel were also required to examine the completed spreadsheets to detect errors. In fact, of the many spreadsheets created, only one was found to be totally error-free. The local Payments Processing manager called the Risk Management group to alert them of the implementation of their business continuity plan and was advised to "keep them posted." This was a breakdown in the role of the Risk Management group. With their knowledge of crisis management and process flow and their familiarity with contacting other groups such as Human Resources, Legal, and Corporate Communications, they could have provided a substantial level of assistance in handling this disaster. But like so many departments, Risk Management was short staffed due to vacations. Without this assistance and coordination, the local manager in Payments Processing was soon overwhelmed with calls from other groups for scheduling and recovery operations. The demands of this activity on the manager's time and the time of the other people in her group further impacted their ability to respond to the business needs. The other result of the lack of input from Risk Management was that proper communication with the unions on the property were not established and, instead of receiving support for their recovery efforts, the manager was soon faced with several grievances pertaining to people from the wrong jurisdiction doing another bargaining unit's work. This may not have been avoidable, depending on the overall tone of labor/management relations, but proper communication and involvement may have prevented further animosity and stress in an already tense situation.

On Tuesday morning, the Maint Group technician arrived with the patches for the operating system. Once installed, these patches provided some functionality but many of the error-detection and balancing controls were absent. Also, the server was unable to establish a communications link with the mainframe. The last time this link had been set up, it had taken two technicians three days to determine the correct settings. Once again, the documentation was missing, and with it, this critical piece of information. Fortunately, a copy of the configuration was found in the recycling bin by a LAN support person who had been doing an inventory of communications links several months earlier.

Over the next week, Serv-co was able to catch up on its payments processing, but the cost in manpower and goodwill was extensive.

It is noteworthy that at the time of this failure, Serv-co had already bought a replacement system but it had not yet been delivered by the vendor. This process had started more than two years earlier with the notification of the obsolete equipment, but it had encountered several hurdles along the way. Management had twice sent the purchase proposal back to the Payment Processing department to explore other options (such as outsourcing) and less-expensive solutions. This delayed the replacement long enough for the existing equipment to finally fail.

Once again, however, the Payments Processing area had purchased the replacement equipment without the input and oversight of the Information Systems Standards group. As a result, the new equipment was similar to the old equipment in that it only had a single hard drive and a single power supply. It was also designed as a stand-alone system and plans had not been made to back it up to the corporate enterprise storage system. In fact, the Information Systems Standards group had once again declared that it would not support the new system, and its only concern with the project was that the interface to its legacy systems would work correctly.

So, what did Serv-co learn from this disaster? And what can the reader learn? A lot.

Professional Support

Ensure that all systems are installed with the oversight of information systems (IS) professionals and according to corporate standards. The active involvement of the IS staff in the procurement and support of stand-alone systems will prevent many minor errors from turning into major disasters. If the corporation does not have the standards it needs to develop them, this will also prevent further holes from developing in the security infrastructure through incompatible equipment. The more standard the equipment is, the easier it is to have in-house knowledge and keep the correct operating system patches up to date. Standard equipment also allows for easier load sharing and minimizes single points of failure. As a part of this, all companies should ensure that they have knowledgeable support for all of their systems. Especially when a system has been developed by an outside contractor, ensure that the knowledge of the system is not lost at the completion of the project. Once this disaster was resolved, Serv-co's Payments Processing and IS departments began to cooperate and redesign the replacement system. This included a regular backup to the enterprise storage system and the purchase of server-class equipment.

Backups

It goes without saying that proper backups must be done on all operating systems. Often, it is configurations (communications, routers, etc.) and rule bases (firewalls) that are overlooked. In all cases, backups should be done often enough to ensure that a processing cycle can be rebuilt if necessary. There are many examples of situations in which a system has only kept two or three generations of certain files. In the event of a failure (especially when the failure was related to application program change), the on-call programmer tries to rerun the job. If the subsequent rerun fails, it could happen that the last good backup has already been aged off and deleted before the problem is corrected. It is also important to ensure that all legal requirements for backups are met, such as long-term retention of financial records.

There are many different types of backup media available these days, including various tape products and CDs. The latest documentation on CDs indicates that they have a life expectancy even in adverse conditions of up to 200 years. In that case, the lifespan of the product is not the problem; the challenge is to ensure that any encryption keys are securely stored and available, and the software needed to read the CDs is also available the day that the data is required.

When recording backups, always ensure that the backup copy is readable. One company recently attempted to recover from a disk-head write failure only to discover that four of its 20 newly purchased tape cartridges were faulty. When it comes to the point of needing to recover from a backup, if the backup is faulty, the extent of the problem grows exponentially.

Equipment Aging

More and more of the equipment in use in corporations and agencies these days has already exceeded its lifespan. This is especially true for hard drives, power supplies, and tapes. A regular inventory of all equipment should be taken and the equipment specifications reviewed to ensure that the equipment is still reliable.

Dependencies

Many systems and business processes are not even aware of the other systems that depend on them, and that they themselves depend on for processing. Detailed data flow diagrams showing all internal and external system dependencies should be drawn up so that if a system fails, it is immediately apparent who else has been affected. This is especially important for financial systems and areas subject to regulatory requirements where the absence of a file may not be noticed but could have significant impact on processing or legal penalties.

Encryption

If the system has any form of encryption, it is necessary to keep all keys in a secure place for retrieval. Often, once a system has been operating for some period of time, the keys are forgotten; and when the system experiences a failure, it can be extremely dangerous if the keys are unavailable. Whenever an employee is using

encryption for company documents or files, a copy of the keys should be retained in a secure, trusted location. It has happened that the loss of an employee through accident or termination has left a company unable to recover critical files. In one recent case, an employee who was about to be terminated for inappropriate behavior was able to hold the company "hostage" by refusing to disclose his keys and the administrative passwords to several key systems.

Vendor Failure

One of the most prevalent characteristics of the entire information processing field has to be vendor change. On a nearly daily basis, vendors are opening, closing, merging, or changing business direction. When this is accompanied by the rapid replacement of one technology with a newer product, this can have a significant impact on business resumption plans. Information systems professionals need to be continuously aware of the state of their vendor support network. A list of vendor phone numbers and contact lists must be kept together with the business resumption plan, and many plans should also include a commitment from vendors to supply new equipment on a priority basis in the event of a major failure.

Vendor-supplied software should be kept in escrow (held in trust by a third party) so that it is available if the vendor is unable to meet its maintenance or upgrade contractual conditions.

When purchasing new equipment, the risk is always whether it will continue to be manufactured and supported. More than one company has been unable to obtain a maintenance agreement for equipment that it had recently purchased because the vendor moved to a new line of business and abandoned a certain product line.

When selecting a vendor, the decision must be made whether to go with a possibly higher-priced vendor that has a large network of support and spare equipment availability, or with a smaller or local vendor and mitigate the risk through the purchase of spare parts or retaining greater in-house expertise.

BCP: Up to Date

To get a comprehensive and complete business resumption plan set up is difficult, but the effort does not stop there. A corporation, department, or agency still needs to identify the person responsible for the plan on an ongoing basis. Plans need to be reviewed at least once a year and after any major change in departmental structure. This responsibility should be built into the job description of the person who will maintain the business resumption plan and represent the department on the corporate Risk Management team. If the department does routine job reviews, the adherence to this responsibility should also be reviewed.

Union

Unions are a fact of life in many companies and agencies these days, and that places certain legal restrictions on the employees and managers. In most jurisdictions, it is illegal to negotiate a separate agreement with an individual who is represented by a union. Often in a crisis, a manager has attempted to negotiate a separate pay or compensation agreement directly with employees. This may seem practical but it can also be illegal and unenforceable. The business resumption plan must include a method of contacting a union representative for a unionized group that could be involved or affected by a business interruption. Hopefully, through prompt communication, the union can be available to assist in the recovery and personnel coordination activity, rather than add increased complexity to the disaster through labor disruption.

Whether or not there is a union on the property, the Human Resources department should be involved in the recovery efforts to ensure that any applicable labor codes or laws are being followed.

Risk Management Involvement

Many corporations and agencies now have a Risk Management group that has overall responsibility for coordinating the departmental plans, liason with external and internal groups, and leadership in a crisis. This group needs to have unrestricted access to the senior management of the company and must have the mandate to assist or lead in any business disruption. Without this mandate, Risk Management groups often have

difficulty obtaining the subject matter experts (SMEs) to assist in a crisis because a manager in another group has refused to release them from their regular duties.

The focus areas of this group in a crisis are communication, collaboration, control, and coordination (the 4 Cs). With a properly set up group, a corporation will avoid the "Alexander Haig syndrome" of competing groups unsure of who is in charge and delivering conflicting statements.

One of the members of this group, on an as-needed basis, should be a member of the Health and Safety group of the company. This is to ensure that proper attention is being paid to the health issues, both mental and physical, of individual workers in a crisis scenario.

In a disaster, the Risk Management group should also ensure that all advertising campaigns related to the company or the disaster are halted or amended, and that a separate individual or organization is monitoring the media and providing feedback on how the corporation's statement or message is being received in the community.

Two factors that can be missed in many Risk Management groups are housekeeping and security of the Emergency Operations Center (EOC) and the site of the failure during disaster recovery efforts. Limiting access to the EOC and keeping it clean and uncluttered will aid in the smooth operation of the center.

The EOC should have separate access lines for the families of employees that are involved in the recovery operation so that they can pass on messages or receive updates. The understanding and resolution of family issues are critical to the involved individuals being able to focus on the recovery efforts. In addition, the company should have a telephone line with an answering machine that provides regular updates to other employees not directly related to the crisis. This can also be used to relay worksite and reporting information to the employees.

A disaster recovery operation often includes the disbursement of funds that exceeds the normal limit of local managers. A chain of command that accelerates the approval process or grants an increased spending limit on a temporary basis should be developed. There also needs to be a payroll process or provision for advance funds to be released to the families and individuals affected by the crisis.

The Risk Management group should have a list of the major customers of a company so that calls can immediately be made to these firms indicating that the company is still operational and outlining revised contact methods. This may prevent the loss of contracts or eroded confidence by the client community.

Downsizing

Downsizing has had a devastating effect on information systems security. It has led to the amalgamation of many functions, thereby removing separation of duties, and it has led to many individuals assuming responsibility for many tasks for which they have not received adequate training or experience. This is where inadequate documentation can harm a corporation. Often, many of the little jobs that were being done and the reasons for those actions are lost once a person has been released. Support people are especially vulnerable to downsizing because the benefit and importance of their work is not realized.

Downsizing also impacts morale and loyalty to the corporation. It has been estimated that a downsizing initiative deprives a corporation of four week's worth of productivity. Increased attention to security risks and possible malicious behavior must be included in the activity of the information systems security professional at this time. Most estimates are that 10 percent of an employee base will take advantage of an opportunity to defraud a corporation at any time. During a period of downsizing, this will usually rise to approximately 30 percent.

Documentation

Although documention was previously discussed, it is timely to add one further comment. Following any failure or test of the business resumption plan or a disaster recovery effort, review all documentation promptly to record all improvements and amendments to the documentation. Ensure that only the latest version of documentation is available (this can be accomplished by numbering the documents).

Partial Processing: Who Gets Priority

During a disaster every department wants priority service. This is not the time to make these decisions or to try to juggle multiple tasks. An integral part of developing business resumption and disaster recovery plans is to determine which areas of the company get first attention. In many plans, the plan does not include enough hardware or processing power to recover all business processes. Ensure that the correct ones are the ones that are recovered. Once a plan has been developed, have all managers sign off on it so that they realize and accept who will get first priority in the event of an incident.

Multiple Disasters: Be Aware of Other Disasters that May Impact the Primary Recovery Site

A daily task of the Risk Management group, and all business resumption planners, has to be monitoring of ongoing events that could affect a corporation's business processes or disaster recovery plans. For example, a corporation should attempt never to be surprised by an event at a neighboring facility or an environmental hazard that affects its ability to operate. This includes an awareness of ongoing disasters that may be affecting its disaster plan. An example of this was experienced following the World Trade Center bombing. A few weeks later, another company that lost its data center due to a structural failure (heavy snow load on the roof) was unable to move into its contracted hot site as planned because it was already in use by companies displaced from the World Trade Center. If that company had been attentive to this, it could have realized that this would have an effect on its disaster recovery plans and taken measures to arrange for an alternate site if necessary prior to its own failure.

A disaster recovery plan may be needed for an extended period of time; recent ice storms, for example, have disrupted commercial power for some firms for several weeks. Despite the fact that they were able to initially resume business operations, they were unable to continue because they only planned for providing alternate power for a few days.

Summary

Information systems security professionals have become keys players in the whole field of business resumption planning and disaster recovery. This is a radical departure from the normal duties of most information systems security personnel. Rather than a strictly technical or systems understanding, it requires them to gain an understanding of the entire business process and how they can support and enable those processes in a disaster scenario. The knowledgeable and professional advice that information systems security professionals provide will also significantly enhance the ability of most organizations, corporations, and agencies to prepare for and react to any incidents that could impair their business processes or threaten their very survival in a competitive and fast-moving marketplace.

Business Continuity Planning: A Collaborative Approach

Kevin Henry, CISA, CISSP

Business continuity planning (BCP) has received more attention and emphasis in the past year than it has probably had cumulatively during the past several decades. This is an opportune time for organizations to leverage this attention into adequate resourcing, proper preparation, and workable business continuity plans. Business continuity planning is not glamorous, not usually considered to be fun, and often a little mundane. It can have all the appeal of planning how to get home from the airport at the end of an all-too-short vacation.

This chapter examines some of the factors involved in setting up a credible, useful, and maintainable business continuity program. From executive support through good leadership, proper risk analysis and a structured methodology, business continuity planning depends on key personnel making business-oriented and wise decisions, involving user departments and supporting services.

Business continuity planning can be defined as preparing for any incident that could affect business operations. The objective of such planning is to maintain or resume business operations despite the possible disruption. BCP is a preincident activity, working closely with risk management to identify threats and risks and reducing the likelihood or impact of any of these risks occurring. Many such incidents develop into a crisis, and the focus of the effort turns to crisis management. It is at this time that the value of prior planning becomes apparent.

The format of this chapter is to outline the responsibilities of information systems security personnel and information systems auditors in the BCP process. A successful BCP program is one that will work when needed and is built on a process of involvement, input, review, testing, and maintenance. The challenge is that a BCP program is developed in times of relative calm and stability, and yet it needs to operate in times of extreme stress and uncertainty. As we look further into the role of leadership in this chapter, we will see the key role that the leader has in times of crisis and the importance of the leader's ability to handle the extreme stress and pressures of a crisis situation.

A significant role of the BCP program is to develop a trained and committed team to lead, manage, and direct the organization through the crisis.

Through this chapter we will examine the aspects of crisis development, risk management, information gathering, and plan preparation. We will not go into as much detail about the plan development framework because this is not normally a function of IT or security professionals, yet understanding the role and intent of the business continuity program coordinator will permit IT professionals to provide effective and valued assistance to the BCP team.

So what is the purpose of the BCP program? It is to be prepared to meet any potential disruption to a business process with an effective plan, the best decisions, and a minimization of interruption.

A BCP program is developed to prepare a company to recover from a crisis — an event that may have serious impact on the organization, up to threatening the survival of the organization itself. Therefore, BCP is a process that must be taken seriously, must be thorough, and must be designed to handle any form of crisis that may occur. Let us therefore look at the elements of a crisis so that our BCP program will address it properly.

The Crisis

A crisis does not happen in isolation. It is usually the combination of a number of events or risks that, although they may not be catastrophic in themselves, in combination they may have catastrophic results. It has sometimes been said that it takes three mistakes to kill you, and any interruption in this series of events may prevent the catastrophe from taking place. These events can be the result of preexisting conditions or weaknesses that, when combined with the correct timing and business environment, initiate the crisis. This can be called a "catalyst" or "crisis trigger."

Once the crisis has begun, it evolves and grows, often impacting other areas beyond its original scope and influence. This growth of the crisis is the most stressful period for the people and the organization. This is the commencement of the crisis management phase and the transition from a preparatory environment to a reactionary environment. Decisions must be made on incomplete information amid demands and pressure from management and outside groups such as the media and customers. An organization with an effective plan will be in the best position to survive the disaster and recover; however, many organizations find that their plan is not adequate and are forced to make numerous decisions and consider plans of action not previously contemplated. Unfortunately, most people find that Rudin's Law begins to take effect:

> When a crisis forces choosing among alternatives, most people will choose the worst possible one.
>
> **— Rudin's Law**

Let us take a closer look at each of these phases of a crisis and how we can ensure that our BCP program addresses each phase in an effective and timely manner.

Preexisting Conditions

In a sporting event, the opposition scores; when reviewing the video tapes later, the coach can clearly see the defensive breakdowns that led to the goal. A player out of position, a good "deke" by the opponent (used in hockey and soccer when an opposing player fools the goalie into believing that he is going in one direction and yet he actually goes in a different direction, thereby pulling the goaltender out of position and potentially setting up a good opportunity to score), a player too tired to keep pace — each contributing to the ability of the unwanted event to occur. Reviewing tapes is a good postevent procedure. A lot can be learned from previous incidents. Preparations can be made to prevent recurrence by improvements to the training of the players, reduction of weakness (maybe through replacing or trading players), and knowledge of the techniques of the opponents.

In business we are in a similar situation. All too often organizations have experienced a series of minor breakdowns. Perhaps they never became catastrophes or crises, and in many cases they may have been covered up or downplayed. These are the best learning events available for the organization. They need to be uncovered and examined. What led to the breakdown or near-catastrophe, what was the best response technique, who were the key players involved — who was a star, and who, unfortunately, did not measure up in times of crisis? These incidents uncover the preexisting conditions that may lead to a much more serious event in the future. Examining these events, documenting effective response techniques, listing affected areas, all provide input to a program that may reduce the preexisting conditions and thereby avert a catastrophe — or at least assist in the creation of a BCP that will be effective.

Other methods of detecting preexisting conditions are through tests and audits, interviewing the people on the floor, and measuring the culture of the organization. We often hear of penetration tests — what are they designed to do? Find a weakness before a hostile party does. What can an audit do? Find a lack of internal control or a process weakness before it is exploited. Why do we talk to the people on the floor? In many cases, simply reading the policy and procedure manuals does not give a true sense of the culture of the organization. One organization that recently received an award for its E-commerce site was immediately approached by several other organizations for a description of its procedure for developing the Web site. This was willingly provided — except that in conversation with the people involved, it was discovered that in actual fact the

process was never followed. It looked good on paper, and a lot of administrative time and effort had gone into laying out this program; but the award-winning site was not based on this program. It was found to be too cumbersome, theoretical, and, for all intents and purposes, useless. Often, merely reviewing the policy will never give the reader a sense of the true culture of the organization. For an effective crisis management program and therefore a solid, useable BCP program, it is important to know the true culture, process, and environment — not only the theoretical, documented version.

One telecommunications organization was considering designing its BCP for the customer service area based on the training program given to the customer service representatives. In fact, even during the training the instructors would repeatedly say, "This may not be the way things will be done back in your business unit, this is the ideal or theoretical way to do things; but you will need to learn the real way things are done when you get back to your group." Therefore, a BCP program that was designed according to the training manual would not be workable if needed in a crisis. The BCP needs to reflect the group for which it is designed. This also highlighted another risk or preexisting condition. The lack of standardization was a risk in that multiple BCP programs had to be developed for each business operation, and personnel from one group may not be able to quickly assume the work or personnel of another group that has been displaced by a crisis. Detecting this prior to a catastrophe may allow the organization to adjust its culture and reduce this threat through standardization and process streamlining.

One of the main ways to find preexisting conditions is through the risk analysis and management process. This is often done by other groups within and outside the organization as well — the insurance company, the risk management group, internal and external audit groups, security, and human resources. The BCP team needs to coordinate its efforts with each of these groups — a collaborative approach so that as much information is provided as possible to design and develop a solid, workable BCP program. The human resources group in particular is often looking at risks such as labor difficulties, executive succession, adequate policy, and loss of key personnel. These areas also need to be incorporated into a BCP program.

The IT group plays a key role in discovering preexisting conditions. Nearly every business process today relies on, and in many cases cannot operate without, some form of IT infrastructure. For most organizations this infrastructure has grown, evolved, and changed at a tremendous rate. Keeping an inventory of IT equipment and network layouts is nearly impossible. However, because the business units rely so heavily on this infrastructure, no BCP program can work without the assistance and planning of the IT group. From an IT perspective, there are many areas to be considered in detecting preexisting conditions: applications, operating systems, hardware, communications networks, remote access, printers, telecommunications systems, databases, Internet links, stand-alone or desktop-based systems, defense systems, components such as anti-virus tools, firewalls, and intrusion detection systems, and interfaces to other organizations such as suppliers and customers.

For each component, the IT group must examine whether there are single points of failure, documented lists of equipment including vendors, operating version, patches installed, users, configuration tables, backups, communications protocols and setups, software versions, and desktop configurations. When the IT group has detected possible weaknesses, it may be possible to alert management to this condition as a part of the BCP process in order to gain additional support for new resources, equipment, or support for standardization or centralized control.

The risk in many organizations is the fear of a "shoot the messenger" reaction from management when a potential threat has been brought to the attention of management. We all like to hear good news, and few managers really appreciate hearing about vulnerabilities and recommendations for increased expenditures in the few moments they have between budget meetings. For that reason, a unified approach using credible facts, proposals, solutions, and costs, presented by several departments and project teams, may assist the IT group in achieving greater standards of security and disaster preparedness. The unfortunate reality is that many of the most serious events that have occurred in the past few years could have been averted if organizations had fostered a culture of accurate reporting, honesty, and integrity instead of hiding behind inaccurate statistics or encouraging personnel to report what they thought management wanted to hear instead of the true state of the situation. This includes incidents that have led to loss of life or financial collapse of large organizations through city water contamination, misleading financial records, or quality-of-service reporting.

It is important to note the impact that terrorist activity has had on the BCP process. Risks that had never before been seriously considered now have to be contemplated in a BCP process. One of the weaknesses in some former plans involved reliance on in-office fireproof safes, air transit for key data and personnel, and proximity to high-risk targets. An organization not even directly impacted by the actual crisis may not be able to get access to its location because of crime-scene access limitations, clean-up activity, and infrastructure

breakdowns. Since the terrorist actions in New York, several firms have identified the area as a high-risk location and chosen to relocate to sites outside the core business area. One firm had recently completed construction of a new office complex close to the site of the terrorist activity and has subsequently chosen to sell the complex and relocate to another area.

On the other hand, there are several examples of BCP programs that worked properly during the September 11, 2001, crisis, including tragic incidents where key personnel were lost. A BCP program that is properly designed will operate effectively regardless of the reason for the loss of the facility, and all BCP programs should contemplate and prepare for such an event.

Crisis Triggers

The next step in a crisis situation is the catalyst that sets off the chain of events that leads to the crisis. The trigger may be anything from a minor incident to a major event such as a weather-related or natural disaster, a human error or malicious attack, or a fire or utility failure. In any event, the trigger is not the real problem. An organization that has properly considered the preconditions that may lead to a crisis will have taken all precautions to limit the amount of damage from the trigger and hopefully prevent the next phase of the crisis — the crisis expansion phase — from growing out of control. Far too often, in a *post mortem* analysis of a crisis, it is too easy to focus on the trigger for the event and look for ways to prevent the trigger from occurring — instead of focusing on the preconditions that led to the extended impact of the crisis.

When all attempts have been made to eliminate the weaknesses and vulnerabilities in the system, then attention can be given to preventing the triggers from occurring.

Crisis Management/Crisis Expansion

As the crisis begins to unfold, the organization transitions from a preparatory stage, where the focus is on preventing and preparing for a disaster, to a reactionary stage, where efforts are needed to contain the damage, recover business operations, limit corporate exposure to liability and loss, prevent fraud or looting, begin to assess the overall impact, and commence a recovery process toward the ultimate goal of resumption of normal operations. Often, the organization is faced with incomplete information, inadequate coordinating efforts, complications from outside agencies or organizations, queries and investigations by the media, unavailability of key personnel, interrupted communications, and personnel who may not be able to work together under pressure and uncertainty.

During a time of crisis, key personnel will rise to the occasion and produce the extra effort, clarity of focus and thought, and energy and attitude to lead other personnel and the organization through the incident. These people need to be noticed and marked for involvement in future incident preparation handling. Leadership is a skill, an art, and a talent. Henry Kissinger defines leadership as the ability to "take people from where they are to places where they have never been." Like any other talent, leadership is also a learned art. No one is born a perfect leader, just as no one is born the world's best golfer. Just as every professional athlete has worked hard and received coaching and guidance to perfect and refine his ability, so a leader needs training in leadership style, attention to human issues, and project planning and management.

One of the most commonly overlooked aspects of a BCP program is the human impact. Unlike hardware and software components that can be counted, purchased, and discarded, the employees, customers, and families impacted by the crisis must be considered. No employee is going to be able to provide unlimited support — there must be provisions for rest, nourishment, support, and security for the employees and their families.

The crisis may quickly expand to several departments, other organizations, the stock market, and community security. Through all of this the organization must rapidly recognize the growth of the disaster and be ready to respond appropriately.

The organization must be able to provide reassurance and factual information to the media, families, shareholders, customers, employees, and vendors. Part of this is accomplished through knowing how to disseminate information accurately, representing the organization with credible and knowledgeable representatives, and restricting the uncontrolled release of speculation and rumor. During any crisis, people are looking for answers, and they will often grasp and believe the most unbelievable and ridiculous rumors if there is no access to reliable sources of information. Working recovery programs have even been interrupted and halted by the spread of inaccurate information or rumors.

Leadership is the ability to remain effective despite a stressful situation; remain composed, reliable, able to accept criticism (much of it personally directed); handle multiple sources of information; multitask and delegate; provide careful analysis and recommendations; and inspire confidence. Not a simple or small task by any means.

In many cases the secret to a good BCP program is not the plan itself, but the understanding of the needs of the business and providing the leadership and coordination to make the plan a reality.

Some organizations have been dismayed to discover that the people who had worked diligently to prepare a BCP program, coordinating endless meetings and shuffling paperwork like a Las Vegas blackjack dealer, were totally unsuited to execute the very plans they had developed.

The leader of a disaster recovery team must be able to be both flexible and creative. No disaster or crisis will happen "by the book." The plan will always have some deficiencies or invalid assumptions. There may be excellent and creative responses and answers to the crisis that had not been considered; and, although this is not the time to rewrite the plan, accepting and embracing new solutions may well save the organization considerable expense, downtime, and embarrassment. One approach may be the use of wireless technology to get a LAN up and running in a minimal amount of time without reliance on traditional cable. Another example is the use of microwave to link to another site without the delay of waiting for establishment of a new T1 line. These are only suggestions, and they have limitations — especially in regard to security — but they may also provide new and rapid answers to a crisis. This is often a time to consider a new technological approach to the crisis — use of Voice-over-IP to replace a telecommunications switch that has been lost, or use of remote access via the Internet so employees can operate from home until new facilities are operational.

Business resumption or business continuity planning can be described as the ability to continue business operations while in the process of recovering from a disaster.

The ability to see the whole picture and understand hidden relationships among processes, organizations, and work are critical to stopping the expansion of the crisis and disaster. Determining how to respond is a skill. The leaders in the crisis must know who to call and alert, on whom to rely, and when to initiate alternate processing programs and recovery procedures. They need to accurately assess the extent of the damage and expansion rate of the crisis. They need to react swiftly and decisively without overreacting and yet need to ensure that all affected areas have been alerted.

The disaster recovery team must be able to assure the employees, customers, management team, and shareholders that, despite the confusion, uncertainty, and risks associated with a disaster, the organization is competently responding to, managing, and recovering from the failure.

Crisis Resolution

The final phase of a crisis is when the issue is resolved and the organization has recovered from the incident. This is not the same as when normal operations have recommenced. It may be weeks or years that the impact is felt financially or emotionally. The loss of credibility or trust may take months to rebuild. The recovery of lost customers may be nearly impossible; and when data is lost, it may well be that no amount of money or effort will recover the lost information. Some corporations have found that an interruption in processing for several days may be nearly impossible to recover because there is not enough processing time or capacity to catch up.

The crisis resolution phase is a critical period in the organization. It pays to reflect on what went well, what lessons were learned, who were the key personnel, and which processes and assumptions were found to be missed or contrarily invalid. One organization, having gone through an extended labor disruption, found that many job functions were no longer needed or terribly inefficient. This was a valuable learning experience for the organization. First, many unnecessary functions and efforts could be eliminated; but second, why was the management unable to identify these unnecessary functions earlier? It indicated a poor management structure and job monitoring.

The Business Continuity Process

Now that we have examined the scenarios where we require a workable business continuity plan, we can begin to explore how to build a workable program. It is good to have the end result in mind when building the

program. We need to build with the thought to respond to actual incidents — not only to develop a plan from a theoretical approach.

A business continuity plan must consider all areas of the organization. Therefore, all areas of the organization must be involved in developing the plan. Some areas may require a very elementary plan — others require a highly detailed and precise plan with strict timelines and measurable objectives. For this reason, many BCP programs available today are ineffective. They take a standard one-size-fits-all approach to constructing a program. This leads to frustration in areas that are overplanned and ineffectiveness in areas that are not taken seriously enough.

There are several excellent Web sites and organizations that can assist a corporation in BCP training, designing an effective BCP, and certification of BCP project leaders. Several sites also offer regular trade journals that are full of valuable information, examples of BCP implementations, and disaster recovery situations. Some of these include:

- *Disaster Recovery Journal,* www.drj.com
- Disaster Recovery Institute Canada, www.dri.ca
- Disaster Recovery Information Exchange, www.drie.org
- American Society for Industrial Security, www.asisonline.org
- Disaster Recovery Institute International, www.dr.org
- Business Continuity Institute, www.thebci.org
- International Association of Emergency Managers, www.nccem.org
- Survive — The Business Continuity Group, www.survive.com

There are also numerous sites and organizations offering tools, checklists, and software to assist in establishing or upgrading a BCP program.

Regardless of the Web site accessed by a BCP team member, the underlying process in establishing a BCP program is relatively the same.

- Risk and business impact analysis
- Plan development
- Plan testing
- Maintenance

The Disaster Recovery Institute recommends an excellent ten-step methodology for preparing a BCP program. The *Disaster Recovery Journal* Web site presents a seven-step model based on the DRI model, and also lists the articles published in its newsletters that provide education and examples of each step. Regardless of the type of methodology an organization chooses to use, the core concepts remain the same. Sample core steps are:

- Project initiation (setting the groundwork)
- Business impact analysis (project requirements definition)
- Design and development (exploring alternatives and putting the pieces together)
- Implementation (producing a workable result)
- Testing (proving that it is a feasible plan and finding weaknesses)
- Maintenance and update (preserving the value of the investment)
- Execution (where the rubber meets the road — a disaster strikes)

As previously stated, the intent of this chapter is not to provide in-depth training in establishing a BCP program. Rather, it is to present the overall objectives of the BCP initiative so that, as information systems security personnel or auditors, we can provide assistance and understand our role in creating a workable and effective business continuity plan.

Let us look at the high-level objectives of each step in a BCP program methodology.

Project Initiation

Without clearly defined objectives, goals, and timelines, most projects flounder, receive reduced funding, are appraised skeptically by management, and never come to completion or delivery of a sound product. This is

especially true in an administrative project like a BCP program. Although the awareness has been raised about BCP due to recent events, this attention will only last as long as other financial pressures do not erode the confidence that management has in realizing worthwhile results from the project.

A BCP project needs clearly defined mandates and deliverables. Does it include the entire corporation or only a few of the more critical areas to start with? Is the funding provided at a centrally based corporate level or departmentally? When should the plans be provided? Does the project have the support of senior management to the extent that time, resources, and cooperation will be provided on request as needed by the BCP project team?

Without the support of the local business units, the project will suffer from lack of good foundational understanding of business operations. Therefore, as discussed earlier, it is doubtful that the resulting plan will accurately reflect the business needs of the business units.

Without clearly defined timelines, the project may tend to take on a life of its own, with never-ending meetings, discussions, and checklists, but never providing a measurable result.

Security professionals need to realize the importance of providing good support for this initial phase — recommending and describing the benefits of a good BCP program and explaining the technical challenges related to providing rapid data or processing recovery. As auditors, the emphasis is on having a solid project plan and budget responsibility so that the project meets its objectives within budget and on time.

Business Impact Analysis

The business impact analysis (BIA) phase examines each business unit to determine what impact a disaster or crisis may have on its operations. This means the business unit must define its core operations and, together with the IT group, outline its reliance on technology, the minimum requirements to maintain operations, and the maximum tolerable downtime (MTD) for its operations. The results of this effort are usually unique to each business unit within the corporation. The MTD can be dependant on costs (costs may begin to increase exponentially as the downtime increases), reputation (loss of credibility among customers, shareholders, regulatory agencies), or even technical issues (manufacturing equipment or data may be damaged or corrupted by an interruption in operations).

The IT group needs to work closely during this phase to understand the technological requirements of the business unit. From this knowledge, a list of alternatives for recovery processing can be established.

The audit group needs to ensure that proper focus is placed on the importance of each function. Not all departments are equally critical, and not all systems within a department are equally important. E-mail or Internet access may not be as important as availability of the customer database. The accounting department — despite its loud objections — may not need all of its functionality prioritized and provided the same day as the core customer support group. Audit can provide some balance and objective input to the recovery strategy and time frames through analysis and review of critical systems, highest impact areas, and objective consideration.

Design and Development

Once the BCP team understands the most critical needs of the business from both an operational and technology standpoint, it must consider how to provide a plan that will meet these needs within the critical timeframes of the MTD. There are several alternatives, depending on the type of disaster that occurs, but one alternative that should be considered is outsourcing of some operations. This can be the outsourcing of customer calls such as warranty claims to a call center, or outsourcing payroll or basic accounting functions.

Many organizations rely on a hot site or alternate processing facility to accommodate their information processing requirements. The IT group needs to be especially involved in working together with the business units to ensure that the most critical processing is provided at such a site without incurring expense for the usage of unnecessary processing or storage capability.

The audit group needs to ensure that the proper cost/benefit analysis has been done and that the provisions of the contract with the hot site are fulfilled and reasonable for the business needs.

The development of the business continuity plan must be reviewed and approved by the managers and representatives in the local business groups. This is where the continuous involvement of key people within these groups is beneficial. The ideal is to prepare a plan that is workable, simple, and timely. A plan that is too

cumbersome, theoretical, or unrelated to true business needs may well make recovery operations more difficult rather than expedite operational recovery.

During this phase is it noticed that, if the BCP process does not have an effective leader, key personnel will begin to drop out. No one has time for meaningless and endless meetings, and the key personnel from the business units need to be assured that their investment of time and input to the BCP project is time well spent.

Implementation of the Business Continuity Plan

All of the prior effort has been aimed at this point in time — the production of a workable result. That is, the production of a plan that can be relied on in a crisis to provide a framework for action, decision making, and definition of roles and responsibilities.

IT needs to review this plan to see its role. Can IT meet its objectives for providing supporting infrastructures? Does IT have access to equipment, backups, configurations, and personnel to make it all happen? Does IT have the contact numbers of vendors, suppliers, and key employees in off-site locations? Does the business unit know who to call in the area for support and interaction?

The audit group should review the finished product for consistency, completeness, management review, testing schedules, maintenance plans, and reasonable assumptions. This should ensure that the final product is reliable, that everyone is using the same version, that the plan is protected from destruction or tampering, and that it is kept in a secure format with copies available off-site.

Testing the Plans

Almost no organization can have just one recovery strategy. It is usual to have several recovery strategies based on the type of incident or crisis that affects the business. These plans need to be tested. Tests are verification of the assumptions, timelines, strategies, and responsibilities of the personnel tasked with executing a business continuity plan. Tests should not only consist of checks to see if the plan will work under ideal circumstances. Tests should stress the plan through unavailability of some key personnel and loss of use of facilities. The testing should be focused on finding weaknesses or errors in the plan structure. It is far better to find these problems in a sterile test environment than to experience them in the midst of a crisis.

The IT staff should especially test for validity of assumptions regarding providing or restoring equipment, data links, and communications links. They need to ensure that they have the trained people and plans to meet the restoration objectives of the plan.

Auditors should ensure that weaknesses found in the plans through testing are documented and addressed. The auditors should routinely sit in on tests to verify that the test scenario is realistic and that no shortcuts or compromises are made that could impair the validity of the test.

Maintenance of the BCP (Preserving the Value of the Investment)

A lot of money and time goes into the establishment of a good BCP program. The resulting plans are key components of an organization's survival plan. However, organizations and personnel change so rapidly that almost any BCP is out of date within a very short timeframe. It needs to be defined in the job descriptions of the BCP team members — especially the representatives from the business units — to provide continuous updates and modifications to the plan as changes occur in business unit structure, location, operating procedures, or personnel.

The IT group is especially vulnerable to outdating plans. Hardware and software change rapidly, and procurement of new products needs to trigger an update to the plan. When new products are purchased, consideration must be given to ensuring that the new products will not impede recovery efforts through unavailability of replacements, lack of standardization, or lack of knowledgeable support personnel.

Audit must review plans on a regular basis to see that the business units have maintained the plans and that they reflect the real-world environment for which the plans are designed. Audit should also ensure that adequate funding and support is given to the BCP project on an ongoing basis so that a workable plan is available when required.

Conclusion

A business continuity plan is a form of insurance for an organization — and, like insurance, we all hope that we never have to rely on it. However, proper preparation and training will provide the organization with a plan that should hold up and ease the pressures related to a crisis. A good plan should minimize the need to make decisions in the midst of a crisis and outline the roles and responsibilities of each team member so that the business can resume operations, restore damaged or corrupted equipment or data, and return to normal processing as rapidly and painlessly as possible.

140

The Business Impact Assessment Process

Carl B. Jackson, CISSP, CBCP

The initial version of this chapter was written for the 1999 edition of the *Handbook of Information Security Management*. Since then, Y2K has come and gone, E-commerce has seized the spotlight, and Web-based technologies are the emerging solution for almost everything. The constant throughout these occurrences is that no matter what the climate, fundamental business processes have changed little. And, as always, the focus of any business impact assessment is to assess the time-critical priority of these business processes. With these more recent realities in mind, this chapter has been updated and is now offered for your consideration.

The objective of this chapter is to examine the business impact assessment (BIA) process in detail and focus on the fundamentals of a successful BIA.

There is no question that business continuity planning (BCP) is a business process issue, not a technical one. Although each critical component of the enterprise must participate during the development, testing, and maintenance of the BCP process, it is the results of the business impact assessment (BIA) that will be used to make a case for further action.

Why perform a business impact assessment? The author's experiences in this area have shown that all too often, recovery strategies, such as hot sites, duplicate facilities, material or inventory stockpiling, etc., are based on emotional motivations rather than the results of a thorough business impact assessment. The key to success in performing BIAs lies in obtaining a firm and formal agreement from management as to the precise maximum tolerable downtimes (MTDs), also referred to in some circles as recovery time objectives (RTOs), for each critical business process. The formalized MTDs/RTOs, once determined, must be validated by each business unit, then communicated to the service organizations (i.e., IT, Network Management, Facilities, HR, etc.) that support the business units. This process helps ensure that realistic recovery alternatives are acquired and recovery measures are developed and deployed.

There are several reasons why a properly conducted and communicated BIA is so valuable to the organization. These include: (1) identifying and prioritizing time-critical business processes; (2) determining MTDs/RTOs for these processes and associated supporting resources, (3) raising positive awareness as to the importance of business continuity, and (4) providing empirical data upon which management can base its decision for establishing overall continuous operations and recovery strategies and acquiring supporting resources. Therefore, the significance of the BIA is that it sets the stage for shaping a business-oriented judgment concerning the appropriation of resources for recovery planning and continuous operations. (E-commerce — see below).

The Impact of the Internet and E-Commerce on Traditional BCP

Internet-enabled E-commerce has profoundly influenced the way organizations do business. This paradigm shift has dramatically affected how technology is used to support the organization's supply chain, and because of this, will also have a significant effect on the manner in which the organization views and undertakes business continuity planning. It is no longer a matter of just preparing to recover from a serious disaster or disruption. It is now incumbent upon technology management to do all it can to avoid any kind of outage whatsoever.

EXHIBIT 140.1 Continuous Availability/Recovery Planning Component Framework

Continuous Operations/Availability Disciplines	Traditional Recovery/BCP Disciplines
Current state assessment	Current state assessment
Business impact assessment	Business impact assessment
Leading practices/benchmarking	Leading practices/benchmarking
Continuous operations strategy development	Recovery strategy development
Continuous operations strategy deployment	Recovery plan development/deployment
Testing/maintenance	Testing/maintenance
Awareness/training	Awareness/training
Process measurement/metrics/value	Process measurement/metrics/value

The technical disciplines necessary to ensure continuous operations or E-availability include building redundancy, diversity, and security into the E-commerce-related supply-chain technologies (e.g., hardware, software, systems, and communications networks) (see Exhibit 140.1).

This framework attempts to focus attention on the traditional recovery planning process components as well as to highlight those process steps that are unique to the continuous operations/E-availability process.

The BCP professional must become conversant with the disciplines associated with continuous operations/E-availability in order to ensure that organizational E-availability and recovery objectives are met.

The BCP Process Approach

The BIA process is only one phase of recovery planning and E-availability. The following is a brief description of a six-phase methodological approach. This approach is commonly used for development of business unit continuity plans, crisis management plans, technological platform, and communications network recovery plans.

- Phase I — Determine scope of BCP project and develop project plan. This phase examines business operations and information system support services, in order to form a project plan to direct subsequent phases. Project planning must define the precise scope, organization, timing, staffing, and other issues. This enables articulation of project status and requirements throughout the organization, chiefly to those departments and personnel who will be playing the most meaningful roles during the development of the BCP.
- Phase II — Conduct business impact assessment. This phase involves identification of time-critical business processes, and determines the impact of a significant interruption or disaster. These impacts may be financial in terms of dollar loss, or operational in nature, such as the ability to deliver and monitor quality customer service, etc.
- Phase III — Develop recovery/E-availability strategies. The information collected in Phase II is employed to approximate the recovery resources (i.e., business unit or departmental space and resource requirements, technological platform services, and communications networks requirements) necessary to support time-critical business processes and sub-processes. During this phase, an appraisal of E-availability/recovery alternatives and associated cost estimates are prepared and presented to management.
- Phase IV — Perform recovery plan development. This phase develops the actual plans (i.e., business unit, E-availability, crisis management, technology-based plans). Explicit documentation is required for execution of an effective recovery process. The plan must include administrative inventory information and detailed recovery team action plans, among other information.
- Phase V — Implement, test, and maintain the BCP. This phase establishes a rigorous, ongoing testing and maintenance management program.
- Phase VI — Implement awareness and process measurement. The final and probably the most crucial long-term phase establishes a framework for measuring the recovery planning and E-availability processes against the value they provide the organization. In addition, this phase includes training of personnel in the execution of specific continuity/recovery activities and tasks. It is vital that they are aware of their role as members of E-availability/recovery teams.

BIA Process Description

As mentioned above, the intent of the BIA process is to assist the organization's management in understanding the impacts associated with possible threats. Management must then employ that intelligence to calculate the maximum tolerable downtime (MTD) for time-critical support services and resources. For most organizations, these resources include:

1. Personnel
2. Facilities
3. Technological platforms (traditional and E-commerce-related systems)
4. Software
5. Data networks and equipment
6. Voice networks and equipment
7. Vital records
8. Data
9. Supply chain partners

The Importance of Documenting a Formal MTD/RTO Decision

The BIA process concludes when executive management makes a formalized decision as to the MTD it is willing to live with after analyzing the impacts to the business processes due to outages of vital support services. This includes the decision to communicate these MTD decision(s) to each business unit and support service manager involved.

The Importance of a Formalized Decision

A formalized decision must be clearly communicated by senior management because the failure to document and communicate precise MTD information leaves each manager with imprecise direction on: (1) selection of an appropriate recovery alternative method; and (2) the depth of detail that will be required when developing recovery procedures, including their scope and content.

The author has seen many well-executed BIAs with excellent results wasted because senior management failed to articulate its acceptance of the results and communicate to each affected manager that the time requirements had been defined for recovery processes.

BIA Information-Gathering Techniques

There are various schools of thought regarding how best to gather BIA information.Conducting individual one-on-one BIA interviews is popular, but organizational size and location issues sometimes make conducting one-on-one interviews impossible. Other popular techniques include group sessions, the use of an electronic medium (i.e., data or voice network), or a combination of all of these. Exhibit 140.2 is a BIA checklist. The following points highlight the pros and cons of these interviewing techniques:

1. *One-on-one BIA interviews.* In the author's opinion, the one-on-one interview with organizational representatives is the preferred manner in which to gather BIA information. The advantages of this method are the ability to discuss the issues face-to-face and observe the person. This one-on-one discussion will give the interviewer a great deal of both verbal and visual information concerning the topic at hand. In addition, personal rapport can be built between the interviewee and the BIA team, with the potential for additional assistance and support to follow. This rapport can be very beneficial during later stages of the BCP development effort if the person being interviewed understands that the BCP process was undertaken to help them get the job done in times of emergency or disaster. The disadvantages of this approach are that it can become very time-consuming, and can add time to the critical path of the BIA process.
2. *Group BIA interview sessions or exercises.* This type of information-gathering activity can be very efficient in ensuring that a lot of data is gathered in a short period of time and can speed the BIA

EXHIBIT 140.2 BIA Dos Checklist

BIA To Dos

- Customize the BIA information-gathering tools questions to suit the organization's customs/culture.
- Focus on time-critical business processes and support resources (i.e., systems, applications, voice and date networks, facilities, people, etc.).
- Assume worst-case disaster (day of week, month of year, etc.).
- Assume no recovery capability exists.
- Obtain raw numbers in orders of magnitude.
- Return for financial information.
- Validate BIA data with BIA participants.
- Formalize decision from senior management so lower-level managers (MTD timeframes, scope, and depth of recovery procedures, etc.) can make precise plans.

Conducting BIA Interviews

- When interviewing business unit personnel, explain that you are here to get the information you need to help IT build their recovery plan. But emphasize that the resulting IT recovery is really theirs, and the recovery plan is really yours. One is obtaining their input as an aid in ensuring that MIS constructs the proper recovery planning strategy.
- Interviews last no longer that 45 minutes to 1 hour and 15 minutes.
- The number of interviewees at one session should be at best one, and at worst two to three. More than that and the ability of the individual to take notes is questionable.
- If possible, at least two personnel should be in attendance at the interview. Each should have a blank copy of the questionnaire on which to take notes.
- One person should probably not perform more than four interviews per day. This is due to the requirement to successfully document the results of each interview as soon as possible and because of fatigue factors.
- Never become confrontational with the interviewees. There is no reason that interviewees should be defensive in their answers unless they do not properly understand the purpose of the BIA interview.
- Relate to interviewees that their comments will be taken into consideration and documented with the others gathered. And that they will be requested to review, at a later date, the output from the process for accuracy and provide their concurrence.

process tremendously. The drawback to this approach is that if not conducted properly, it can result in a meeting of a number of people without very much useful information being obtained.

3. *Executive management mandate.* Although not always recommended, there may be certain circumstances where conducting only selected interviews with very high-level executive management will suffice for BIA purposes. Such situations might include development of continuous operations/E-availability strategies where extremely short recovery timeframes are already obvious, or where times for development of appropriate strategies for recovery are severely shortened (as in the Y2K recovery plan development example). The level of confidence is not as high in comparison to performing many more exhaustive sets of interviews (at various levels of the organization, not just with the senior management group), but it does speed up the process.
4. *Electronic medium.* Use of voice and data communications technologies, videoconferencing, and Web-based technologies and media are becoming increasingly accepted and popular. Many times, the physical or geographical size and diversity, as well as the structural complexity of the organization, lends itself to this type of information-gathering technique. The pros are that distances can be diminished and travel expenses reduced. The use of automated questionnaires and other data-gathering methods can facilitate the capture of tabular data and ease consolidation of this information. Less attractive, however,

is the fact that this type of communication lacks the human touch, and sometimes ignores the importance of the ability of the interviewer to read the verbal and visual communications of the interviewee. *Note:* Especially worrisome is the universal broadcast of BIA-related questionnaires. These inquiries are sent to uninformed groups of users on a network, whereby they are asked to supply answers to qualitative and quantitative BIA questions without regard to the point or nuance of the question or the intent of the use of the result. Such practices almost always lend themselves to misleading and downright wrong results. This type of unsupported data-gathering technique for purposes of formulating a thoughtful strategy for recovery should be avoided.

Most likely, an organization will need to use a mix of these suggested methods, or use others as suited to the situation and culture of the enterprise.

The Use of BIA Questionnaires

There is no question that the people-to-people contact of the BIA process is *the* most important component in understanding the potential a disaster will have on an organization. People run the organization, and people can best describe business functionality and their business unit's degree of reliance on support services. The issue here, however, is deciding what is the best and most practical technique for gathering information from these people.

There are differing schools of thought regarding the use of questionnaires during the BIA process. The author's opinion is that a well-crafted and customized BIA questionnaire will provide the structure needed to guide the BIA and E-availability project team(s). This consistent interview structure requires that the same questions be asked of each BIA interviewee. Reliance can then be placed on the results because answers to questions can be compared to one another with assurance that the comparisons are based on the same criterion.

Although a questionnaire is a valuable tool, the structure of the questions is subject to a great deal of customization. This customization of the questions depends largely on the reason why the BIA is being conducted in the first place.

The BIA process can be approached differently, depending on the needs of the organization. Each BIA situation should be evaluated in order to properly design the scope and approach of the BIA process. BIAs are desirable for several reasons, including:

1. Initiation of a BCP process where no BIA has been done before, as part of the phased implementation methodology
2. Reinitiating a BCP process where there was a BIA performed in the past, but now it needs to be brought up to date
3. Conducting a BIA in order to incorporate the impacts of a loss of E-commerce-related supply-chain technologies into the overall recovery strategies of the organization
4. Conducting a BIA in order to justify BCP activities that have already been undertaken (i.e., the acquisition of a hotsite or other recovery alternative)
5. Initiating a BIA as a prelude to beginning a full BCP process for understanding or as a vehicle to sell management on the need to develop a BCP

Customizing the BIA Questionnaire

There are a number of ways that a questionnaire can be constructed or customized to adapt itself for the purpose of serving as an efficient tool for accurately gathering BIA information. There are also an unlimited number of examples of BIA questionnaires in use by organizations. It should go without saying that any questionnaire — BIA or otherwise — can be constructed so as to elicit the response one would like. It is important that the goal of the BIA be in the mind of the questionnaire developers so that the questions asked and the responses collected will meet the objective of the BIA process.

BIA Questionnaire Construction

Exhibit 140.3 is an example of a BIA questionnaire. Basically, the BIA questionnaire is made up of the following types of questions:

EXHIBIT 140.3 Sample BIA Questionnaire

Introduction
Business Unit Name:

Date of Interview:

Contact Name(s):

Identification of business process and/or business unit (BU) function:

Briefly describe the overall business functions of the BU (with focus on time-critical functions/processes, and link each time-critical function/process to the IT application/network, etc.) and understanding of business process and applications/networks, etc. interrelationships:

Financial Impacts
Revenue Loss Impacts Estimations (revenue or sales loss, lost trade discounts, interest paid on borrowed money, interest lost on float, penalties for late payment to vendors or lost discounts, contractual fines or penalties, unavailability of funds, canceled orders due to late delivery, etc.):

Extraordinary expense impact estimations (acquisition of outside services, temporary employees, emergency purchases, rental/lease equipment, wages paid to idle staff, temporary relocation of employees, etc.):

Operational Impacts
Business interruption impact estimations (loss of customer service capabilities, inability to serve internal customers/management/etc.):

Loss of confidence estimations (loss of confidence on behalf of customers/shareholders/regulatory agencies/employees, etc.):

Technological Dependence
Systems/business functions/applications reliance description (attempt to identify specific automated systems/processes/applications that support BU operations):

Systems interdependencies descriptions:

State of existing BCP measures:

Other BIA-related discussion issues:

First question phrased: "What else should I have asked you that I did not, relative to this process?"

Other questions customized to environment of the organization, as needed:

- *Quantitative questions.* These are the questions asked the interviewee to consider and describe the economic or financial impacts of a potential disruption. Measured in monetary terms, an estimation of these impacts will aid the organization in understanding loss potential, in terms of lost income as well as in an increase in extraordinary expense. The typical quantitative impact categories might include revenue or sales loss, lost trade discounts, interest paid on borrowed money, interest lost on float, penalties for late payment to vendors or lost discounts, contractual fines or penalties, unavailability of funds, canceled orders due to late delivery, etc. Extraordinary expense categories might include acqui-

sition of outside services, temporary employees, emergency purchases, rental/lease equipment, wages paid to idle staff, and temporary relocation of employees.

- *Qualitative questions.* Although the economic impacts can be stated in terms of dollar loss, the qualitative questions ask the participants to estimate potential loss impact in terms of their emotional understanding or feelings. It is surprising how often the qualitative measurements are used to put forth a convincing argument for a shorter recovery window. The typical qualitative impact categories might include loss of customer services capability, loss of confidence, etc.
- *Specialized questions.* Make sure that the questionnaire is customized to the organization. It is especially important to make sure that both the economic and operational impact categories (lost sales, interest paid on borrowed funds, business interruption, customer inconvenience, etc.) are stated in such a way that each interviewee will understand the intent of the measurement. Simple is better here.

Using an Automated Tool

If an automated tool is being used to collect and correlate the BIA interview information, make sure that the questions in the database and questions of the questionnaire are synchronized to avoid duplication of effort or going back to interviewees with questions that might have been handled initially.

A word of warning here, however. This author has seen people pick up a BIA questionnaire off the Internet or from book or periodical (like this one) and use it without regard to the culture and practices of their own organization. Never, ever, use a noncustomized BIA questionnaire. The qualitative and quantitative questions must be structured to the environment and style of the organization. There is a real opportunity for failure should this point be dismissed.

BIA Interview Logistics and Coordination

This portion of the report will address the logistics and coordination while performing the BIA interviews themselves. Having scoped the BIA process, the next step is to determine who and how many people one is going to interview. To do this, here are some techniques that one might use.

Methods for Identifying Appropriate BIA Interviewees

One certainly is not going to interview everyone in the organization. One must select a sample of those management and staff personnel who will provide the best information in the shortest period. To do that, one must have a precise feel for the scope of the project (i.e., technological platform recovery, business unit recovery, communications recovery, crisis management plans, etc.) and with that understanding one can use:

- *Organizational process models.* Identification of organizational mega and major business processes is the first place to start. Enterprises that are organized along process lines lend themselves to development of recovery planning strategies that will eventually result in the most efficient recovery infrastructure. Use of or development of models that reflect organizational processes will go a long way toward assisting BIA team members in identifying those personnel crucial to determining time-critical process requirements. Exhibit 140.4 attempts to demonstrate that while the enterprisewide recovery planning/E-continuity infrastructure includes consideration of crisis management, technology disaster recovery, business unit resumption, and E-commerce E-availability components, all aspects of the resulting infrastructure flow from proper identification of time-critical business processes.
- *Organizational chart reviews.* The use of formal, or sometimes even informal organization charts is the first place to start. This method includes examining the organizational chart of the enterprise to understand those functional positions that should be included. Review the organizational chart to determine which organizational structures will be directly involved in the overall effort as well as those that will be the recipients of the benefits of the finished recovery plan.
- *Overlaying systems technology.* Overlay systems technology (applications, networks, etc.) configuration information over the organization chart to understand the components of the organization that may be affected by an outage of the systems. Mapping applications, systems, and networks to the organizations business functions will help tremendously when attempting to identify the appropriate names and numbers of people to interview.

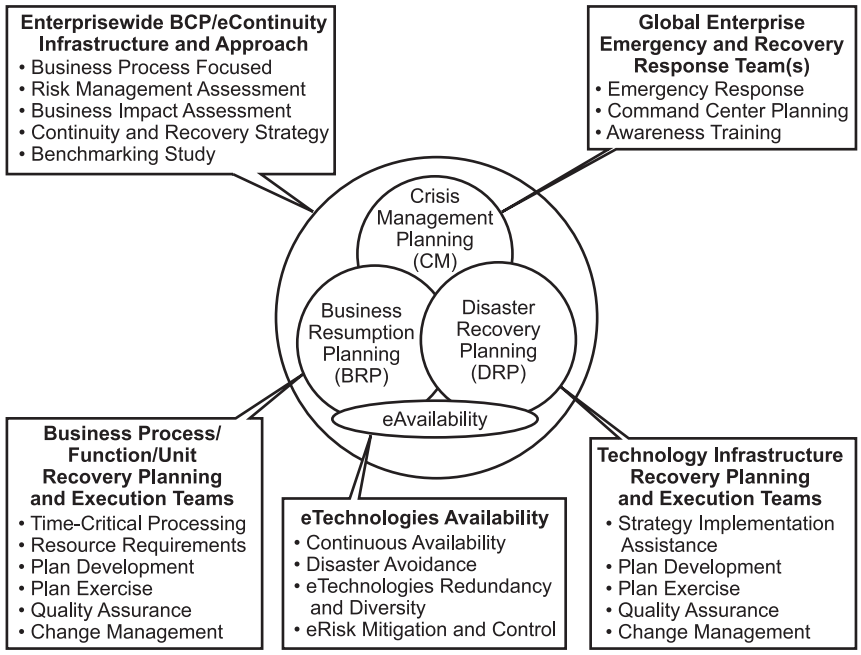

EXHIBIT 140.4 Enterprisewide BCP/E-continuity infrastructure.

- *Executive management interviews.* This method includes conducting introductory interviews with selected senior management representatives in order to identify critical personnel to be included in the BIA interview process, as well as to receive high-level guidance and to raise overall executive-level management awareness and support.

Coordinate with the IT Group

If the scope of the BIA process is recovery of technological platforms or communications systems, then conducting interviews with a number of IT personnel could help shorten the data-gathering effort. Although IT users will certainly need to be spoken to, IT personnel can often provide much valuable information, but should not be solely relied on as the primary source of business impact outage information (i.e., revenue loss, extra expense, etc.).

Send Questionnaire Out in Advance

It is a useful technique to distribute the questionnaire to the interviewees in advance. Whether in hardcopy or electronic media format, the person being interviewed should have a chance to review the questions, and be able to invite others into the interview or redirect the interview to others, and begin to develop the responses. One should emphasize to the people who receive the questionnaire in advance to not fill it out, but to simply review it and be prepared to address the questions.

Scheduling of Interviews

Ideally, the BIA interview should last between 45 minutes and 1 hour and 15 minutes. It sometimes can be an advantage to go longer than this; but if one sees many of the interviews lasting longer than the 1 hour, 15 minute window, there may be a BIA scoping issue that should be addressed, necessitating the need to schedule and conduct a larger number of additional interviews.

Limit Number of Interviewees

It is important to limit the number of interviewees in the session to one, two, or three, but no more. Given the amount and quality of information one is hoping to elicit from this group, more than three people can deliver a tremendous amount of good information that can be missed when too many people are delivering the message at the same time.

Try to Schedule Two Interviewers

When setting up the BIA interview schedule, try to ensure that at least two interviewers can attend and take notes. This will help eliminate the possibility that good information may be missed. Every additional trip back to an interviewee for confirmation of details will add overhead to the process.

Validate Financial Impact Thresholds

An often-overlooked component of the process includes discussing with executive management the thresholds of pain that could be associated with a disaster. Asking the question as to whether a $5 million loss or a $50 million loss impact has enough significance to the long-term bottom line of the organization can lead to interesting results. A lack of understanding on the BIA team's part as to what financial impacts are acceptable, or conversely unacceptable, is crucial to framing BIA financial loss questions and the final findings and recommendations that the BIA report will reflect.

Conducting the BIA

When actually explaining the intent of the BIA to those being interviewed, the following concepts should be observed and perhaps discussed with the participants.

Intelligent Questions Asked of Knowledgeable People

Based loosely on the concept that if one asks enough reasonably intelligent people a consistent set of measurable questions, one will eventually reach a conclusion that is more or less correct. The BIA questions serve to elicit qualitative results from a number of knowledgeable people. The precise number of people interviewed obviously depends on the scope of the BCP activity and the size of the organization. However, when consistently directing a well-developed number of questions to an informed audience, the results will reflect a high degree of reliability. This is the point when conducting qualitatively oriented BIA: ask the right people good questions and one will come up with the right results.

Ask to Be Directed to the Correct People

As the interview unfolds, it may become evident that the interviewee is the wrong person to be answering the questions. One should ask who else within this area would be better suited to address these issues. They might be invited into the room at that point, or one may want to schedule a meeting with them at another time.

Assure Them that Their Contribution Is Valuable

A very important way to build the esteem of the interviewee is to mention that their input to this process is considered valuable, as it will be used to formulate strategies necessary to recover the organization following a disruption or disaster. Explaining to them that one is there to help by getting their business unit's relevant information for input to planning a recovery strategy can sometimes change the tone of the interview in a positive manner.

Explain that the Plan Is Not Strictly an IT Plan

Even if the purpose of the BIA is for IT recovery and, when interviewing business unit management for the process of preparing a technological platform recovery plan, it is sometimes useful to couch the discussion in

terms of … "a good IT recovery plan, while helping IT recover, is really a business unit plan … Why? … Because the IT plan will recover the business functionality of the interviewees business unit as well, and that is why one is there."

Focus on Who Will Really Be Exercising the Plan

Another technique is to mention that the recovery plan that will eventually be developed can be used by the interviewees, but is not necessarily developed for them. Why? Because the people being interviewed probably already understand what to do following a disaster, without having to refer to extensive written recovery procedures. But the fact of the matter is that following the disruption, these people may not be available. It may well be the responsibility of the next generation of management to recover, and it will be the issues identified by this interviewee that will serve as the recovery roadmap.

Focus on Time-Critical Business Processes and Support Resources

As the BIA interview progresses, it is important to fall back from time to time and reinforce the concept of being interested in the identification of time-critical functions and processes.

Assume Worst-Case Disaster

When faced with the question as to when the disruption will occur, the answer should be: "It will occur at the worst possible time for your business unit. If you close your books on 12/31, and you need the computer system the most on 12/30 and 12/31, the disaster will occur on 12/29." Only when measuring the impacts of a disruption at the worst time can the interviewer get an idea as to the full impact of the disaster, and so that the impact information can be meaningfully compared from one business unit to the next.

Assume No Recovery Capability Exists

To reach results that are comparable, it is essential to insist that the interviewee assume that no recovery capability will exist as they answer the impact questions. The reason for this is that when they attempt to quantify or qualify the impact potential, they may confuse a preexisting recovery plan or capability with no impact, and that is incorrect. No matter the existing recovery capability, the impact of a loss of services must be measured in raw terms so that as one compares the results of the interviews from business unit to business unit, the results are comparable (apples to apples, so to speak). Exhibit 140.5 provides an example. In this example, if one allows Interviewees #2 and #4 to assume that they can go somewhere else and use an alternate resource to support their process, the true impact of the potential disruption is reduced by one-half ($40K vs. $80K). By not allowing them to assume that an appropriate recovery alternative exists, one will recognize the true impact of a disruption, that of $80,000 per-day. The $80,000-per day impact is what one is trying to understand, whether or not a recovery alternative already exists.

EXHIBIT 140.5 Comparing the Results of the Interviews

Interviewee	Total Loss Impact if Disaster?	Preconceived Recovery Alternative?	Resulting Estimated Loss Potential	No Allowance for Preconceived Recovery Alternative
#1	$20K per day	No	$20,000	$20,000
#2	$20K per day	Yes	0	20,000
#3	$20K per day	No	20,000	20,000
#4	$20K per day	Yes	0	20,000
Totals	—	—	$40,000[a]	$80,000[b]

[a] Incorrect estimate, as one should not allow the interviewee to assume a recovery alternative exists (although one may very well exist).

[b] Correct estimate, based on raw loss potential regardless of preexisting recovery alternatives (which may or may not be valid should a disruption or disaster occur).

Order-of-Magnitude Numbers and Estimates

The financial impact information is needed in orders-of-magnitude estimates only. Do not get bogged down in minutia, as it is easy to get lost in the detail. The BIA process is not a quantitative risk assessment. It is not meant to be. It is qualitative in nature and, as such, orders-of-magnitude impacts are completely appropriate and even desirable. Why? Because preciseness in estimation of loss impact almost always results in arguments about the numbers. When this occurs, the true goal of the BIA is lost, because it turns the discussion into a numbers game, not a balanced discussion concerning financial and operational impact potentials. Because of the unlimited and unknown numbers of varieties of disasters that could possibly befall an organization, the true numbers can never ever be precisely known, at least until after the disaster. The financial impact numbers are merely estimates intended to illustrate degrees of impacts. So skip the numbers exercise and get to the point.

Stay Focused on the BCP Scope

Whether the BIA process is for development of technological platforms, end user, facilities recovery, voice network, etc., it is very important that one not allow scope creep in the minds of the interviewees. The discussion can become very unwieldy if one does not hold the focus of the loss impact discussions on the precise scope of the BCP project.

There Are No Wrong Answers

Because all the results will be compared with one another before the BIA report is forwarded, one can emphasize that the interviewee should not worry about wrong numbers. As the BIA process evolves, each business unit's financial and operational impacts will be compared with the others, and those impact estimates that are out of line with the rest will be challenged and adjusted accordingly.

Do Not Insist on Getting the Financial Information on the Spot

Sometimes, the compilation of financial loss impact information requires a little time to accomplish. The author often tells the interviewee that he will return within a few days to collect the information, so that additional care can be taken in preparation, making sure that he does actually return and picks up the information later.

The Value of Pushback

Do not underestimate the value of pushback when conducting BIA interviews. Business unit personnel will, most times, tend to view their activities as extremely time-critical, with little or no downtime acceptable. In reality, their operations will be arranged in some priority order with the other business processes of the organization for recovery priority. Realistic MTDs must be reached, and sometimes the interviewer must push back and challenge what may be considered unrealistic recovery requirements. Be realistic in challenging, and request that the interviewee be realistic in estimating their business unit's MTDs. Common ground will eventually be found that will be more meaningful to those who will read the *BIA Findings and Recommendations* — the senior management group.

Interpreting and Documenting the Results

As the BIA interview information is gathered, there is a considerable tabular and written information that begins to quickly accumulate. This information must be correlated and analyzed. Many issues will arise here that may result in some follow-up interviews or information-gathering requirements. The focus at this point in the BIA process should be as follows.

Begin Documentation of the Results Immediately

Even as the initial BIA interviews are being scheduled and completed, it is a good idea to begin preparation of the *BIA Findings and Recommendations* and actually start entering preliminary information. The reason is

twofold. The first is that if one waits to the end of the process to start formally documenting the results, it is going to be more difficult to recall details that should be included. Second, as the report begins to evolve, there will be issues that arise where one will want to perform additional investigation, while one still has time to ensure the investigation can be thoroughly performed.

Develop Individual Business Unit BIA Summary Sheets

Another practical technique is to document each and every BIA interview with its own *BIA Summary Sheet*. This information can eventually be used directly by importing it into the *BIA Findings and Recommendations,* and can also be distributed back out to each particular interviewee to authenticate the results of the interview. The *BIA Summary Sheet* contains a summation of all the verbal information that was documented during the interview. This information will be of great value later as the BIA process evolves.

Send Early Results Back to Interviewees for Confirmation

By returning the *BIA Summary Sheet* for each of the interviews back to the interviewee, one can continue to build consensus for the BCP project and begin to ensure that any future misunderstandings regarding the results can be avoided. Sometimes, one may want to get a formal sign-off, and other times the process is simply informal.

We Are Not Trying to Surprise Anyone

The purpose for diligently pursuing the formalization of the BIA interviews and returning to confirm the understandings from the interview process is to make very sure that there are no surprises later. This is especially important in large BCP projects where the BIA process takes a substantial amount of time. There is always a possibility that someone might forget what was said.

Definition of Time-Critical Business Functions/Processes

As has been emphasized, all issues should focus back to the true time-critical business processes of the organization. Allowing the attention to be shifted to specific recovery scenarios too early in the BIA phase will result in confusion and lack of attention toward what is really important.

Tabulation of Financial Impact Information

There can be a tremendous amount of tabular information generated through the BIA process. It should be boiled down to its essence and presented in such a way as to support the eventual conclusions of the BIA project team. It is easy to overdo it with numbers. Just ensure that the numbers do not overwhelm the reader and that they fairly represent the impacts.

Understanding the Implications of the Operational Impact Information

Often times, the weight of evidence and the basis for the recovery alternative decision are based on operational rather than the financial information. Why? Usually, the financial impacts are more difficult to accurately quantify because the precise disaster situation and the recovery circumstances are difficult to visualize. One knows that there will be a customer service impact because of a fire, for example. But one would have a difficult time telling someone, with any degree of confidence, what the revenue loss impact would be for a fire that affects one particular location of the organization. Because the BIA process should provide a qualitative estimate (orders of magnitude), the basis for making the difficult decisions regarding acquisition of recovery resources are, in many cases, based on the operational impact estimates rather than hard financial impact information.

Preparing the Management Presentation

Presentation of the results of the BIA to concerned management should result in no surprises for them. If one is careful to ensure that the BIA findings are communicated and adjusted as the process has unfolded, then

the management review process should really become more of a formality in most cases. The final presentation meeting with the senior management group is not the time to surface new issues and make public startling results for the first time.

To achieve the best results in the management presentation, the following suggestions are offered.

Draft Report for Review Internally First

Begin drafting the report following the initial interviews. By doing this, one captures fresh information. This information will be used to build the tables, graphs, and other visual demonstrations of the results, and it will be used to record the interpretations of the results in the verbiage of the final *BIA Findings and Recommendations Report*. One method for accomplishing a well-constructed *BIA Findings and Recommendations* from the very beginning is to, at the completion of each interview, record the tabular information into the BIA database or manual filing system in use to record this information. Second, the verbal information should be transcribed into a *BIA Summary Sheet* for each interview. This *BIA Summary Sheet* should be completed for each interviewee and contain the highlights of the interview in summarized form. As the BIA process continues, the BIA tabular information and the transcribed verbal information can be combined into the draft *BIA Findings and Recommendations*. The table of contents for a BIA Report might look like the one depicted in Exhibit 140.6.

Schedule Individual Senior Management Meetings as Necessary

Near the time for final BIA presentation, it is sometimes a good idea to conduct a series of one-on-one meetings with selected senior management representatives in order to brief them on the results and gather their feedback for inclusion in the final deliverables. In addition, this is a good time to begin building grassroots support for the final recommendations that will come out of the BIA process and at the same time provide an opportunity to practice making one's points and discussing the pros and cons of the recommendations.

Prepare Senior Management Presentation (Bullet Point)

The author's experience reveals that senior management-level presentations, most often, are better prepared in a brief and focused manner. It will undoubtedly become necessary to present much of the background information used to make the decisions and recommendations, but the formal presentation should be in bullet-point format, crisp, and to the point. Of course, every organization has its own culture, so be sure to understand and comply with the traditional means of making presentations within that environment. Copies of the report, which have been thoroughly reviewed, corrected, bound, and bundled for delivery, can be distributed at the beginning or end of the presentation, depending on circumstances. In addition, copies of the bullet-point handouts can also be supplied so attendees can make notes and for reference at a later time. Remember, the BIA process should end with a formalized agreement as to management's intentions with regard to MTDs, so that business unit and support services managers can be guided accordingly. It is here that that formalized agreement should be discussed and the mechanism for acquiring and communicating it determined.

Distribute Report

Once the management team has had an opportunity to review the contents of the BIA Report and made appropriate decisions or given other input, the final report should be distributed within the organization to the appropriate numbers of interested individuals.

Past Y2K and Current E-availability Considerations

The author's experience with development of Y2K-related recovery plans was that time was of the essence. Because of the constricted timeframe for development of Y2K plans, it was necessary to truncate the BIA process as much as possible to meet timelines. Modification of the process to shorten the critical path was necessary — resulting in several group meetings focusing on a very selective set of BIA criteria.

Limit Interviews and Focus on Upper-Level Management

To become a little creative in obtaining BIA information in this Y2K example, it was necessary to severely limit the number of interviews and to interview higher-level executives to receive overall guidance, and then move to recovery alternative selection and implementation rapidly.

Truncated BIAs for E-availability Application

Additionally, when considering gathering BIA information during an E-availability application, it is important to remember that delivery of E-commerce-related services through the Internet means that supply-chain downtime tolerances — including E-commerce technologies and channels — are usually extremely short (minutes or even seconds), and that it may not be necessary to perform an exhaustive BIA to determine the MTD/RTO only. What is necessary for a BIA under these circumstances, however, is that it helps to determine which business processes truly rely on E-commerce technologies and channels so that they (business unit personnel) can be prepared to react in a timely manner should E-commerce technologies be impacted by a disruption or disaster.

Next Steps

The BIA is truly completed when formalized senior management decisions have been made regarding: (1) MTDs/RTOs, (2) priorities for business process and support services recovery, and (3) recovery/E-availability resource funding sources.

The next step is the selection of the most effective recovery alternative. The work gets a little easier here. One knows what the recovery windows are, and one understands what the recovery priorities are. One must now investigate and select recovery alternative solutions that fit the recovery window and recovery priority expectations of the organization. Once the alternatives have been agreed upon, the actual recovery plans can be developed and tested, with organization personnel organized and trained to execute the recovery plans when needed.

Summary

The process of business continuity planning has matured substantially since the 1980s. BCP is no longer viewed as just a technological question. A practical and cost-effective approach toward planning for disruptions or disasters begins with the business impact assessment. In addition, the rapidly evolving dependence on E-commerce-related supply-chain technologies has caused a refocus of the traditional BCP professional on not only recovery, but also continuous operations or E-availability imperatives.

The goal of the BIA is to assist the management group in identifying time-critical processes, and determining their degree of reliance on support services. Then, map these processes to supporting IT, voice and data networks, facilities, human resources, E-commerce initiatives, etc. Time-critical business processes are prior-

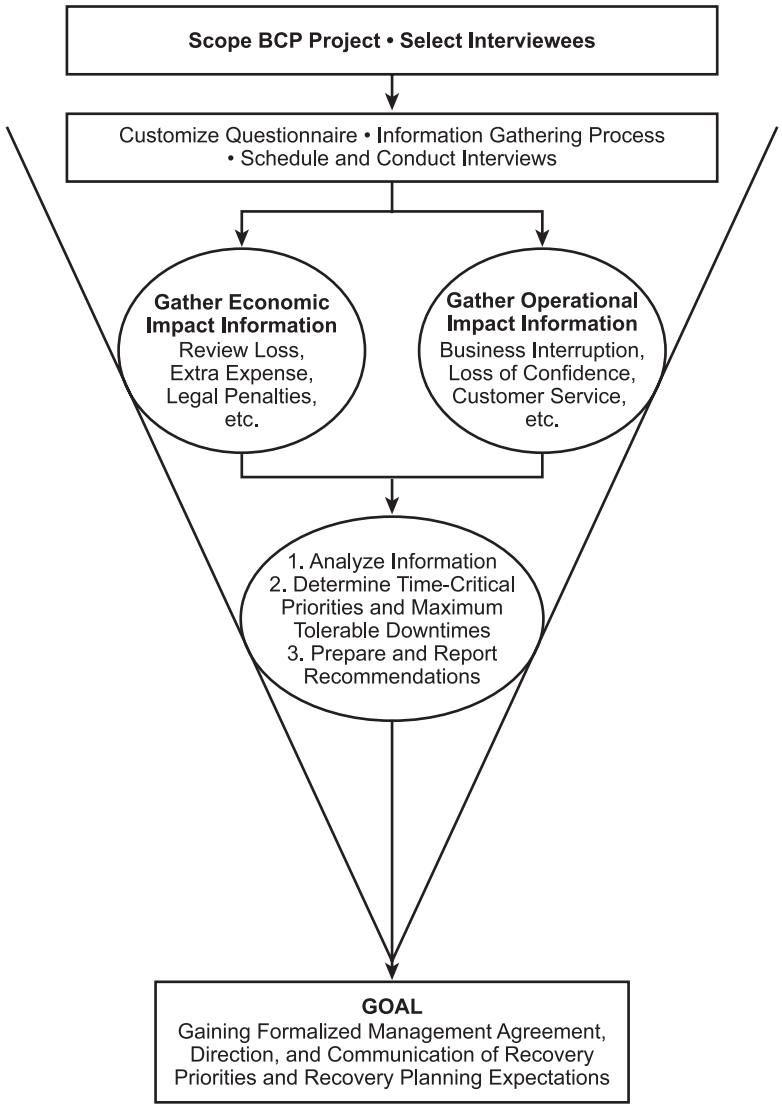

EXHIBIT 140.7 Business continuity planning route map.

itized in terms of their MTDs/RTOs, so that executive management can make reasonable decisions as to the recovery costs and timeframes that it is willing to fund and support.

This chapter has focused on how organizations can facilitate the BIA process. See the BCP Route Map in Exhibit 140.7 for a pictorial representation of the BIA process. Understanding and applying the various methods and techniques for gathering the BIA information is the key to success.

Only when executive management formalizes its decisions regarding recovery timeframes and priorities can each business unit and support service manager formulate acceptable and efficient plans for recovery of operations in the event of disruption or disaster. It is for this reason that the BIA process is so important when developing efficient and cost-effective business continuity plans and E-availability strategies.

Domain 9
Law, Investigations, and Ethics

The Law, Investigations, and Ethics Domain addresses computer crime laws and regulations. It reviews investigative measures and techniques used to determine if a crime has been committed and methods to gather evidence. It also reviews the ethical constraints that provide a code of conduct for the security professional.

In this domain we discuss methods for determining if a computer crime has been committed and the laws that are applicable for the crime. We examine laws prohibiting specific types of computer crime and methods to gather and preserve evidence of a computer crime. We review investigative methods and techniques. Finally, we study ways in which RFC 1087 and the $(ISC)^2$ Code of Ethics can be applied to resolve ethical dilemmas.

Jurisdictional Issues in Global Transmissions

Ralph Spencer Poore, CISSP, CISA, CFE

In the information age where teleconferences replace in-person meetings, where telecommuting replaces going to the office, and where international networks facilitate global transmissions with the apparent ease of calling your neighbor, valuable assets change ownership at the speed of light. Louis Jionet, secretary-general of the French Commission on Data Processing and Liberties stated: "Information is power and economic information is economic power." Customs officials and border patrols cannot control the movement of these assets. But does this mean companies may transmit the data which either represents or is *the* valuable asset without regard to the legal jurisdictions through which they pass? To adequately address this question we will discuss both the legal issues and the practical issues involved in transnational data flows.

Legal Issues

All legally incorporated enterprises have official books of record. Whether these are in manual or automated form, they are the records governmental authorities turn to when determining the status of an enterprise. The ability to enforce a subpoena or court order for these records reflects the effective sovereignty of the nation in which the enterprise operates. Most countries require enterprises incorporated, created, or registered in their jurisdiction to maintain official books of record physically within their borders. For example, a company relying on a service bureau in another country for data processing services may cause the official records to exist only in that other country. This could occur if the printouts reflected only a historical position of the company, perhaps month-end conditions, where the current position of the company — the position on which management relies — exists only through online access to the company's executive information system. From a nation's perspective, two issues of sovereignty arise:

1. That other country might exercise its rights and take custody of the company's records — possibly forcing it out of business — for actions alleged against the company that the company's "home" nation considers legal.
2. The company's "home" nation may be unable to enforce its access rights.

Another, usually overriding factor is a nation's ability to enforce its tax laws. Many nations have value-added taxes (VATs) or taxes on "publications," "computer software," and "services." Your organization's data may qualify as a "publication" or as "computer software" or even as "services" in some jurisdictions. Thus, many nations have an interest in the data that flows across their borders because it may qualify for taxation. In some cases, the tax is a tariff intended to discourage the importation of "computer software" or "publications" in order to protect the nation's own emerging businesses. More so than when the tax is solely for revenue generation, protective tariffs may carry heavy fines and be more difficult to negotiate around. With the advent of Internet businesses, determining a business' nexus for tax purposes has become even more complex. Such

businesses may have income, franchise, and inventory or property tax issues in addition to sales tax, excise tax, and import or export duties. Business taxes, registration or license fees, and even reporting requirements depend on the applicability of a given jurisdiction.

National security interests may include controlling the import and export of information. State secrecy laws exist for almost all nations. The United States, for example, restricts government-classified data (e.g., Confidential, Secret, Top Secret), but also restricts some information even if it is not classified (e.g., technical data about nuclear munitions, some biological research, some advanced computer technology, and, to varying degrees, cryptography).

Among those nations concerned with an individual's privacy rights, the laws vary greatly. Laws like the United States' Privacy Act of 1974 (5 USC 552a) have limited applicability (generally applying only to government agencies and their contractors). The United Kingdom's Data Protection Act of 1984 (1984 c 35 [*Halsbury's Statutes 4th Edition*, Butterworths, London, 1992, vol. 6, pp. 899–949]), however, applies to the commercial sector as does the 1981 Council of Europe's Convention for the Protection of Individuals with Regard to Automatic Processing of Personal Data. (An excellent discussion of this can be found in Anne W. Brandscomb's *Toward a Law of Global Communications Networks*, The Science and Technology section of the American Bar Association, Longman, New York, 1986.) Privacy laws generally have at least the following three characteristics:

1. They provide notice to the subject of the existence of a database containing the subject's personal data (usually by requiring registration of the database).
2. They provide a process for the subject to inspect and to correct the personal data.
3. They provide a requirement for maintaining an audit trail of accessors to the private data.

The granularity of privacy law requirements also varies greatly. Some laws, e.g., the U.S. Fair Credit Reporting Act of 1970 (see 15 USC 1681 *et seq.*), require only the name of the company that requested the information. Other laws require accountability to a specific office or individual. Because the granularity of accountability may differ from jurisdiction to jurisdiction, organizations may need to develop their applications to meet the most stringent requirements, i.e., individual accountability. In my experience, few electronic data interchange (EDI) systems support this level of accountability. (*UNCID Uniform Rules of Conduct for Interchange of Trade Data by Teletransmission*, ICC Publishing Corporation, New York, 1988. All protective measures and audit measures are described as options with granularity left to the discretion of the parties.)

To further complicate data transfer issues, patent, copyright, and trade secrets laws are not uniform. Although international conventions exist, e.g., General Agreement on Tariffs and Trade (GATT), not all nations subscribe to these conventions, and the conventions often allow for substantial differences among signatories. Rights you may have and can enforce in one jurisdiction may not exist (or may not be enforceable) in another. In some cases, the rights you have in one jurisdiction constitute an infringement in another jurisdiction. For example, you may hold a U.S. registered trademark on a product. A trademark is a design (often a stylized name or monogram) showing the origin or ownership of merchandise and reserved to the owner's exclusive use. The Trade-Mark Act of 1946 (see 15 USC 1124) provides that no article shall be imported that copies or simulates a trademark registered under U.S. laws. A similar law protecting, for example, trademarks registered in India might prevent your using the trademark in India if a similar or identical trademark is already registered there.

Disclosure of information not in accordance with the laws of the jurisdictions involved may subject the parties to criminal penalties. For example, the U.K.'s Official Secrets Act of 1989 clearly defines areas wherein disclosure of the government's secrets is a criminal offense. Most nations have similar laws (of varying specificity) making the disclosure of state secrets a crime. However, technical information considered public in one jurisdiction may be considered a state secret in another. Similarly, biographical information on a national leader may be mere background information for a news story in one country, but be viewed as espionage by another. These areas are particularly difficult because most governments will not advise you in advance what constitutes a state secret (as this might compromise the secret). Unless your organization has a presence in each jurisdiction sensitive to these political and legal issues to whom you can turn for guidance, you should seek competent legal advice before transmitting text or textual database materials containing information about individuals or organizations.

From a business perspective, civil law rather than criminal law may take center stage. Although the United States probably has the dubious distinction as the nation in which it is easiest to initiate litigation, law suits are possible in most jurisdictions worldwide. No company wants to become entangled in litigation, especially in foreign jurisdictions. However, when information is transmitted from one nation to another, the rules may

change significantly. For example, what are the implied warranties in the receiving jurisdiction? What constitutes profanity, defamation, libel, or similar actionable content? What contract terms are unenforceable (e.g., can you enforce a nondisclosure agreement of 10 years' duration)?

In some jurisdictions ecclesiastical courts may have jurisdiction for offenses against a state-supported religion. Circumstances viewed in one jurisdiction as standard business practices (e.g., "gifts") may be viewed in another as unethical or illegal. Even whether an organization has standing (i.e., may be represented in court) varies among nations. An organization's rights to defend itself, for example, vary from excellent to nil in jurisdictions ranging from Canada to Iran.

Fortunately, companies may generally choose the jurisdictions in which they will hold assets. Most countries enforce their laws (and the actions of their courts) against corporations by threat of asset seizure. A company with no seizable assets (and no desire to conduct future business) in a country is effectively judgment-proof. The reverse can also be true, i.e., a company may be unable to enforce a contract (or legal judgment) because the other party has no assets within a jurisdiction willing to enforce the contract or judgment. When you contract with a company to develop software, for example, and that company exists solely in a foreign country, your organization should research the enforceability of any contract and, if you have any doubt, require a bond be posted in your jurisdiction to ensure at least bond forfeiture as recourse.

Specific and General Jurisdiction

In September 1997, in *Bensusan Restaurant Corp. v. King* (1997 U.S. App. Lexis 23742 (2d Cir., Sept. 10, 1997)), the second U.S. Circuit Court of Appeals held that a Missouri resident's Web site, accessed in New York, did not give rise to jurisdiction under New York's long-arm statute. The court ruled there was no jurisdiction because the defendant was not physically in New York when he created the offending Web page. However, a similar case in California with a similar ruling was reversed on appeal (*Hall v. LaRonde*, 1997 Cal. App. Lexis 633 (Aug. 7, 1997)). Citing the changing "role that electronic communications plays in business transactions," the court decided that jurisdiction should not be determined by whether the defendant's communications were made physically within the state, instead concluding: "[t]here is no reason why the requisite minimum contacts cannot be electronic."

To comply with due process, the exercise of specific jurisdiction generally requires that the defendant took advantage of the benefits of the jurisdiction intentionally, and so could have expected to be hauled into court there. The nature of electronic communications and their growing role in commerce have contributed to findings that defendants' Internet communications constitute "purposeful availment" (legalese for intentionally taking advantage of the benefits) and establish jurisdiction. For example, in *California Software Inc. v. Reliability Research Inc.* (631 F. Supp. 1356 (C.D. Cal. 1986)) the court held that a nonresident's defamatory e-mail to a resident was sufficient to establish specific jurisdiction. The court noted that, as modern technology makes nationwide commercial transactions more feasible, it broadens the scope of jurisdiction.

Courts have also pointed out the distinguishing features of the Internet when holding that a Web site gives rise to specific jurisdiction for infringement claims arising out of the site's content. In *Maritz Inc. v. Cybergold Inc.*, (947 F. Supp. 1328, 1332, 1334 (E.D. Mo. 1996)) the court suggested that Web site advertising more likely amounts to purposeful availment than advertising by direct mail or an "800" telephone number, noting the "different nature" of electronic communications.

Conceivably, a Web site could reflect contacts with a state's residents that were sufficiently continuous and systematic to establish general jurisdiction over the site owner. Courts have held, however, that the mere creation of a Web site does not create general jurisdiction. See, for example, *McDonough v. Fallon McElligott, Inc.*, (1996 U.S. Dist. Lexis 15139 (S.D. Cal., Aug. 6, 1996)). Further, courts have held in more traditional contexts that merely placing advertisements in nationally distributed periodicals or communicating through a national computer-based information system does not subject a nonresident to jurisdiction. See, for example, *Federal Rural Elec. Ins. Corp. v. Kootenai Elec. Corp.* (17 F.3d 1302, 1305 (10th Cir. 1994)).

This area of law is evolving rapidly, with many jurisdictions asserting what amounts to extraterritorial jurisdiction on the basis of electronic transactions into, through, or out of their territory. The Council of Europe's Convention for the Protection of Individuals with Regard to Automatic Processing of Personal Data is but one of many examples. The entire area of cryptography, for example, is another. In January 1999, the French dramatically eased their long-standing restriction on the use of cryptography within its jurisdiction. This announcement came only six weeks after France joined with 32 other countries to sign an update of a document known as the Wassenaar Agreement. Signatories to this agreement promised to tighten restrictions

on the import or export of cryptography. The so-called "long arm" provisions of many laws and the lack of consensus among nations on important issues including privacy, intellectual property rights, communications security, and taxes will challenge (or plague) us for the foreseeable future.

Technical Issues

Any nation wishing to enforce its laws with regard to data transmitted within or across its borders must have (1) the ability to monitor/intercept the data and (2) the ability to interpret/understand the data. Almost all nations can intercept wire (i.e., telephone/telegraph) communications. Most can intercept radio, microwave, and satellite transmissions. Unless your organization uses exotic technologies (e.g., point-to-point laser, extremely low frequency (ELF), super high frequency, spread spectrum), interception will remain likely.

The second requirement, however, is another matter. Even simple messages encoded in accordance with international standards may have meaning only in a specific context or template not inherent in the message itself. For example: "142667456043052" could be a phone number (e.g., 1-426-674-5604 x3052), or it could be a Social Security number and birthday (e.g., 142-66-7456 04/30/52), or it could be dollar amounts ($14,266.74 $560,430.52), or inventory counts by part number (PN) (e.g., PN 142667 Quantity 45, PN 604305 Quantity 2), or zip codes (e.g., 41266, 74560, 43052). Almost limitless possibilities exist even without using codes or ciphers. And this example used human-readable digits. Many transmissions may be graphic images, object code, or compressed text files completely unintelligible to a human "reading" the data on a datascope.

From the preceding, you might conclude that interception and interpretation by even a technologically advanced nation was too great a challenge. This is, however, far from true. Every "kind" of data has a signature or set of attributes which, when known, permits its detection and identification. This includes encrypted data where the fact of encryption is determinable. Where transmitting or receiving encrypted messages is a crime, a company using encryption risks detection. Once the "kind" of data is determined, applying the correct application is often a trivial exercise. Some examples of such strong typing of data include:

- Rich text format (RTF) documents and most word processing documents
- SQL transactions
- Spreadsheets (e.g., Lotus 1-2-3, Microsoft Excel)
- DOS, Windows, UNIX, and other operating system executables
- Standardized EDI messages
- ASCII vs. EBCDIC

If this were not the case, sending data from one computer to another would require extensive advanced planning at the receiving computer — severely impacting data portability and interoperability, two attributes widely sought in business transactions.

Countries with sufficient technology to intercept and interpret your organization's data may pose an additional problem beyond their law enforcement: government-sponsored industrial espionage. Many countries have engaged in espionage with the specific objective of obtaining technical or financial information of benefit to the countries' businesses. A search of news accounts of industrial espionage resulted in a list including the following countries: Argentina, Cuba, France, Germany, Greece, India, Iran, Iraq, Israel, Japan, North Korea, People's Republic of China, Russia, South Korea, and Turkey. Most of these countries have public policies against such espionage, and countries like the United States find it awkward to accuse allies of such activities (both because the technical means of catching them at it may be a state secret and because what one nation views as counter-espionage another nation might view as espionage!).

Protective Technologies

For most businesses, the integrity of transmitted data is more important than its privacy. Cryptographic techniques a business might otherwise be unable to use because of import or export restrictions associated with the cryptographic process or the use of a privacy-protected message may be used in some applications for data integrity. For example, the Data Encryption Standard (DES), when used for message authentication in accordance with the American National Standard X9.9 for the protection of electronic funds transfers between financial institutions, may be approved by the U.S. Department of the Treasury without having to meet the requirements of the International Trade in Arms Regulations (ITAR). (Note that technological

advances may also impact this. For example, the key space exhaustion attack in January 1999 of a DES Challenge was successful in 22.25 hours. Both the U.S. and French governments made policy changes that permit stronger cryptography for export and import than had previously been permitted.)

Integrity measures generally address one or both of the following problems:

- Unauthorized (including accidental) modification or substitution of the message
- Falsification of identity or repudiation of the message

The techniques used to address the first problem are generally called message authentication techniques. Those addressing the second class of problems are generally called digital signature techniques.

Message authentication works by applying a cryptographic algorithm to a message in such a way as to produce a resulting message authentication code (MAC), which has a very high probability of being affected by a change to any bit or bits in the message. The receiving party recalculates the MAC and compares it to the transmitted MAC. If they match, the message is considered authentic (i.e, received as sent); otherwise, the message is rejected.

Because international standards include standards for message authentication (e.g., ISO 9797), an enterprise wanting to protect the integrity of its messages can find suitable algorithms that should be (and historically have been) acceptable to most jurisdictions worldwide. With some exceptions, even the Data Encryption Algorithm (DEA), also known as the Data Encryption Standard (DES), may be used in hardware implementations of message authentication. For digital signature this may also be true, although several excellent implementations (both public key and secret key) rely on algorithms with import/export restrictions. The data protected by digital signature or message authentication, however, is not the problem, as both message authentication and digital signature leave the message in plaintext. Objections to their use center primarily on access to the cryptographic security hardware or software needed to support these services. If the cryptographic hardware or software can be obtained legally within a given jurisdiction without violating export restrictions, then using these services rarely poses any problems.

Digital signature techniques exist for both public key and secret key algorithm systems (also known respectively as asymmetric- and symmetric-key systems). The purpose of digital signature is to authenticate the sender's identity and to prevent repudiation (where an alleged sender claims not to have sent the message). The digital signature implementation may or may not also authenticate the contents of the signed message.

Privacy measures address the concern for unauthorized disclosure of a message in transit. Cipher systems, e.g., DEA, transform data into what appear to be random streams of bits. Some ciphers, e.g., a Vernam cipher with a keystream equal to or longer than the message stream, provide almost unbreakable privacy. As such, the better cipher systems almost always run afoul of export or import restrictions. In May 2002, NIST announced that the Rijndael algorithm had been selected as the AES standard, FIPS 197, to replace DES. One of the policy isssues with AES will be its exportability, as it will allow 128- and 256-bit encryption keys.

In some cases, the use of codes is practical and less likely to run into restrictions. As long as the "codebook" containing the interpretations of the codes is kept secret, an organization could send very sensitive messages without risk of disclosure if intercepted in route. For example, an oil company preparing its bid for an offshore property might arrange a set of codes as shown in Exhibit 141.1.

The message "RED SUN NOVEMBER MAY MAY" would make little sense to an eavesdropper but would tell your representative the maximum authorized bid is 900 (the units would be prearranged, so this could mean $900,000).

Other privacy techniques that do not rely on secret codes or ciphers include:

1. Continuous stream messages (the good message is hidden in a continuous stream of otherwise meaningless text). For example: "THVSTOPREAXZTRECEEBNKLLWSYAINNTHELAUNCHGBMEAZY" contains the message "STOP THE LAUNCH." When short messages are sent as part of a continuous, binary stream, this technique (one of a class known as steganography) can be effective. This technique is often combined with cipher techniques where very high levels of message security are needed.
2. Split knowledge routing (a bit pattern is sent along a route independent of another route on which a second bit pattern is sent; the two bit streams are exclusive-ORed together by the receiving party to form the original message). For example, if the bit pattern of the message you wished to send was 0011 1001 1101 0110, a random pattern of equal length would be exclusive-ORed with the message, e.g., 1001 1110 0101 0010, to make a new message 1010 0111 1000 0100. The random pattern would be sent along one telecommunication path, and the new message would be sent along another, independent telecommunications path. The recipient would exclusively OR the two messages back together, resulting

in the original message. Because no cryptographic key management is required and because the exclusive-OR operation is very fast, this is an attractive technique where the requirement of independent routing can be met.

3. The use of templates (which must remain secret) that permit the receiver to retrieve the important values and ignore others in the same message. For example, our string used above: "THVSTOPRE-AXZTRECEEBNKLLWSYAINNTHELAUNCHGBMEAZY" used with the following template reveals a different message: "XXXXXXXNNXXXNNNXXXXXXXXXXXXNXXXNXXXXXXXXXXXXXXX" where only the letters at the places marked with "N" are used: RETREAT.

The first technique may also be effective against traffic analysis. The second technique requires the ability to ensure independent telecommunications routes (often infeasible). The third technique has roughly the same distribution problems that codebook systems have, i.e., the templates must be delivered to the receiver in advance of the transmission and in a secure manner. These techniques do, however, avoid the import and export problems associated with cryptographic systems.

In addition to cryptographic systems, most industrialized nations restrict the export of specific technologies, including those with a direct military use (or police use) and those advanced technologies easily misused by other nations to suppress human rights, improve intelligence gathering, or counter security measures. Thus, an efficient relational database product might be restricted from export because oppressive third-world nations might use it to maintain data on their citizens (e.g., "subversive activities lists"). Restrictions on software export can sometimes be averted by finding a nation in which the desired product is sold legally without the export restriction. (*Note*: Check with your legal counsel in your enterprise's official jurisdiction as this work-around may be illegal — some countries claim extraterritorial jurisdiction, or claim that their laws take precedence for legal entities residing within their borders.) For example, the Foreign Corrupt Practices Act (see 15 USC 78) of the United States prohibits giving gifts (i.e., paying graft or bribes) by U.S. corporations even if such practice is legal and traditional in a country within which you are doing business. Similarly, if the People's Republic of China produces clones of hardware and software that violate intellectual property laws of other countries but which are not viewed by China as a punishable offense, using such a product to permit processing between the United States and China would doubtlessly be viewed by U.S. authorities as unacceptable.

The Long View

New technologies (e.g., Software Defined Digital Network (SDDN) and Frame Relay) will make our networks increasingly intelligent, capable of enforcing complex compliance rules and allowing each enterprise to carefully craft the jurisdictions from which, through which, and into which its data will flow. North America, the European Community, Japan, and similar information age countries will see these technologies soon. But many nations will not have these capabilities for decades.

Most jurisdictions will acquire the ability to detect cryptographic messages and to process cleartext messages even before they acquire the networking technologies that would honor an enterprise's routing requests. The result may be a long period of risk for those organizations determined to send and to receive whatever data they deem necessary through whatever jurisdictions happen to provide the most expeditious routing.

The use of public key infrastructures (PKI) and the reliance on certificate authorities (CA) for electronic commerce will force many changes in international law. The jurisdictional location of a registration authority (RA), for example, may dictate whose personal data may be captured for registration. In a ruling by the EC Privacy Council early in 1999 with regard to IP addresses, it was determined that a static IP address constituted privacy-protected data, just as a name and mailing address would. The existence of a CA in a jurisdiction may constitute a nexus for an assertion of general jurisdiction or for taxation if the certificates signed by this CA are used for commercial purposes. Although this technology promises solutions to many problems — including restricting access to data on a selective basis that could bound jurisdictions — it also introduces rapid change and complexity with which societies (and legal systems) are already struggling.

Summary

Data daily flows from jurisdiction to jurisdiction with most organizations unaware of the obligations they may incur. As nations become more sophisticated in detecting data traffic transiting their borders, organizations will face more effective enforcement of laws, treaties, and regulations ranging from privacy to state secrets, and from tax law to intellectual property rights. The risk of state-sponsored industrial espionage will also increase. Because organizations value the information transferred electronically, more and more will turn to cryptography to protect their information. Cryptography, however, has import and export implications in many jurisdictions worldwide. The technology required to intelligently control the routing of communications is increasingly available, but will not solve the problems in the short term. Rather, the advancing technology will complicate matters further in two ways:

1. Where the controls become available, it will make their nonuse indefensible.
2. Where the controls are used, it will make the jurisdictions intentional, thereby strengthening the state's case that it has jurisdiction.

With more legal entities asserting jurisdiction, conflict of laws cases will increase. Implicit contracts will become extremely hazardous (e.g., an e-mail message may be sufficient to constitute a contract, but what are its default terms?). Ultimately, the need for effective commerce will prevail and jurisdictional issues will be resolved. But for the near term, jurisdictional issues in global transmissions remains a growth industry for legal professionals, politicians, lobbyists, tax accountants, and electronic commerce consultants.

Companies will need to exercise care when they place their data on open networks, the routings of which they cannot control. They will need to understand the jurisdictions in which and through which their global information infrastructure operates. The information security professional will want to have competent legal assistance on the team and to stay well informed. The effectiveness of the enterprise's information security program is now irreversibly intertwined with the jurisdictional issues of global electronic commerce.

142

Liability for Lax Computer Security in DDoS Attacks

Dorsey Morrow, JD, CISSP

In the middle of February 2000, Internet security changed dramatically when Amazon.com, CNN, Yahoo! E*Trade, ZDNet, and others fell victim to what has come to be known as a distributed denial-of-service attack or, more commonly, DDoS. Although denial-of-service attacks can be found as far back as 1998, it was not until these sites were brought down through the use of distributed computing that the media spotlight focused on such attacks. No longer were the attackers few in number and relatively easy to trace. A DDoS attack occurs when a targeted system is flooded with traffic by hundreds or even thousands of coordinated computer systems simultaneously. These attacking computer systems are surreptitiously *commandeered* by a single source well in advance of the actual attack. Through the use of a well-placed Trojan program that awaits further commands from the originating computer, the attacking computer is turned into what is commonly referred to as a *zombie*. These zombie computers are then coordinated in an assault against single or multiple targets. Zombie computers are typically targeted and utilized because of their lax security. Although a DDoS attack has two victims — the attacking zombie computer and the ultimate target — it is the latter of these two that suffers the most damage. Not only has the security and performance of the victim's computer system been compromised, but economic damage can run into the millions of dollars for some companies. Thus, the question arises: does the attack by a zombie computer system, because of lax security, create liability on the part of the zombie system to the target? To address this issue, this chapter provides a jurisdictional-independent analysis of the tort of negligence and the duty that attaches upon connection to the Internet.

There is a universal caveat in tort law stating that, whenever you are out of a familiar element, a reasonable and prudent person becomes even more cautious. The Internet fits the profile of an unfamiliar element in every sense of the word, be it transactional, jurisdictional, or legal. There is no clear, concise, ecumenical standard for the Internet as it applies to business transactions, political borders, or legal jurisdictions and standards. Thus, every computer user, service provider, and business entity on the Internet should exercise extra caution in travels across the Internet. But, beyond such a general duty to be extra cautious, is there more expected of those who join the broad Internet community and become *Netizens*? Specifically, is there a duty to others online?

Computer security is a dynamic field; and in today's business and legal environments, the demands for confidentiality, integrity, and availability of computer data are increasing at fantastic rates. But at what level is computer security sufficient? For years we have looked to a 1932 case in the 2nd Circuit (see *In re T.J. Hooper*, 60 F.2d 737) that involved a tugboat caught up in a tremendous storm and was subsequently involved in an accident that resulted in the loss of property. Naturally, a lawsuit resulted; and the captain was found guilty of negligence for failing to use a device that was not industry-standard at the time, but was available nonetheless — a two-way radio. The court succinctly stated, "There are precautions so imperative that even their universal disregard will not excuse their omission." In essence, the court stated that, despite what the industry might be doing, or more precisely, failing to do, there are certain precautions we must implement to avoid disaster and

liability. What the courts look to is what the reasonable and prudent person (or member of industry) might do in such unfamiliar territory.

Because computer security is so dynamic, instead of trying to define a universal standard of what to do, the more practical method would be to attempt to define what rises to the standard of negligence. Negligence has developed into a common law standard of three elements. First, there must be some duty owed between the plaintiff and the defendant; second, there must be a breach of that duty by the defendant; third, the breach of duty is a proximate cause of damages that result. (See *City of Mobile v. Havard*, 289 Ala. 532, 268 So.2d 805, [1972]. See also *United States Liab. Ins. Co. v. Haidinger-Hayes, Inc.* [1970] 1 Cal.3d 586, 594, 463 P.2d 770.) So it seems we must first address whether there is a duty between the plaintiff (the victim of a DDoS attack) and the defendant zombie computer in such an attack.

Does being tied to the Internet impose a duty of security upon businesses? Do businesses have an implicit requirement to ensure their security is functional and that their systems will not harm others on the wild, wild Internet? It is important to remember that the theory of negligence does not make us insurers of all around us, but rather that we act as a reasonable and prudent person would in the same circumstances. We have already established that the Internet, despite being commercially viable for the past ten years, is still a new frontier. As such, it is challenging historical business and legal concepts. This, of course, creates a new paradigm of caution for the reasonable person or business. The Internet creates an unbridled connection among all who would join. It is undisputed that no one *owns* the Internet or is charged with regulating content, format, or acceptable use. However, there is a duty imposed upon all who connect and become part of the Internet. As in the physical world, we owe a duty to *do no harm* to those around us. Although the ultimate determination of *duty* lies properly within the discretion of the courts as a matter of law, there are a number of *duties* that have been routinely recognized by the courts.

Perhaps the duty from which we can draw the greatest inference is the duty of landowners to maintain their land. This general duty of maintenance, which is owed to tenants and patrons, has been held to include "the duty to take reasonable steps to secure common areas against foreseeable criminal acts of third parties that are likely to occur in the absence of such precautionary measures." (See *Frances T. v. Village Green Owners Assoc.* [1986] 42 Cal.3d 490, 499–501 [229 Cal.Rptr 456, 723 P.2d 573, 59 A.L.R.4th 447].) Similarly, in Illinois, there is no duty imposed to protect others from criminal attacks by a third party, *unless* the criminal attack was reasonably foreseeable and the parties had a "special relationship." (See *Figueroa v. Evangelical Covenant Church*, 879 F.2d 1427 [7th Cir. 1989].) And, in *Comolli v. 81 And 13 Cortland Assoc.*, ___A.D.2d _____ (3d Dept. 2001), the New York Appellate Division, quoting *Rivera v. Goldstein*, 152 A.D.2d 556, 557, stated, "There will ordinarily be no duty imposed on a defendant to prevent a third party from causing harm to another unless the intervening act which caused the plaintiff's injuries was a normal or foreseeable consequence of the situation created by the defendant's negligence." As a shop owner in a high-crime area owes a greater duty of security and safety to those who come to his shop because criminal action is more likely and reasonably foreseeable, thus a computer system tied to the Internet owes a duty of security to others tied to the Internet because of the reasonably foreseeable criminal actions of others. Similarly, if we live in an area where there have been repeated car thefts, and those stolen cars have been used to strike and assault those who walk in the area, it could be reasonably stated we have a duty to the walkers to secure our vehicles. It is reasonably foreseeable that our car would be stolen and used to injure someone if we left it in the open and accessible. The extent to which we left it accessible would determine whether we breached that duty and, pursuant to law, left to the decision of a jury. Whether it was parked in the street, unlocked, and the keys in it, or locked with an active alarm system would be factors the jury would consider in determining if we had been negligent in securing the automobile. Granted, this is a rather extreme and unlikely scenario; but it nonetheless illustrates our duty to others in the digital community.

Statistics that bolster the claim that computer crime is a reasonably foreseeable event include a study by the Computer Security Institute and the San Francisco Federal Bureau of Investigation Computer Intrusion Squad of various organizations on the issue of computer security compiled in March 2001. In their study, 85 percent of respondents detected computer security breaches within the previous 12 months; 38 percent detected DoS attacks in 2001 compared to 27 percent for 2000; and 95 percent of those surveyed detected computer viruses. These numbers clearly show a need for computer security and how reasonably foreseeable computer crime is when connected to the Internet.

When viewed in the light of increasing numbers of viruses, Trojan horses, and security breaches, and the extensive media attention given them, computer crime on the Internet almost passes beyond "reasonably foreseeable" to "expected." A case in Texas, *Dickinson Arms-Reo v. Campbell*, 4 S.W.3d 333 (Tex.App. [1st Dist.]

1999) held that the element of "'foreseeability" would require only that the general danger, not the exact sequence of events that produced the harm, be foreseeable. The court went further to identify specific factors in considering "foreseeability" to include: (1) the proximity of other crimes; (2) the recency and frequency of other crimes; (3) the similarity of other crimes; and (4) the publicity of other crimes. Although this is not a ubiquitous checklist to be used as a universal standard, it does give a good reference point with which to measure whether a computer crime could be reasonably expected and foreseeable. Of course, in cyberspace, there is no physical land, tenants, or licensees. However, there is still a duty to secure systems against unauthorized use, whether mandated by statute (Health Insurance Portability and Accountability Act, Graham-Leach-Bliley Act), by regulation, or by common sense. Because of the public nature of the recent DDoS attacks, we now have a better understanding of the synergistic and interconnected nature of the Internet and the ramifications of poor security.

Perhaps the most striking argument for the duty of precaution comes from a 1933 Mississippi case in which the court stated:

> Precaution is a duty only so far as there is reason for apprehension. Ordinary care of a reasonably prudent man does not demand that a person should prevision or anticipate an unusual, improbable, or extraordinary occurrence, though such happening is within the range of possibilities. Care or foresight as to the probable effect of an act is not to be weighed on jewelers' scales, nor calculated by the expert mind of the philosopher, from cause to effect, in all situations. Probability arises in the law of negligence when viewed from the standpoint of the judgment of a reasonably prudent man, as a reasonable thing to be expected. Remote possibilities do not constitute negligence from the judicial standpoint.
>
> ***— Illinois Central RR Co. v. Bloodworth***
> **166 Miss. 602, 145 So. 333 (1933)**

A 1962 Mississippi case (*Dr. Pepper Bottling Co. v. Bruner*, 245 Miss. 276, 148 So.2d 199) went further in stating that:

> As a general rule, it is the natural inherent duty owed by one person to his fellowmen, in his intercourse with them, to protect life and limb against peril, when it is in his power to reasonably do so. The law imposes upon every person who undertakes the performance of an act which, it is apparent, if not done carefully, will be dangerous to other persons, or the property of other persons — the duty to exercise his senses and intelligence to avoid injury, and he may be held accountable at law for an injury to person or property which is directly attributable to a breach of such duty…. Stated broadly, one who undertakes to do an act or discharge a duty by which conduct of others may be properly regulated and governed is under a duty to shape his conduct in such matter that those rightfully led to act on the faith of his performance shall not suffer loss or injury through his negligence.

We have established the requirement of a duty; but in the context of computer security, what rises to the level of a breach of such a duty? Assuming that a duty is found, a plaintiff must establish that a defendant's acts or omissions violated the applicable standard of care. We must then ask, "What is the standard of care?" According to a 1971 case from the Fifth Circuit, evidence of the custom and practice in a particular business or industry is usually admissible as to the standard of care in negligence actions. (See *Ward v. Hobart Mfg. Co.*, 460 F.2d 1176, 1185.) When a practice becomes so well defined within an industry that a reasonable person is charged with knowing that is the way it is done, a standard has been established. Although computer security is an industry unto itself, its standards vary due to environmental constraints of the industry or business within which it is used. Although both a chicken processing plant and a nuclear processing plant use computer security, the risks are of two extremes. To further skew our ability to arrive at a common standard, the courts have held that evidence of accepted customs and practices of a trade or industry does not *conclusively* establish the legal standard of care. (See *Anderson v. Malloy*, 700 F.2d 1208, 1212 [1983].) In fact, the cost justification of the custom may be considered a relevant factor by some courts, including the determination of whether the expected accident cost associated with the practice exceeded the cost of abandoning the practice. (See *United States Fidelity & Guar. Co. v. Plovidba*, 683 F.2d 1022, 1026 [7th Cir. 1982].) So if we are unable to arrive at a uniform standard of care for computer security in general, what do we look to? Clearly there must be a minimum standard for computer security with which we benchmark our duty to others on the Internet. To

arrive at that standard we must use a balancing test of utility versus risk. Such a test helps to determine whether a certain computer security measure ought to be done by weighing the risk of not doing it versus the social utility or benefit of doing it, notwithstanding the cost. In June 2001, in *Moody v. Blanchard Place*, 34,587 (La.App. 2nd Cir. 6/20/01); ___ So.2d ___, the Court of Appeals for Louisiana held that, in determining the risk and utility of doing something, there are several factors to consider: (1) a determination of whether a thing presents an unreasonable risk of harm should be made "in light of all relevant moral, economic, and social considerations" (quoting *Celestine v. Union Oil Co. of California*, 94-1868 [La. 4/10/95], 652 So.2d 1299; quoting *Entrevia v. Hood*, 427 So.2d 1146 [La. 1983]); and (2) in applying the risk–utility balancing test, the fact finder must weigh factors such as gravity and risk of harm, individual and societal rights and obligations, and the social utility involved. (Quoting *Boyle v. Board of Supervisors, Louisiana State University*, 96-1158 [La. 1/14/97], 685 So.2d 1080.) So whether to implement a security measure may be considered in light of economical and social considerations weighed against the gravity and risk of harm. This in turn works to establish the standard of care. If the defendant failed to meet this standard of care, then the duty to the plaintiff has been breached.

Finally, we must consider whether the breach of duty by the defendant to the plaintiff was the proximate cause of damages the plaintiff experienced. To arrive at such a claim, we must have damages. Over the years the courts have generally required physical harm or damages. In fact, economic loss, absent some correlating physical loss, has traditionally been unrecoverable. (See *Pennsylvania v. General Public Utilities Corp.* [1983, CA3 Pa] 710 F.2d 117.) Over the past two decades, however, the courts have been allowing for the recovery of purely economic losses. (See *People Express Airlines v. Consol. Rail Corp.*, 194 N.J. Super. 349 [1984], 476 A.2d 1256.) Thus, although the computer and Internet are not physically dangerous machines (unless attached to some other equipment that is dangerous) and thus incapable of creating a physical loss or causing physical damage, they can produce far-reaching economic damage. This is especially true as more and more of our infrastructure and financial systems are controlled by computer and attached to the Internet. Hence, we arrive at the ability to have damages as the result of action by a computer.

The final question is whether the action or inaction by the defendant to secure his computer systems is a proximate cause of the damages suffered by the plaintiff as the result of a DDoS attack by a third party. And, of course, this question is left to the jury as a matter of fact. Each case carrying its own unique set of circumstances and timelines creates issues that must be resolved by the trier of fact — the jury. However, in order to be a proximate cause, the defendant's conduct must be a cause-in-fact. In other words, if the DDoS attack would not have occurred without the defendant's conduct, it is not a cause-in-fact. Of course, in any DDoS there are a multitude of other parties who also contributed to the attack by their failure to adequately secure their systems from becoming zombies. But this does nothing to suppress the liability of the single defendant. It merely makes others suitable parties to the suit as alternatively liable. If the defendant's action was a material element and a substantial factor in bringing about the event, regardless of the liability of any other party, their conduct was still a cause-in-fact and thus a proximate cause. In 1995, an Ohio court addressed the issue of having multiple defendants for a single proximate cause, even if some of the potential defendants were not named in the suit. In *Jackson v. Glidden*, 98 Ohio App.2d 100 (1995), 647 N.E.2d 879, the court, quoting an earlier case, stated:

> In *Minnich v. Ashland Oil Co.* (1984), 15 Ohio St.3d 396, 15 OBR 511, 473 N.E.2d 1199, the Ohio Supreme Court recognized the theory of alternative liability. The court held in its syllabus:
>
> "Where the conduct of two or more actors is tortious, and it is proved that harm has been caused to the plaintiff by only one of them, but there is uncertainty as to which one has caused it, the burden is upon each such actor to prove that he has not caused the harm. (2 Restatement of the Law 2d, Torts, Section 433[B][3], adopted.)"
>
> The court stated that the shifting of the burden of proof avoids the injustice of permitting proved wrongdoers, who among them have inflicted an injury upon an innocent plaintiff, to escape liability merely because the nature of their conduct and the resulting harm have made it difficult or impossible to prove which of them have caused the harm.
>
> The court specifically held that the plaintiff must still prove (1) that two or more defendants committed tortious acts, and (2) that plaintiff was injured as a proximate result of the wrongdoing of one of the defendants. The burden then shifts to the defendants to prove that they were not the cause

of the plaintiff's injuries. The court noted that there were multiple defendants but a single proximate cause.

This case does not create a loophole for a defendant in a DDoS attack to escape liability by denying his computer security created the basis for the attack; rather, it allows the plaintiff to list all possible defendants and then require them to prove they did not contribute to the injury. If a computer system was part of the zombie attack, it is a potential party and must prove otherwise that its computer security measures met the standard of care and due diligence required to avoid such a breach.

In conclusion, we must look to the totality of circumstances in any attack to determine liability. Naturally, the ultimate responsibility lies at the feet of the instigator of the attack. It is imperative that the Internet community prosecute these nefarious and illegitimate users of computer resources to the fullest and reduce such assaults through every legitimate and legal means available. However, this does not reduce the economic damages suffered by the victim. For that, we look to "deep pockets" and their roles in the attacks. Typically, the deep pockets will be the zombies. But the true determination of their liability is in their security. We must look to the standard of care in the computer security field, in the zombie's particular industry, and the utility and risk of implementing certain security procedures that could have prevented the attack. Could this attack have been prevented or mitigated by the implementation of certain security measures, policies, or procedures? Was there a technological "silver bullet" that was available, inexpensive, and that the defendant knew or should have known about? Would a firewall or intrusion detection system have made a difference? Did the attack exploit a well-known and documented weakness that the defendant zombie should have corrected? Each of these questions will be raised and considered by a jury to arrive at the answer of liability. Each of these questions should be asked and answered by every company before such an attack even transpires.

It is highly probable that those who allow their computer systems, because of weak security, to become jumping-off points for attacks on other systems will be liable to those that are the victims of such attacks. It is incumbent upon all who wish to become part of the community that is the Internet to exercise reasonable care in such an uncertain environment. Ensuring the security of one's own computer systems inherently increases the security of all other systems on the Internet.

143

The Final HIPAA Security Rule Is Here! Now What?

Todd Fitzgerald, CISSP, CISA

We are privileged to live in a society that values freedom and the individual rights of its citizens to have the opportunity to make choices that affect their own well-being. These freedoms are exercised on a daily basis without conscious thought and are many times taken for granted. For example, people make choices about where they will eat lunch, where they will have cars repaired, who will provide care for their children, where they will spend their money, what leisure activities they will participate in, and how they will use their time. One of the most important choices individuals make is the selection of healthcare. The choice of healthcare provider, be it a doctor, a hospital, or an integrated clinical system with a network of doctors and treatment facilities, is a personal choice based on many factors such as professional competence, practice location, specialty of the medicine, and trust in the ability of the medical professional. Selection of someone to provide medical attention is no small matter to be taken lightly; being able to trust the medical professional is arguably of the utmost importance.

In a generation where access to information is literally only seconds away, this trust is not blind. The Internet is used extensively by patients or concerned family members for researching medical ailments and then suggesting treatments or questioning the physician's recommended course of action. Even though a high level of trust may be invested with the physician, individuals still feel a need to find other sources of information that corroborate the recommended treatment. Due to this phenomenon, the patient is much more informed about treatment choices, medications, and potential outcomes. The Internet has accelerated this shift, which started as "Baby Boomers," also known as the "sandwich generation," needed to care simultaneously for their children and elderly parents, in addition to being concerned with the medical effects of their own aging.

Just as patients must be able to trust their medical professionals for their treatment, patients trust that they are using the medical health information, their personal medical health information, solely for the purposes of treatment, payment, or operations. They also trust that this information is kept private and that appropriate measures are taken to ensure that the information is not inadvertently disclosed, destroyed, or changed in a way that could adversely affect their treatment or create personal embarrassment. However, analogous to the trust that is placed in the medical professional, much more information is available today about privacy issues; thus people are also much more informed. The media has communicated countless examples such as hackers disclosing personal medical information by posting on the Internet, company e-mails inadvertently revealing patients using a particular medication, being solicited through someone having knowledge of personal medical history, or disclosure within an organization of psychological notes of other employees. People expect that their confidentiality will be maintained and the trust relationship between patient and provider is not compromised. Privacy issues address the rights of the individual with respect to this trust relationship, whereas security is the mechanism that ensures that this privacy is reasonably maintained throughout the system. True privacy of information cannot be achieved without adequate security controls. The Health Insurance Portability and Accountability Act (HIPAA) has several objectives, one of which is to ensure the appropriate security safeguards are in place to protect the privacy of health information.

HIPAA Arrives on the Scene

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 was enacted by Congress (Public Law 104-191) with two purposes in mind: (1) to reform health insurance to protect insurance coverage for workers and their families when they changed or lost their jobs, and (2) to simplify the administrative processes by adopting standards to improve the efficiency and effectiveness of the nation's healthcare system. Title I of HIPAA contains provisions to address health insurance reform. Title II addresses national standards for electronic transactions, unique health identifiers, privacy, and security. Title II is known as Administrative Simplification and is intended to reduce the costs of healthcare through the widespread use of electronic data interchange. Administrative Simplification was added to Title XI of the Social Security Act through subtitle F of Title II of the enacted HIPAA law.

Although the initial intent of Administrative Simplification was to reduce the administrative costs associated with processing healthcare transactions, Congress recognized that standardizing and electronically aggregating healthcare information would increase the risk of disclosure of confidential information, and the patient's privacy rights needed to be protected. Security provisions were needed not only to protect the confidentiality of information, but also to ensure that information retained the appropriate integrity. Consider the situation where the diagnosis or vital sign information is changed on a medical record, and subsequent treatment decisions are based on this information. The impact of not being able to rely on the information stored within the healthcare environment could have life-threatening consequences. Thus, privacy issues are primarily centered on the confidentiality of information to ensure that only the appropriate individuals have access to the information, whereas the security standards take on a larger scope to address issues of integrity and availability of information.

The Rule-Making Process

Each provision of Administrative Simplification must follow a rule-making process that is designed to achieve consensus within the Department of Health and Human Services (HHS) and other federal departments. When the rule is approved within the government, the public has the opportunity to comment on the proposal, and then these comments are evaluated in the determination of the final rule. Once the rules have gone through this process, they have the force of federal law. The Department of Health and Human Services implementation teams draft Notices of Proposed Rule Making (NPRMs), which are subsequently published in the Federal Register after being reviewed within the federal government, according to the process shown in Exhibit 143.1. Once the NPRMs are published, they are available for a 60-day public comment period, which provides for input and for interested parties to influence the outcome of the final regulation. After the publication of the final rule, most large health plans, clearinghouses, and providers have 24 months to be in compliance, and smaller parties have 36 months.

The proposed security and electronic signature standards were originally published in the Federal Register on August 12, 1998. The Security Rule has been delayed on several occasions, as resources were committed to and focused on the proposed transaction and code set and Privacy Rules, both of which generated a large number of public comments. The number of public comments can be large, and each one must be reviewed. Over 17,000 public comments were received on the Transaction and Code Sets NPRM and several thousand on the Privacy Rule and on the proposed Security Rule. The transaction and code set compliance date was also delayed by one year, to October 16, 2003, as long as the covered entity filed an extension request by October

EXHIBIT 143.1 Administrative Simplification Rule-Making Process

1. HHS implementation team drafts Notice of Proposed Rule-Making (NPRM) for review
2. HHS Data Council Committee on Health Data Standards reviews
3. Advisors to HHS Secretary (division agency heads) agree
4. Office of Management and Budget (OMB) reviews
5. Proposed NPRM published in Federal Register
6. Public comments are solicited for 60-day period
7. Comments open for public view
8. Comments are analyzed and content summarized by implementation team
9. Final rule is published, standards become effective 24 months after adoption, 36 months for small health plans

15, 2002. Additionally, the Security Rule was initiated during the Clinton administration and was carried over into the Bush administration, which created political challenges for expedient passage of the rule. As a result, the language was rewritten during 2002 to coincide with the Privacy Rule, which needed to go through the HHS clearance process prior to final rule publication. During 2002, the Centers for Medicare and Medicaid Services several times provided their best estimates of publication of the final rule, which passed through the clearance process and was submitted to the Office of Management and Budget (OMB) in early 2003 and was published in the Federal Register as 45 CFR Parts 160, 162, and 164 on February 20, 2003. The regulations became effective on April 21, 2003, and covered entities must comply with the requirements by April 21, 2005. Small health plans have until April 21, 2006, to comply with the rule.

The Security Objectives of the Final Rule Did Not Change Substantially

Many organizations had been "waiting" for the final rule to be published before seriously embarking on security issues. Some started HIPAA security gap analysis efforts, but many were reluctant to invest large sums of money when there was the potential that the rules might change. The reality is that the rule embodies security practices that should be performed during the normal course of business to protect the information assets and should be initiated regardless of the rule. Waiting only shortens the time available to dedicate to reasonable security and can also have the negative effect of driving up costs at a later date. For example, if a new Web-based application is in the process of being designed and adequate attention to security is not taking place during early phases of the system development cycle, the costs of retrofitting security after implementation will be 10 to 20 times the cost. Reanalysis, rewriting of the applications, integrating technical security mechanisms, and retesting and implementing the system a second time all drive up the cost. There is also the business opportunity cost of deploying scarce information technology and business resources toward retrofitting the application vs. building new functionality.

Many of the security constructs remained in the rule, as these constructs are generally industry security practices necessary to secure information that have been applied successfully in other arenas requiring higher levels of security, such as the Department of Defense, financial institutions, and companies heavily engaged in E-commerce. The final HIPAA Security Rule recognizes the need to protect electronic health information with the appropriate administrative, physical, and technical safeguards that have been applied to other industries.

The final Security Rule was reoriented to support the final Privacy Rule, which was issued on December 28, 2000, and was last modified on August 14, 2002. The Privacy Rule compliance date for most covered entities was April 14, 2003. The proposed Security Rule focused on information maintained or transmitted by a covered entity in electronic form. The scope of the information now covered by the final Security Rule has been narrowed to health information addressed by the Privacy Rule. The Privacy Rule addresses individually identifiable health information known as protected health information (PHI) in all forms, including electronic and paper. The final Security Rule focuses only on the PHI that is in electronic form (e-PHI), in transit or in storage (data at rest); otherwise, the scope is the same as the Privacy Rule. This eliminates some of the confusion surrounding what information needed to be addressed by the Security Rule, which seemed to be in conflict with the Privacy Rule in the Security Rule NPRM.

In addition to the reorientation with the Privacy Rule, the final Security Rule changed the nomenclature of the "requirements" and "implementation features" and replaced these with "standards" and "implementation specifications," respectively. The implementation specifications were also categorized as "required" or "addressable." This was done to provide consistency with the Privacy Rule and the Transactions Rule and provide common terminology. The new approach is much cleaner, manageable, and easier to interpret. In making this change, the original 69 implementation features were reduced to 14 required implementation specifications to support the requirements, now referred to as the Security Standards.

There also appeared to be a change from a proscriptive approach to one that requires a covered entity to look at the risks and vulnerabilities to the protected health information that it transmits or maintains in electronic form and determine the reasonable and appropriate security measures to provide adequate protection of this information. The Administrative Simplification revisions to the Social Security Act required that that Secretary of HHS adopt standards that consider:

1. The technical capabilities of the record systems used to maintain the information
2. Costs of the security measures

3. Training needs for those who have access to health information
4. The value of audit trails in computerized record systems
5. The needs and capabilities of small health and rural health providers

Whereas these requirements apply to the broader topic of "health information," the final Security Rule has taken this approach with respect to electronic protected health information. Therefore, each organization must make the judgments as to what is "reasonable and appropriate" based on its size, complexity of systems, capabilities, cost of security measures, and probability and criticality of potential risks to e-PHI. Larger organizations are expected to provide more resources and have the financial ability to introduce more complex solutions.

Approximately 2350 comments were received on the initial Security Rule. These comments were assessed and taken into account with keeping the underlying goals of information protection in mind. Some of the proposed implementation specification changes were seen as resulting in standards that would be too difficult to understand or apply. Some comments proposed the expansion of applicability to all entities involved in healthcare, others sought clarification of their particular entity's requirements. Some comments demonstrated the confusion with understanding the requirements, or felt that the requirements were too granular or restrictive, or that the definitions needed further explanation. These comments were reviewed and considered in the final rule, with HHS providing changes to the rule based on industry practices, government regulations, and its mandate to produce a set of security standards.

Privacy Rule Requirements for Security

Even in the absence of the final Security Rule being available for most of the period that organizations were addressing Privacy Rule issues, the references in the Privacy Rule, which was originally published for public comment on November 11, 1999, and subsequently issued with a compliance date of April 14, 2003, as shown in Exhibit 143.2, clearly indicated the need for a reasonable level of security practices to be in place. The safeguard standard contained within §164.530 of the Privacy Rule states:

> A covered entity must have in place appropriate administrative, technical, and physical safeguards to protect the privacy of protected health information.

This appears to suggest a linkage to the Security Rule requirements, which have a compliance date much further out (at least two years) from the compliance date of the Privacy Rule!

The implementation specification for safeguards in the final Privacy Rule continues this thought, by stating:

> A covered entity must reasonably safeguard protected health information from any intentional or unintentional use or disclosure that is in violation of the standards, implementation specifications or other requirements of this subpart…. A covered entity must reasonably safeguard protected health

EXHIBIT 143.2 Notice of Proposed Rule-Making (NPRM) Dates

Proposed Rule	NPRM Date	Final Date	Compliance Date
Transaction and code sets	5/07/1998	8/17/2000[a]	10/16/2003[a]
Privacy	11/11/1999	March 2001[b]	4/14/2003[c]
Security	8/12/1998	2/20/2003	4/21/2005[d]
Employer ID	6/16/1998	3/31/2002	7/30/2004[e]

[a] Compliance date for Transaction and Code Sets was extended through legislation enacted on December 27, 2001, titled the Administrative Simplification Compliance Act, as long as providers submitted a request for extension by October 15, 2002. Modifications were made February 20, 2003, and corrected on March 10, 2003.

[b] Privacy rule changes were proposed March 27, 2002, and the final rule published August 14, 2002; however, the compliance date was not changed from the original date. Guidance was previously issued on July 6, 2001.

[c] Small health plans must be compliant by April 14, 2004.

[d] Small health plans must be compliant by April 21, 2006.

[e] Small health plans must be compliant by August 1, 2005.

> information to limit incidental uses or disclosures made pursuant to an otherwise permitted or required use or disclosure.

It is clear from these excerpts that "reasonable" security is expected to be implemented for the Privacy Rule to protect the privacy of health information. Moreover, the proposed Security Rule only applies to electronic information, whereas the Privacy Rule applies to all forms of protected health information. This creates a situation where the Privacy Rule assumes broader application in the form of protected information being addressed than the proposed Security Rule.

The Final HIPAA Security Rule

The Administrative Simplification (Part C of Title XI of the Social Security Act) provisions state that covered entities that maintain or transmit health information are required to:

> …maintain reasonable and appropriate administrative, physical, and technical safeguards to ensure the integrity and confidentiality of the information and to protect against any reasonable anticipated threats or hazards to the security or integrity of the information and unauthorized use or disclosure of the information.

Because the final Security Rule was written to be consistent with the Privacy Rule, the focus of security standards applied to "health information" in support of the Administrative Simplification requirements were shifted to PHI and specifically to e-PHI. The applicability statement of the final Security Rule states:

> A covered entity must comply with the applicable standards, implementation specifications, and requirements of this subpart with respect to electronic protected health information.

Covered entities are defined as (1) a health plan, (2) a healthcare clearinghouse, and (3) a healthcare provider who transmits any health information in electronic form in connection with a transaction covered by Part 162 of Title 45 of the Code of Federal Regulations (CFR).

This is where the security standards become important. According to the Security Rule, these standards were written to "define the administrative, physical, and technical safeguards to protect the confidentiality, integrity, and availability of electronic protected health information." Therefore, by applying the security standards on electronic PHI as the scope, the objectives of Administrative Simplification will be satisfied. All of the security standards must be satisfied, some through required implementation specifications and some through addressable implementation specifications.

As shown in Exhibit 143.3, protecting the confidentiality, integrity, and availability of electronic protected health information is at the core of the security requirements, while reasonably anticipated threats (security), uses, and disclosures (privacy) must also be protected and compliance of the workforce with the security standards ensured.

Let's Just Be Reasonable

The definition of "reasonable" can vary from person to person. The final assessment appears to be headed for the courts and will be determined by case law as a result of lawsuits. Consider the case where an employer has installed a proximity card reader for 500 employees at a data center containing protected health information. Assume the facility has a guard during the daytime; however, during the evening hours the computer operators watch the surveillance cameras for suspicious activity. One evening, while the night operator went to the restroom, someone using an unreturned visitor's badge obtained during the day entered the building and removed three laptops. Were reasonable steps taken to prevent the theft? Was the fact that the operator left his station unattended unreasonable? Was it unreasonable that the unreturned visitor's badge still worked? Or, would a jury view this situation as one that could be reasonably expected to occur? Consider another example where patient information is discovered after a Web server is hacked. If correct firewall configurations were set 99 percent of the time, except for one instance where the network engineer was upgrading the server and inadvertently opened some ports after a long, tiring weekend, was the information not reasonably protected? Is "most of the time" reasonable?

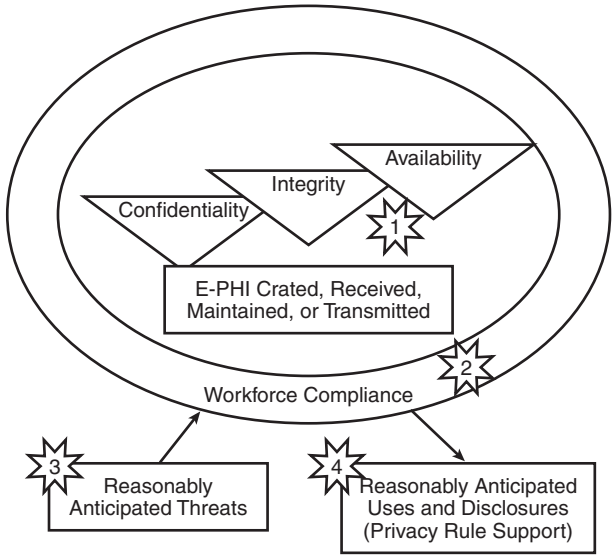

EXHIBIT 143.3 Security Rule general requirements.

Different organizations make different security decisions based on the risk that they are willing to assume. Organizations take into account the costs, technical abilities, and the risk that they are willing to assume based on their business objectives. It is critical that companies assess the threats, vulnerabilities, and risks to electronic information and develop reasonable steps to address the risk. Each of these decisions and their rationale should be documented so that it can be understood at a later point in time why the decision was made. Documenting these decisions also forces the organization to really look at the decisions that are being made and whether or not they make sense. It is not uncommon to go through this process, only to find out that management team members were making different assumptions as to the level of risk and were accepting an unreasonable level of risk without being aware that they were.

The Security Standards

The 1998 proposed Security Rule defined standards for the security of individual health information under the control of the covered entities (health plans, clearinghouses, and healthcare providers). The three safeguard categories of Administrative, Physical, and Technical contain a total of 18 security standards (vs. 24 requirements in the proposed rule) that must be addressed, as shown in Exhibit 143.4. The standards are intended to be technology neutral so that advances in technology can be used to the best advantage as they evolve.

In support of the security standards, there are 14 required implementation specifications that address seven of the eighteen security standards, as some security standards are comprised of multiple required implementation specifications. For example, the Security Management Process security standard contains four required implementation specifications, including Risk Analysis, Risk Management, Sanction Policy, and Information System Activity Review.

The covered entity must decide, through executing the risk analysis, risk mitigation strategy, cost of implementation, and evaluating the security measures that are already in place, whether or not the "addressable implementation specification" is reasonable and appropriate and should be implemented. If the specification is viewed as not reasonable and appropriate, but for the standard to be met another security safeguard is necessary to be implemented, the entity may implement the safeguard using an alternative control as long as it accomplishes the same result as the addressable implementation specification. In other words, an organization could select other controls as long as the security standard is met. In this case, the organization must document the decision not to implement the addressable implementation specification, the rationale behind it, and the alternative control that was implemented in its place. There are 22 addressable implementation specifications,

which address nine of the Security Standards; four of the Security Standards also contain required implementation specifications as well.

The six remaining Security Standards contain neither an addressable implementation specification nor a required implementation specification. In these cases it was felt that the definition of the standard itself was sufficient to understand the implementation required. For example, the Assigned Security Responsibility Standard is "identify the security official who is responsible for the development and implementation of the policies and procedures required by this subpart [Security Rule] for the entity." Additional explanation is really not necessary to understand the standard; someone needs to be designated to fulfill this role to satisfy the standard.

To "meet the Security Standards," 36 required or addressable implementation specifications must be reviewed and complied with, either through the required implementation specification, the prescribed (addressable) implementation specification, or an alternative control; combined with six Security Standards without any implementation specification noted totals 42 areas that are required to be acted upon in some manner. Although some of these tasks can be completed quickly depending on the current security profile of the organization, this still represents a significant undertaking, requiring about two of these areas to be evaluated each and every month from now until the compliance date! If someone is not "charged with the security responsibility," this would be a great time to satisfy the Assigned Security Responsibility Security Standard and draft someone. In many organizations, the need was recognized and the positions filled during the attention to the Privacy Rule due to the requirements to "have in place appropriate administrative, technical, and physical safeguards to protect the privacy of protected health information."

Changes to the Proposed Standards in the Final Rule

The following is a brief summary of the intent of each Security Standard, along with the changes from the proposed Security Rule. Each of the security standards descriptions contains references to addressable or required implementation specifications. The reader is referred to Exhibit 143.4 for the specific implementation specification designation (required or addressable).

Administrative Safeguards

Administrative safeguards consist of the formal organizational practices that manage the selection and execution of security measures to protect data and the conduct of personnel in the protection of the data. It is important that these practices are documented in the form of policies, procedures, standards, or guidelines that are followed by the organization. Although there may be accepted practices that are followed within the organization, without proper documentation it is difficult to demonstrate that all employees are working with the same assumptions. Additionally, without the documented procedures new employees may not be adequately informed as to their security responsibilities.

Much of the detail of this section was removed and the requirements were generalized to be less proscriptive. The order of the previous requirements (alphabetical) was rearranged to be more logical, with the establishment of the security management process occurring first, as everything else within the security program should be built on this. The previous requirements for system configurations and for a formal mechanism for processing records were dropped from the final rule as they were seen as redundant, unnecessary, or ambiguous with other requirements for documentation and processes.

Security Management Process

Conduct risk analysis to assess vulnerabilities and risks to the confidentiality, integrity, and availability of e-PHI, risk management of the implemented security measures, apply appropriate sanctions to workforce members who fail to comply with the security policies and procedures, and implement procedures to regularly review records of information system activity (i.e., audit logs, access reports, security incident tracking reports). The specification of "Internal Audit" was changed from the proposed rule, as it was not intended to have a rigid, costly review process over the system activity related to security, but rather to ensure that appropriate attention to security continues to take place over time. Sanction policies were seen as necessary to meet the requirement of "ensuring" compliance of the officers and employees and that the introduction of negative consequences for noncompliance increases the chances that compliance will be achieved. It is a typical result

EXHIBIT 143.4 HIPAA Security Standards and Implementation Specifications

Security Standard	Required Implementation Specification	Addressable Implementation Specification
Administrative Safeguards		
Security management process	Risk analysis Risk management Sanction policy Information system activity review	
Assigned security responsibility	Required (no implementation specification)	
Workforce security		Authorization and supervision Workforce clearance procedure Termination procedures
Information access management	Isolating healthcare clearinghouse function	Access authorization Access establishment and modification
Security awareness and training		Security reminders Protection from malicious software Log-in monitoring Password management
Security incident procedures	Response and reporting	
Contingency plan	Data backup plan Disaster recovery plan Emergency mode operation plan	Testing and revision procedure Applications and data criticality analysis
Evaluation	Required (no implementation specification)	
Business associate contracts and other arrangements	Written contract or other arrangement	
Physical Safeguards		
Facility access controls		Contingency operations Facility security plan Access control and validation procedures Maintenance records
Workstation use	Required (no implementation specification)	
Workstation security	Required (no implementation specification)	
Device and media controls	Disposal Media reuse	Accountability Data backup and storage
Technical Safeguards		
Access control	Unique user identification Emergency access procedure	Automatic log-off Encryption and decryption
Audit controls	Required (no implementation specification)	
Integrity		Mechanism to authenticate electronic protected health information
Person or entity authentication	Required (no implementation specification)	
Transmission security		Integrity controls Encryption

that if employees know that something is being monitored and followed, they are less likely to be in noncompliance with the expectations.

Security management is an ongoing function with a continuous cycle of risk analysis, risk management, and issuance of security policies and their sanctions. Over time, attention to security within organizations tends to dissipate, which (unknowingly) increases the risk profile.

Assigned Security Responsibility

An individual must be identified who is responsible for the development and implementation of security policies and procedures. Many individuals may be involved in security for the organization, but there must be one individual named with the responsibility of protecting e-PHI. The proposed rule indicated an individual or organization could be named; however, this is no longer the case; it must be a single official. Multiple people are typically involved in the security function in larger organizations; however, someone must be named with accountability for the function to ensure that policies and procedures are developed and implemented as required by the rule. The individual and supporting organization utilize the security management processes to carry out the mission of the information security program.

Workforce Security

Implement policies and procedures to ensure that every member of the workforce has appropriate access to e-PHI and prevent those who should not have access through authorization/supervision of workforce members, clearance procedures, and termination procedures. The specifications are all addressable because it will vary by organization as to whether or not they need to be formalized. Background checks are not required for all employees through the clearance specification; however, some form of screening needs to take place prior to permitting access to e-PHI. The detailed requirements of the termination procedures have been removed, again to be less proscriptive and allow flexibility for the specific environments. The intent is to ensure that when individuals with access to e-PHI are no longer associated with the entity, the exposure for potential damage is mitigated by removing their access. Small offices would most likely not require the formalized procedures that large organizations would require to meet the standard.

Information Access Management

Implement policies and procedures for establishing, authorizing, reviewing, documenting, and modifying a user's right to access a workstation, transaction, program, process, or other means of accessing e-PHI. This forms the basis of acceptable information security access management practices through (1) authorizing appropriate access, and then (2) establishing the access. This standard supports the minimum necessary requirements of the Privacy Rule, and as such, specific references to "role-based," "user-based," "context-based," discretionary/mandatory access control, and the distinctions between authorization and access control were omitted from the final rule. An added required implementation specification to isolate the clearinghouse functions from the larger organization through their own policies and procedures was added to this requirement.

Security Awareness and Training

Implement a security awareness and training program for all members of the workforce, including management, training on protection from malicious software (viruses, Trojan horses, worms, scripting, etc.), log-in monitoring, password management, and periodic security reminders. The end users are the key to successful security, and each member of the workforce must receive ongoing training. Flexibility is left up to the organization as to how this can be implemented through techniques such as face-to-face, pamphlets, new employee orientation, Web-based, etc. Many security practitioners feel that security awareness and training are the most effective areas to invest in security. These individuals represent the "security front line" and education here causes individuals to support the security program through awareness and preventing larger security issues. It does little good to implement a complex technical solution, such as implementing dynamic passwords utilizing RADIUS or TACACS+ authentication and token cards, if the user tapes a PIN to the back of the token card. Similarly, having policies that deal with the handling of confidential information would be ineffective if the users were not aware of the types of information considered confidential and needed extra measures to provide adequate protection. Training is a continual process that should focus on different aspects of information security.

Security Incident Procedures

Incident response and reporting procedures are required to mitigate the potential harmful effects of the incident and provide documentation of the incident and outcome. An incident is defined as the attempted or successful unauthorized access, use, disclosure, modification, or destruction of information or interference with system operations. Each organization must define what event would be considered a security incident and the internal/external reporting processes necessary to support the incident.

Formal, current, accurate, and documented procedures for the reporting and response to security incidents are necessary to ensure that violations are reported and handled promptly. Seemingly small incidents may be symptomatic of a larger problem and should be thoroughly investigated. Lack of attention to the small incidents also creates a culture that is desensitized to information security and creates a greater risk that a larger risk may occur. For example, if attention is not paid to the occasional laptop that is missing every few months because the information stored on the laptop was not seen as valuable, then the larger problem of laptop security awareness and the need for locking devices may be missed. Subsequently, a nurse's laptop containing health information or an executive's laptop containing confidential business strategic information may be compromised when it could have been prevented.

Contingency Plan

In the aftermath of September 11, 2001, many organizations have increased their focus toward disaster recovery. The contingency plan provides the organizational readiness to respond to systems emergencies so that critical operations can be continued during an emergency. To meet the requirement, applications and data criticality analysis, data backup plans, disaster recovery plans, emergency-mode operation plans, and testing and revision procedures are included as required or addressable implementation specifications to support the Contingency Plan standard. Most large organizations have disaster recovery plans covering the mainframe environments as a result of the Y2K contingency planning that had previously taken place. However, infrastructure and staffing are constantly changing, and as a result, many of these plans need to be updated. Although most organizations tend to back up network environments on a regular schedule, these environments rarely have adequate disaster recovery plans or are tested on a regular basis. With the continuing shift to the network/server environment for mission-critical applications, increased attention will need to be paid to the contingency planning of these facilities.

Policies and procedures are to be implemented for responding to emergencies or other occurrences (i.e., fire, vandalism, system failure, natural disaster) that damage systems that contain e-PHI. This is accomplished through data backups, disaster recovery plans, emergency mode operation plans (ability to continue business during the crisis), testing and revision procedures, and applications and data criticality analysis. This standard was proposed and remained in the final rule as data becomes most vulnerable during crisis events because security controls are typically bypassed to bring the systems back into operation. e-PHI lost during these events impacts the availability and integrity of the information, exposing the data to confidentiality issues of improper use and disclosure.

Evaluation

Perform a periodic technical and nontechnical evaluation based on the standards initially and also after environmental and operational changes affecting e-PHI. This evaluation can be performed internally or externally and replaces the certification requirement of the earlier rule. It can be expected that independent certification guides, secure software listings, and compliance guidelines will emerge from private enterprise. To form a meaningful evaluation, the risk-level acceptance of the organization should be understood prior to the evaluation, as the security measures chosen should be a result of the risk assessment decisions.

Evaluation processes, whether performed internally or externally, have the positive impact of documenting the security actions taken and obtaining management sign-off, which tends to create greater accountability beyond the security department for the implementation. It also tends to ensure that the agreed-upon security parameters in the design process are carried through to implementation.

Business Associates and Other Arrangements

The final rule eliminated the chain-of-trust agreement and replaced it with the requirement for a covered entity to ensure that appropriate safeguards are assured by the business associate through inclusion of security requirements in written contracts. The scope is limited to e-PHI, as is the rest of the Security Rule. The business associate definitions are those that are utilized within the Privacy Rule. In the event that a covered entity is aware of a pattern or practice that the business associate is engaged in that is considered a violation of the business associate's obligation, the covered entity would be in noncompliance if it failed to take reasonable steps to end the violation. Other arrangements specify situations such as how the rules apply to government entities, other laws, terminations of contracts, etc.

Physical Safeguards

Protecting the covered entity's electronic information systems and the buildings that contain these systems from fire, natural and environmental hazards, and unauthorized intrusion are the focus of the Physical Safeguards. These controls support many of the administrative and technical controls defined in the other safeguard sections. Consider the situation where very tight logical access controls (Technical Safeguard Access Control Security Standard) are defined to support the Administrative Safeguard Standards For Information Access. Assume that a computer containing these controls is located in an area where other building tenants have unrestricted access. Even with two-factor authentication, encryption of files, and properly implemented access control facilities, if the physical server can be accessed, an alternate operating system could be loaded, or worse yet, the server could be stolen, thus providing the intruder with ample opportunity to decipher encrypted files. Unauthorized employees having physical access to the server creates unnecessary additional risk.

Two requirements of the proposed rule, assigned security responsibility and security awareness training, made much more sense in the Administrative Safeguards section, and they were moved to that section in the final Security Rule. Following is a discussion of the Physical Safeguard Standards and related implementation specifications.

Facility Access Controls

Focus on the facilities that provide physical access to the electronic information systems, the standard limits physical access through contingency operations (facility access in the event of an emergency), facility security plan (safeguard facility from unauthorized physical access, tampering, and theft), access control and validation procedures (validate access to facilities based on role, control access to programs for testing and revision), and maintenance records (document repairs to facility security components). The standards appear to be straightforward and permit the organization to review the risks and implement the appropriate controls, unlike the proposed rule, which appeared to require all of the implementation specifications without regard to the risk analysis. It is still the covered entity's responsibility to ensure the facilities where e-PHI is located and transmitted are secured properly, whether or not the facility is owned by the covered entity.

Workstation Use

For workstations that are allowed access to PHI, implement policies and procedures specifying proper functions and the manner in which those functions are to be performed (i.e., locking workstations, logging off, invoking screensavers) and the physical attributes of the space surrounding the workstations. The workstation terminology is used to replace "terminal" and applies to the broad range of computing equipment with access to e-PHI (laptops, desktops, personal digital assistants, etc.) and is not limited to the desktop PC.

Workstation Security

Implement physical safeguards for all workstations that access e-PHI, restricting access to authorized users, consistent with proposed rule. Contents displayed on the workstation, especially those in open areas such as nurses' stations, must be secured so that private information is not viewable by unauthorized persons. Workstations should also be secured so that only authorized personnel would have access to the workstation. In practice, some workstations need to be in open areas and approaches such as turning the monitor away from public viewing, logging off the workstation when unattended, utilizing screensavers, and ensuring that the workstation is protected from theft would appear to be reasonable.

Device and Media Controls

Implement policies and procedures governing the receipt and removal of hardware and software in and out of a facility and movement within a facility through disposal procedures, media reuse procedures, accountability (record of movements), and data backup and storage (in this case, this is related to the backup of e-PHI prior to the moving of equipment). Media reuse procedures were added to the rule to address reuse and recycling. There have been news stories of hard drives purchased on E-Bay that contained sensitive information, which subsequently was retrieved because it was not properly disposed of after final disposition.

Technical Safeguards

The technical security services (processes that protect, control, and monitor information access), and the technical security mechanisms (processes that prevent unauthorized access over a communications network)

have been combined into the Technical Safeguards category. This is very logical, as many organizations viewed these as technical requirements. Data authentication was renamed to the standard security terminology of integrity. Following is a discussion of the Technical Safeguard Standards and related implementation specifications.

Access Control

Implement technical policies and procedures for electronic information systems containing e-PHI to allow access only to those persons who have been granted access through the Information Access Management processes in the Administrative Safeguards. Unique user IDs are necessary to identify and track the individual's activity, emergency access procedures are required to support operations in an emergency situation, and implementation specifications of automatic log-off and the use of encryption can support the access security standards. There was much confusion around the requirements for role-based, context-based, mandatory access control, discretionary access control, etc., in the proposed rule. The new specification is much cleaner and affords the organization the ability to implement the appropriate rules based on the risk. For example, an organization may decide to encrypt highly sensitive e-PHI data-at-rest if there is an assessment that this information could be compromised, such as in the case of fraud investigation involving health information stored on a CD.

A procedure for emergency access during a crisis must be implemented. Consider the situation where a specialist is called in to perform an emergency procedure, but does not have access to needed health information from the local information system. The specialist needs a method to gain emergency access without "waiting for forms to be processed" by the security department.

Audit Controls

Recording system activity is important so that the organization can identify suspect data access activities, assess the effectiveness of the security program, and respond to potential weaknesses. Implementation of hardware, software, and procedural mechanisms that record and examine activity in information systems containing e-PHI is necessary. Some organizations have assumed that the audit trails specified under this requirement would support the Privacy Rule. Typically, the types of information dealt with are different. Whereas the Privacy Rule is concerned with tracking of uses and disclosures, the Security Rule is concerned with tracking system activity, such as log-in attempts, access, and modification to records. Although similar, audit trails within the system context are typically not geared toward tracking the business-level information surrounding the use and disclosures, even though some records may provide supporting information. System audit trails are also not typically turned on to monitor read access to information due to the volume of information.

Integrity (Formerly Data Authentication)

Implement policies and procedures to protect e-PHI from improper alteration or destruction through mechanisms that corroborate that the information has not been destroyed in an unauthorized manner. Techniques such as digital signatures, checksums, and error-correcting memory are all methods of ensuring data integrity. Again, the ability to assess risk, provide technology neutrality, and not be proscriptive enables the covered entity to determine the appropriate methods to ensure the integrity of the data.

Person or Entity Authentication (Combined Authentication Requirements)

Implement procedures to verify that the person or entity seeking access to e-PHI is really the person or entity. The proposed rule was very proscriptive in suggesting biometrics, passwords, telephone callbacks, token systems, PINS, etc., where the rule now allows the implementation to be determined by the entity based on the risk assessment. The requirements for "irrefutable" entity authentication were removed in the final rule.

Transmission Security

Implement technical security guarding against unauthorized access to e-PHI transmitted over an electronic communications network (vs. open network in the proposed rule). Integrity controls and encryption may be applied according to the risk level of the information. In cases such as dial-up lines or over a private network, encryption may not be necessary to achieve the standard's objectives; however, over the Internet the appropriate encryption levels to thwart brute-force cracking may be necessary. This is an area where technology is constantly changing, there are interoperability issues, and the feasibility of solutions may make this prohibitive for small providers.

Documentation and Other Related Standards

To comply with the standards, implementation specifications, and any other requirements of the Security Rule, the covered entity must implement reasonable and appropriate policies and procedures in addition to the security standards specified in the Administrative, Technical, and Physical Safeguards. These must be documented and can be changed at any time. The covered entity can take into consideration the size, complexity, and capabilities of the covered entity; the technical infrastructure, hardware and software security capabilities, the costs of the security measures, and the probability and criticality of potential risks to the e-PHI.

Documentation of policies and procedures may seem to be such a logical practice that it may appear unnecessary to state it. However, many organizations operate without defined policies and procedures, and the work gets done. The difficulty is that many times it is done several different ways, depending on the individual performing the activity. This increases the likelihood that inconsistencies will occur, increasing the potential for security incidents. Although the Security Rule does not specify a requirement to adopt ISO 9000-type standard processes, implementing procedures that follow this approach would further support that a "reasonable" approach was taken. This also permits the opportunity to review and discuss the processes across organizations and work toward improving the processes, thus increasing service delivery capabilities and reducing waste.

Consider as an example the practice of security configuration management changes. Security measures, practices, and procedures need to be documented and integrated with the other system configuration practices to ensure that routine changes to system hardware and software do not contribute to compromising the overall security. Security design efforts placed into new systems could easily be compromised and resources wasted without the appropriate level of security review for what appears to be a simple change. Security management is a continuous process. For example, a systems engineer who was upgrading a server unintentionally opened a security hole on the mail server that provided the capability to perform mail relays. This happened at 1:30 a.m., and the systems engineer discovered his error and closed the hole by 2:00 a.m.. Unfortunately, within that timeframe a hacker discovered the open relay and used the mail server to send "get rich quick" e-mails to more than 2000 individuals. Each of the e-mail addresses included the mail header information, which showed that it was coming from the system engineer's organization. This demonstrates that clear, documented configurations and procedures for changing these configurations are necessary.

Many times, documentation is an afterthought. The more organizations get into the practice of seeing this as an important deliverable of the development process, the more efficient and effective the organization can become because the opportunity for future improvement becomes more visible.

Pragmatic Approach

At first glance, the 18 standards and their related implementation specifications can certainly seem daunting, presenting a case for the senior leadership, the Information Technology team, and the Information Security Officer to head for the emergency room!

The Security Rule was meant to be scalable such that small providers would not be burdened with excessive costs of implementation, and the large providers, health plans, and clearinghouses could take steps appropriate to their business environments. For example, backing up the data of a small provider may be a simple process of rotating the information to an offsite location on a weekly basis from one server, whereas a large operation may contract with a disaster recovery company or may employ electronic vaulting of the information. Decisions have to be made to reasonably protect the information, and document how the decisions were determined. Earlier it was recognized that security is always a risk-based decision, and it is sometimes difficult to determine what is "reasonable" under the circumstances.

A security plan for improvement is the most pragmatic way to move toward HIPAA compliance. Stepwise improvements in the security infrastructure, beginning with an understanding of what risks are being casually accepted within the environment, followed by targeting solutions to mitigate the critical risks, seems reasonable. Early in the process, someone needs to be assigned security responsibility to champion the security efforts. Management support should be obtained through articulation of the risks to the assets, not because "HIPAA requires that we become compliant." This approach only causes management to take a "wait and see" attitude until it is understood what other organizations are doing with the "HIPAA issue." Squarely explaining the risks and incrementally building support through successful delivery is the formula that will provide for longer-term benefits for maintaining the security program. Selling the protection of assets as an ongoing activity provides the view that security is not "done" at the end of the HIPAA project. The idea should be generated

that information is an asset that must be managed on an ongoing basis, just like the financial, human resources, and fixed assets of the organization. Although the temptation may be even stronger to use the "HIPAA Hammer" to pound the message into the organization now that the Final Security Rule has been published, the value of protecting the information assets, providing reduction in long-term "hidden" costs, and the opportunities enabled though secure systems, should be surfaced and promoted. A HIPAA project will have a beginning and an end, but the security program to continue protecting the information assets must survive as a fundamental business operation.

The first task in the plan should be to establish security responsibility, followed by formation of security policy and review committees, development of high-level policies, network assessments, and successive implementation of policies, procedures, and technical implementations to satisfy the various aspects of the HIPAA rule. The key is to get started, somewhere, and begin making progress. Individuals within the organization may already be working on efforts related to one of the security standards — use the opportunity to expand the scope and ensure that the security practices are formalized and documented and will meet the HIPAA security requirements.

Risk, Risk, Risk!

It should be very apparent at this point that much of the "proscriptive" nature of the Security Rule has been changed to an approach that places the emphasis on assessing the risk and determining the implementation choices that are "reasonable and appropriate." True, different organizations may look at the same risk information pertaining to e-PHI and evaluate it differently. This is to be expected, as management teams have different value systems, experiences, and views of criticality. As time goes on, industry best practices for various sizes of organizations, case law, civil suits, cost effective technology innovations, standards development, an increased focus on security and the efforts of local and national associations focused on healthcare and HIPAA will all contribute to the emergence of "*de facto* healthcare security practices." Some of these practices/standards currently exist and others will emerge prior to the compliance date, but this will be an evolutionary refinement process over time as organizations within this industry determine what security approaches support the business of healthcare. Security practices borrowed from other industries are excellent starting points for investigation. Risk assessment and risk management activities should proactively take into account the capabilities to ensure adequate protection of e-PHI.

The change away from the proscriptive nature of the Security Rule makes the rule much easier to read and understand. It also better supports the technology neutrality and scalability principles desired. Some may view the heavy reliance on the risk assessment as the lack of ability to make a "tough" standard. The more appropriate view is that each covered entity must meet the security standard, and the level to which they meet that standard must be consistent with the risk assessment results. In the case of large organizations, with the size, capabilities, and financial ability to implement the addressable specifications, they will most likely be expected to commit the resources. Taking the view that the standard does not need to be taken seriously because it is "addressable" is erroneous.

It is all about risk assessment, documenting the risks, and making good judgments as to the security measures that are reasonable and appropriate for the covered entity's individual situation.

Conclusion

HIPAA should be viewed as an opportunity to address some areas that may not have received attention in the past due to other funding priorities. Protection of health information should be viewed as an opportunity — an opportunity to place some controls around health information such that new processes can be enabled. Technologies continue to emerge with exciting new possibilities, such as wireless access, personal digital assistants, digital photography advances, cell phone proliferation, and instant messaging, to name a few. These new technologies deliver new security challenges as well as new opportunities for collaboration. Creating the proper security foundation will enable these new uses to be exploited, increasing the availability and quality of healthcare, such as Internet health information lookup, while reducing some overhead costs, such as reducing staffing requirements (or providing more funds for increased quality) for customer service.

In the short term, the struggle will continue to move toward compliance. By starting now, HIPAA decisions can be made with more planning and less reaction to the immediate security concern.

How can a covered entity possibly achieve compliance in less than two years (three years for small health plans)? Disney World has the answer. Anyone that has been there knows that it is a magical place where fun things happen and the rest of life is temporarily forgotten. They also know that Disney World has an equally magical way of hiding the length of the lines to the amusements by snaking around one corner, and then the next, showing only a "manageable" line of people directly in front of you. This illusion makes the line seem shorter, as you can see only a little at a time.

Implementing the Security Standards is like Disney World in many ways. It is a very long line, with many dependencies. If we look at the whole line, we might just give up in frustration and decide to try again another day. If we view each security standard as a small line along the way to meeting our goal of protecting e-PHI, the effort does not seem quite so bad.

We are now at Disney World, we have been waiting to stand in line for the past several years, and now is our chance. There is the thrill of anticipation of getting to our destination, coupled with the fear of not getting there on time. But, we are in line now, and we need to celebrate our accomplishments…one turn at a time, and maybe, just maybe, have a little fun along the way.

HIPAA 201: A Framework Approach to HIPAA Security Readiness

David MacLeod, Ph.D., CISSP, Brian Geffert, CISSP, CISA, and David Deckter, CISSP

The Health Insurance Portability and Accountability Act (HIPAA) has presented numerous challenges for most healthcare organizations, but through using a framework approach we have been able to effectively identify gaps and develop plans to address those gaps in a timely and organized manner.

— Wayne Haddad

Chief Information Officer for The Regence Group

HIPAA Security Readiness Framework

Within the U.S. healthcare industry, increased attention is focusing on Health Insurance Portability and Accountability Act (HIPAA) readiness. For the past five years, healthcare organizations (HCOs) across the country have moved to prepare their environments for compliance with the proposed HIPAA security regulations. The past five years have also proved that HIPAA security readiness will not be a point-in-time activity for HCOs. Rather, organizations will need to ensure that HIPAA security readiness becomes a part of their operational processes that need to be maintained on a go-forward basis.

To incorporate HIPAA security readiness into your organization's operational processes, you must be able to functionally decompose your organization to ensure that you have effectively addressed all the areas within your organization. You must also be able to interpret the proposed HIPAA security regulations[1] as they relate to your organization, identify any gaps, develop plans to address any gaps within your current organization, and monitor your progress to ensure you are addressing the identified gaps. For most HCOs, the path to HIPAA security readiness will mean the development of a framework that will allow you to complete the tasks outlined in Exhibit 144.1.

This chapter guides you through the framework that will assist you in identifying and addressing your organization's HIPAA security readiness issues. In doing so, we assume that your organization has already established a HIPAA security team and developed a plan to apply the framework (e.g., Phase 0 activities). Finally, we do not address HIPAA's transactions, code sets, and identifiers (TCI) or privacy requirements, but you will need to consider both sets of requirements as you move through the phases of the framework.

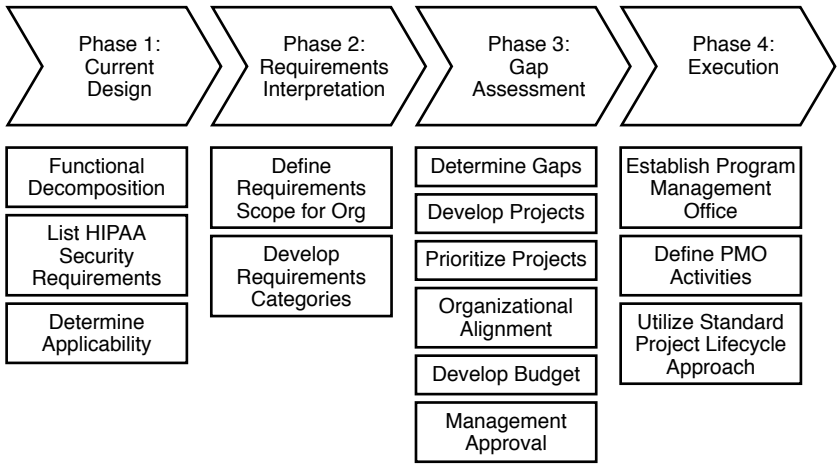

EXHIBIT 144.1 HIPAA security readiness framework.

Phase 1: Current Design[2]

The framework begins with the construction of a matrix that documents your organization's current design. The matrix captures the nuances of the environment (both physical and logical), its business processes, and the initiatives that make your HCO unique. It also lists the HIPAA security requirements and determines the applicability of the requirements to your organization's environment.

Functional Decomposition of the Organization

Organizations have typically approached HIPAA security readiness by starting with the HIPAA security requirements and applying those requirements to their information technology (IT) departments. By relying solely on this approach, organizations have failed to recognize that security is cross-organizational, including business units and individual users alike. Today's Internet era is requiring ever more information sharing, further blurring the boundaries of internal access and external access. How then do you break down your organization to ensure you have adequately addressed all the areas of your organization concerning HIPAA security readiness?

Organizations can functionally decompose themselves in a number of ways, including IT environment, strategic initiatives, key business processes, or locations. To illustrate the idea of functionally decomposing your organization, we provide some examples of processes, applications, IT environment elements, strategic initiatives, and locations for a typical payer and provider in Exhibit 144.2.

List HIPAA Security Requirements

The next step in building the matrix is to list the requirements for the five categories of the HIPAA security regulations as shown in Exhibit 144.3. These include:

- Administrative procedures
- Physical safeguards
- Technical security services
- Technical security mechanisms
- Electronic signatures

Once you have completed the functional decomposition and listed the HIPAA security requirements, you will have created your organization's current design matrix.

EXHIBIT 144.2 HCO Functional Decomposition

Provider (Hospital and Physician)	Payer
Processes	
Administration	Membership and enrollment
Financial	Claims administration
Scheduling	Contract management
Registration	Medical management
Admission, discharge, and transfer	Underwriting and actuarial
Billing and A/R	Provider network management
Insurance verification	Financial management
Practice management	Customer service
Applications	
AMR (EMR, CPR)	Enrollment
Laboratory	Billing and A/R
Radiology	Provider management
Pharmacy	Sales management
Order entry	Medical management
Nurse management	Claims
Financial	Financial

Workstations	Workstations
Facilities	Facilities
Databases	Databases
Strategic Initiatives	
Integrating the healthcare enterprise (IHE)	Customer relationship management (CRM)
Electronic medical records	E-business
Web-enabling clinical applications	Electronic data interchange (EDI)
Electronic data interchange (EDI)	
Location	
Hospital	Headquarters
Outpatient clinic	Remote sales office
Off-site storage	Data center

Determine Applicability

The final step in the current design phase will be to determine the areas from the functional decomposition where the security requirements apply. The outcome of this exercise will be an initial list of areas on which to focus for developing the scope of the requirements. Exhibit 144.4 illustrates a partial current design matrix for a typical payer organization.

Phase 2: Requirements Interpretation

The HIPAA security requirements were designed to be used as guidelines, which means that each organization needs to interpret how it will implement them. In this section, we provide some context for defining the scope of each requirement as it applies to your organization, categorizing the practices for the security requirements,

EXHIBIT 144.3 HIPAA Security Requirements List

Administrative Procedures	.308(a)(1)	Certification	
	.308(a)(2)	Chain of Trust Partner Agreement	
	.308(a)(3)	Contingency Plan	Applications and data criticality analysis Data backup plan Disaster recovery plan Emergency mode operation plan Testing and revision
	.308(a)(4)	Formal Mechanism for Processing Records	
	.308(a)(1)	Information Access Control	Access authorization Access establishment Access modification

and developing the approach for meeting the security requirements based on the practices. In addition, we develop one of the security requirements as an example to support each of the steps in the process.

Define the Scope of the Security Requirements

The first step to define the scope of the security requirements is to understand the generally accepted practices and principles and where they apply for each of the requirements. To determine these generally accepted practices and their applications, you can use a number of different sources that are recognized as standards bodies for information security. The standards bodies typically fall into two categories: general practices and industry-specific practices. This is an important distinction because some industry-specific practices may be different from what is generally accepted across all industries (i.e., healthcare industry versus automotive industry). Utilizing industry standards may be necessary when addressing a very specific area of risk for the organization. Exhibit 144.5 provides a short list of standards bodies, although additional standards bodies can be located in the source listing of the HIPAA security regulations.

The next step is to evaluate the generally accepted practices against the description of each security requirement in the HIPAA security regulations, and then apply them to your environment to develop the scope of the requirements for your organization.

For our example, we use the certification requirement. Generally accepted practices for certification include the review of a system or application during its design to ensure it meets certain security criteria. Once implemented, periodic reviews are conducted to ensure the system or application continues to meet those specified criteria. The certification requirement has been defined by the HIPAA security regulations as follows:

> The technical evaluation performed is part of, and in support of, the accreditation process that establishes the extent to which a particular computer system or network design and implementation meet a prespecified set of security requirements. This evaluation may be performed internally or by an external accrediting agency.

To define the scope based on this definition, we focus on two key sets of wording: *computer systems* and *network*. The term *computer system* is generally accepted to include operating systems, applications, databases, and middleware. The term *network* is generally accepted to include the architecture, design, and implementation of the components of the wide area network (WAN), extranet, dial-in, wireless, and the local area network (LAN); and it typically addresses such items as networking equipment (e.g., routers, switches, cabling, etc.). To summarize the scope of our example, we apply the certification requirement to the following areas:

- Network
- Operating systems
- Applications

EXHIBIT 144.4 Partial Current Design Matrix

				Processes				Locations			Applications			IT Environment		
	HIPAA Security Requirements		Claims/Encounters	Customer Service	Membership	Claims	Data Center	Headquarters	Remote Sales Office	Claims	Sales Management	Enrollment	Internet	WAN	LAN
Administrative Procedures	.308(a)(1)	Certification									X	X	X	X	X	X
	.308(a)(2)	Chain of Trust Partner Agreement				X										
	.308(a)(3)	Contingency Plan	Applications and data criticality analysis					X	X	X	X	X	X	X	X	X
			Data backup plan	X	X	X	X				X	X	X			X
			Disaster recovery plan					X	X	X	X					
			Emergency mode operation plan	X	X	X	X	X	X	X						
			Testing and revision	X	X	X	X	X	X	X	X	X	X			X
	.308(a)(4)	Formal Mechanism for Processing Records		X	X	X	X				X	X	X			
	.308(a)(5)	Information Access Control	Access authorization								X	X	X	X	X	X
			Access establishment								X	X	X	X	X	X
			Access modification								X	X	X	X	X	X

EXHIBIT 144.5 Generally Accepted Information Security Standards Bodies

Standards Bodies	Category
United States Department of Commerce — National Institute of Standards and Technology (NIST)	General
System Administration, Networking, and Security (SANS) Institute	General
Critical Infrastructure Assurance Office (CIAO)	General
International Organization for Standardization (ISO) 17799	General
Health Care Financing Administration (HCFA)	Industry-specific: healthcare

EXHIBIT 144.6 Certification Scope and Assumptions

Scope	Network, operating systems, applications, databases, and middleware
Assumptions	None identified
Categories	Policy/standards
	Procedures
	Tools/infrastructure
	Operational

- Databases
- Middleware

In addition, we document any assumptions made during the scoping process, because they will be important inputs to the solution design and as part of the final compliance assessment to understand why some areas were addressed and others were not. Finally, we store this information in each cell containing an X in our current design matrix from the applicability task in the current design phase as shown in Exhibit 144.6.

Develop Requirements Categories

Developing categories for each of the security requirements assists organizations in understanding what needs to be implemented to meet the requirements. Most organizations develop security controls in a technology vacuum, meaning that they see and understand how the technology fits into their organizations, but do not understand the relationship of that technology to the policies, standards, procedures, or operations of their organizations and business. Using the technology-vacuum approach typically develops security solutions that will deteriorate over time because the solution does not have the supporting operational processes to appropriately maintain itself. We define operations as those areas that support and maintain the technology within the organization, such as assigning owners who are responsible and accountable for the technology and its supporting processes. By taking a more holistic approach that includes policies/standards, procedures, technology, and operations, you will develop security solutions to address your gaps that can be more rapidly implemented and maintained over time. Based on this approach, we typically use the following four categories for grouping the practices identified through defining the scope of requirements in the section above:

1. *Policies or standards.* Policies include senior management's directives to create a computer security function, establish goals for the function, and assign responsibilities for the function. Standards include specific security rules for particular information systems and practices.
2. *Procedures.* Procedures include the activities and tasks that dictate how the policies or supporting standards will be implemented in the organization's environment.
3. *Tools or infrastructure.* Tools or infrastructure includes the elements that are necessary to support implementation of the requirements within the organization such as process, organizational structure, network and system-related controls, and logging and monitoring devices.

EXHIBIT 144.7 Practice Categories — Certification

Administrative Procedures — Certification	
Categories	**Practices**
Policies or standards	Written policy that identifies certification requirements
	Policy identifies individuals responsible for implementing that policy and defines what their duties are
	Policy identifies consequences of noncompliance
	Security standards for the configuration of networks, security services and mechanism, systems, applications, databases, and middleware
Procedures	Identifying certification need review
	Precertification review
	Certification readiness
	Periodic recertification review
Tools or infrastructure	Precertification readiness tool
	Certification criteria tool (standards)
	Certification compliance issue resolution tool
Operational	Operational when the following criteria are established:
	Owner
	Budget
	Charter
	Certification plan

4. *Operational.* Operational includes all the activities and supporting processes associated with maintaining the solution or system and ensuring it is running as intended. Typically, an owner is assigned to manage the execution of the activities and supporting processes. Examples of activities and supporting processes include maintenance, configuration management, technical documentation, backups, software support, and user support.

In addition, the categories will be used to monitor your progress with implementing the practices related to each requirement. To continue with our certification requirement example, we have identified some practices related to certification and placed them into categories as illustrated in Exhibit 144.7.

Finally, we store this information in the current design matrix as illustrated in Exhibit 144.8.

By completing your organization's current design matrix, you have developed your organization's to-be state, which includes a minimum set of practices for each area of your organization based on your interpretation of the HIPAA security requirements. You can now use this to-be state to conduct your gap assessment.

Phase 3: Gap Assessment

With interpretation of the HIPAA security requirements complete, you are ready to conduct your HIPAA security readiness or gap assessment. The time it will take to conduct the assessment will vary greatly, depending on a number of factors that include, at a minimum, the size of the organization, the number of locations, the number of systems/applications, and current level of maturity of the security function within the organization. An example of a mature security organization is an organization with a defined security policy, an established enterprise security architecture (ESA), documented standards, procedures with defined roles and responsibilities that are followed, established metrics that measure the effectiveness of the security controls, and regular reporting to management.

The outcome of the assessment provides you with gaps based on your previously defined scope and practices for each of the security requirements. Because the identified gaps will pose certain risks to your organization, an important point to keep in mind, as your organization reviews the assessment gaps, is that your organization will not be able to address all the gaps due to limited time and resources. Typically, the gaps that you can translate into business risks need to be addressed, particularly the ones that will affect your organization's HIPAA TCI and privacy initiatives. One way of determining if a particular gap poses a business risk to the organization is to answer the question, "So what?" (by which we mean that, if we do not address this risk, how will it adversely impact our business?). For example, application security access controls are lacking on extranet-accessible applications, allow-

EXHIBIT 144.8 Certification Categories

Scope	Network, operating systems, applications, databases, and middleware
Assumptions	None identified
Categories	Policy/standards: 1. Written policy that identifies certification requirements 2. Policy identifies individuals responsible for implementing that policy and what their duties are 3. Policy identifies consequences of noncompliance 4. Security standards for the configuration of networks, security services, and mechanism, systems, applications, databases, and middleware Procedures: 1. Identifying certification need review 2. Precertification review 3. Certification readiness 4. Periodic recertification review Tools/infrastructure: 1. Precertification readiness tool 2. Certification criteria tool (standards) 3. Certification compliance issue resolution tool Operational: 1. Operational when the following criteria are established: A. Owner, budget, charter, and certification plan

ing for the compromise of sensitive health information and clearly having an adverse impact on your bottom line. If the gap does not adversely affect your business at this point in time, document the gap because it may become a business risk in the future. For example, consider an operating system that supports a nonsensitive application that has not been certified. The application, however, will be replaced in 30 days with a newer version that requires another operating system altogether. Therefore, there is no adverse impact on your bottom line. However, if the organization has resources available, then consider taking actions to mitigate the risk posed by the gap.

Once you have completed your assessment and identified your gaps, you need to define a set of projects to remediate the issues. After you have defined these projects, you need to determine the resources and level of effort required to complete the projects, prioritize them, and develop a budget. In addition, you need to obtain organizational alignment around the projects. Finally, you need to get management approval for the projects.

Defining Projects

Gaps are identified based on analysis of prior requirements and then reevaluated against strategic initiatives to determine a project assignment. That is, some gaps are dealt with as stand-alone HIPAA security projects, and others are bundled or packaged within projects that more directly support strategic goals. A typical set of projects developed from an assessment includes the following:

- *High-risk mitigation.* Address high-risk vulnerabilities and exposures to your bottom line that were discovered as part of your assessment.
- *Security management.* Address the development of the core security plans and processes required to manage the day-to-day business operations at an acceptable level of risk, such as reporting and ownership, resources and skills, roles and responsibilities, risk management, data classification, operations, and maintenance for security management systems.

- *Policy development and implementation.* Address the development of security policies and standards with a supporting policy structure, a policy change management process, and a policy compliance function.
- *Education and awareness.* Address areas such as new employee orientation to meet legal and HR requirements, ongoing user and management awareness programs, and ongoing user training and education programs.
- *Security baseline.* Address development of an inventory of information assets, networking equipment, and entity connections to baseline your current environment.
- *Technical control architecture.* Address the development of a standards-based security strategy and architecture that is aligned with the organization's IT and business strategies and is applied across the organization.
- *Identity management solution.* Address the consistent use of authorization, authentication, and access controls for employees, customers, suppliers, and partners.
- *Physical safeguards.* Address physical access controls and safeguards.
- *Business continuity planning/disaster recovery planning.* Address an overall BCP/DRP program (backup and recovery plan, emergency mode operation plan, recovery plan, and restoration plan) to support the critical business functions.
- *Logging and monitoring.* Address monitoring, logging, and reporting requirements, as well as developing and implementing the monitoring architecture, policies, and standards
- *Policy compliance function.* Address the development of a policy compliance auditing and measurement process, which will also identify the process for coordinating with other compliance activities such as internal audit, regulatory, etc.
- *HIPAA security readiness support.* Address the management of the overall SRAP and supporting compliance assessment activities.

Once you have defined the projects, you have to estimate the resources and level of effort required to complete each of the projects. In addition, following management approval, further refinement of the estimate will be necessary during the scoping and planning phase of the project lifecycle.

Prioritizing Projects

For the identified projects, you need to prioritize them based on preselected criteria such as:

- *HIPAA interdependencies.* Does the project support HIPAA readiness for security, privacy, or TCI? For example, a project that includes the development of a data classification scheme can support both privacy and security.
- *Strategic initiatives.* Does the project support strategic initiatives for the organization? For example, a project that includes the development of a service to e-mail members' explanation of benefits (EOB) supports the strategic initiative to reduce paper-based transactions while facilitating HIPAA readiness for security and privacy.
- *Cost reduction.* Does the project help the organization reduce costs? For example, a project that includes the development of a VPN solution can support HIPAA security implementation requirements as well as support cost-reduction efforts related to migrating providers from extranet-based or dial-up access over the WAN to the Internet.
- *Improve customer service/experience.* Will the project improve customer service/experience? For example, implementing user provisioning and Web access control solutions supports HIPAA security implementation requirements, as well as improves the customer experience by allowing for single sign-on (SSO) and the ability for end users to reset their own passwords with a challenge–response.
- *Foundation building.* Does the project facilitate the execution of future projects, or is it in the critical path of other necessary projects? For example, an organization will need to execute the project to develop and implement policies before executing a project to facilitate compliance.

Based on the prioritization, you can then arrange the projects into an initial order of completion or plan to present them for review by the organization.

Develop Budget

Once you have the proposed plan developed, you need to develop an initial budget, which should include:

- Resources to be used to complete the project
- The duration of time needed to complete the project
- Hardware or software required to support the project's completion
- Training for new processes, and hardware or software additions
- Capitalization and accounting guidelines

Organizational Alignment and Management Approval

The plan you present to the organization will consist of the projects you have defined based on the gaps in your assessment, the resources and time needed to complete the projects, and the order of the projects' completion based on prioritization criteria. Based on input from the organization, you can modify your plan accordingly. The outcome of this activity will be to gain organizational buy-in and approval of your plan, which is especially critical when you require resources from outside of your organizational area to complete the projects.

Phase 4: Execution

Execution deals with both the management of projects and the reporting of completion status to the organization.

Program Management Office

Due to the sheer number of projects, the amount of work required to complete those projects, and the need to manage the issues arising from the projects, a formal program management office (PMO) and supporting structure will be required for the successful completion of your projects on time and within budget. You do not necessarily have to create your own security PMO, but instead you may wish to leverage an existing overall HIPAA or enterprise PMO to assist you with your project execution.

Define PMO Activities

Typically, a PMO performs the following activities:

- *Provides oversight for multiple projects.* Prioritize projects, manage project interdependencies and corresponding critical path items.
- *Manages the allocation of resources.* De-conflict resource constraints and shortages resulting from multiple project demands.
- *Manages budget.* Manage the budget for all related projects.
- *Resolves issues.* Facilitate resolution of issues both within projects and between cross-organizational departments.
- *Reports status.* Provide status reports on a periodic basis to oversight committees and management to report on the progress, issues, and challenges of the overall program.

Utilize a Standard Project Lifecycle Approach

Organizations should utilize a project lifecycle approach with a standard set of project documentation. Using a standard project lifecycle approach will streamline the design and implementation activities and support consistent, high-quality standards among different project teams and, potentially, different locations.

Summary

Addressing HIPAA security readiness may seem like an unmanageable task for most organizations. As outlined in this chapter, by applying a framework approach to break down the task into manageable pieces, you should

be able document your organization's current design, effectively identify your organization's gaps, develop an action plan to address those gaps, and execute that plan in an organized and systematic manner.

Notes

Department of Health and Human Services (HHS) 45 CFR, Part 142 — Security and Electronic Standards; Proposed Rule published in the Federal Register (August 12, 1998). Any reference to the HIPAA security regulations in this chapter refer to the proposed HIPAA security regulations.
The framework can be used for any organization to address information security readiness by simply modifying, adding or changing the criteria (HIPAA security regulations, FDA regulations, ISO 17799, NIST, SANS, etc.).

Internet Gripe Sites: *Bally v. Faber*

Edward H. Freeman

EVERY LARGE ORGANIZATION HAS UNHAPPY CUSTOMERS AND DISGRUNTLED EMPLOYEES. Until recently, a dissatisfied person had a limited number of ways of expressing his complaints, reaching only a small group of friends and sympathizers. Organizations would often simply ignore the situation, realizing that public denials would only draw more attention to the complaint.

The phenomenal growth of the Internet has made it easier for unhappy customers to criticize organizations and to have their complaints heard by a large audience. *Gripe sites* have become common on the Internet. Almost every large organization and many smaller ones have been the subject of gripe sites. Such sites not only display the operator's dissatisfaction but also allow unhappy customers, employees, competitors, and vendors to post their complaints against the organization. Sensitive internal documents have found their way onto these Web pages. Potential customers and job seekers often visit these sites before deciding whether to do business or to accept a job offer. Such sites may receive thousands of hits monthly.

Gripe sites can be a small but genuine source of embarrassment, even for large, seemingly untouchable corporations. Due to the open nature of the Internet, anyone with a computer and a complaint can purchase a Web site with a derogatory name for under $100. Complaints posted on the sites are often untraceable so there is no way for potential customers to know whether what they read there is true.

This chapter discusses *Bally v. Faber,* a 1998 federal court decision dealing with gripe sites. Bally Total Fitness, a nationwide chain of exercise clubs, attempted to shut down an Internet gripe site that used its registered trademark negatively. The column deals with trademark in-fringement and dilution and offers practical advice for concerned corporations. Actual court cases are cited as examples throughout the column.

The Legal Issues of Disaster Recovery Planning

Tari Schreider

Payoff

The legal issues involved in corporate contingency planning are some of the most misunderstood and confusing aspects of the entire process of creating a disaster recovery plan. Data center managers often must assume the role of disaster recovery planners, and whereas they are not expected to be as knowledgeable as lawyers in this role, they are encumbered with the responsibility of understanding the minutiae of existing regulatory guidelines and the legal consequences of their companies' failure to implement an effective disaster recovery plan. No specific laws state categorically that an organization must have a disaster recovery plan, but there is a body of legal precedents that can be used to hold companies responsible to those affected by a company's inability to cope with or recover from a disaster. This article outlines those precedents and suggests precautions.

Introduction

Despite the widespread reporting in the media of disasters and their effects, many companies, corporate directors, and officers remain apathetic toward implementing a disaster recovery plan. Companies are generally unwilling to commit the finances and resources to implement a plan unless they are forced to do so. However, implementing a proper disaster recovery plan is a strategic, moral, and legal obligation to one's company.

If the billions of dollars spent annually on technology to maintain a competitive edge is an indication of how reliant society is on technology, then failing to implement a disaster recovery plan is an indication of corporate negligence. Standards of care and due diligence are required of all corporations, public or private. Not having a disaster recovery plan violates that fiduciary standard of care.

The legal issues involved in corporate contingency planning are some of the most misunderstood and confusing aspects of the entire process of creating a disaster recovery plan. Disaster recovery planners are not expected to be lawyers; however, they are encumbered with the responsibility of understanding the minutiae and vagueness of existing regulatory guidelines and the legal consequences of their companies' failure to implement an effective disaster recovery plan. Although no specific laws state categorically that an organization must have a disaster recovery plan, there is a body of legal precedents that can be used to hold companies and individuals responsible to those affected by a company's inability to cope with or recover from a disaster.

The entire basis of law relating to the development of disaster recovery plans is found in civil statutes and an interpretation of applicability to disaster recovery planning. These legal precedents form the basis of this article.

One of the precedents that can be used against companies that fail to plan for a disaster is drawn from the case of FJS Electronics v. Fidelity Bank. In this 1981 case, FJS Electronics sued Fidelity Bank over a failure to stop payment on a check. Although the failure to stop payment of the check was more procedural in nature, the court ruled that Fidelity Bank assumed, and therefore was responsible for, the risk that the system would fail to stop a check. FJS was able to prove that safeguards should have been in place and therefore was awarded damages.

This case shows that the use of a computer system in business does not change or lessen an organization's duty of reasonable care in its daily operations. The court ruled that the bank's failure to install a more flexible, error-tolerant system inevitably led to problems. As a result, information technology professionals will be held to a standard of reasonable care. They can breach that duty to maintain reasonable care by not diligently pursuing the development of a disaster recovery plan.

Categories of Applicable Statutes

To help make the data center manager aware of the areas in which disaster recovery planning and the law intersect, Contingency Planning Research, Inc., a White Plains NY-based management consulting firm, has categorized the applicable statutes and illustrated each with an example. Each area is described; however, this discussion is not intended to present a comprehensive list.

Categories of statutes include but are not limited to the following:

- **Contingency Planning Statutes.** These apply to the development of plans to ensure the recoverability of critical systems. An example is the Federal Financial Institutions Examination Council (FFIEC) guidelines, which replace previously issued Banking Circulars BC-177 and BC-226.

- **Liability Statutes.** These statutes establish levels of liability under the “Prudent Man Laws” for directors and officers of a corporation. An example is the Foreign Corrupt Practices Act (FCPA).

- **Life/Safety Statutes.** These set out specific ordinances for ensuring the protection of employees in the workplace. Examples include the National Fire Protection Association (NFPA) and the Occupational Safety & Health Administration (OSHA).

- **Risk-Reduction Statutes.** These stipulate areas of risk management required to reduce or mitigate (or both) the effects of a disaster. Examples include Office of the Comptroller of the Currency (OCC) Circular 235 and Thrift Bulletin 30.

- **Security Statutes.** These cover areas of computer fraud, abuse, and misappropriation of computerized assets. An example is the Federal Computer Security Act.

- **Vital Records Management Statutes.** These include specifications for the retention and disposition of corporate electronic and hard-copy (i.e., paper) records. An example is the body of IRS Records Retention requirements.

Statutory Examples

When the time comes for the data center manager to defend his or her company against a civil or criminal lawsuit resulting from damages caused by the company's failure to meet a standard of care, he or she needs more than an “Act of God” defense. When no direct law or statute exists for a specific industry, the courts look instead to other industries for guidelines and legal precedents. The following three statutes represent the areas in which a court most likely seek a legal precedent.

The Foreign Corrupt Practices Act (FCPA)

The Foreign Corrupt Practices Act (FCPA) of 1977 was originally designed to eliminate bribery and to make illegal the destruction of corporate documents to cover up a crime. To accomplish this, the FCPA requires corporations to “make and keep books, records, and accounts, which, in reasonable detail, accurately and fairly reflect the transactions and dispositions of the assets...” The section of this act that keeps it at the forefront of disaster recovery liability is the “standard of care” wording, whereby management can be judged on their mismanagement of corporate assets.

The FCPA is unique in that it holds corporate managers personally liable for protecting corporate assets. Failure to comply with the FCPA exposes individuals as well as companies to the following penalties:

- Personal fines up to $10,000.
- Corporate fines up to $1,000,000.
- Prison terms up to five years.

The Federal Financial Institutions Examinations Council

The comptroller of the currency has issued various circulars dating back to 1983 (e.g., Banking Circular BC-177) regarding the need for financial institutions to implement disaster recovery plans. However, in 1989, a joint-agency circular was issued on behalf of the following agencies:

- The Board of Governors of the Federal Reserve System (FRB).
- FDIC.
- The National Credit Union Administration (NCUA).
- The Office of the Comptroller of the Currency (OCC).
- The Office of Thrift Supervision (OTS).

The circular states, “The loss or extended interruption of business operations, including central computing processing, end-user computing, local-area networking, and nationwide telecommunications, poses substantial risk of financial loss and could lead to failure of an institution. As a result, contingency planning now requires an institution-wide emphasis...”

The Federal Financial Institutions Examinations Council guidelines relating to contingency planning are actually contained within 10 technology-related Supervisory Policy Statements. These policies are revised every two years and can be acquired through any of the five agencies listed earlier in this section.

The Consumer Credit Protection Act

On November 10, 1992, the 95th Congress, 2nd Session, amended section 2001of the Consumer Credit Protection Act (15 U.S.C. 1601 et seq.) “TITLE IX-Electronic Funds Transfers.” The purpose of this amendment was to remove any ambiguity the previous

statute had in identifying the rights and liabilities and consumers, financial institutions, and intermediaries in “Electronic Funds Transfers.” This Act covers a wide variety of industries, specifically those involved in electronic transactions originating from point-of-sale transfers, automated teller machines, direct deposits or withdrawals of funds, and fund transfers initiated by telephone. The Act further states that any company that facilitates electronic payment requests that ultimately result in a debit or credit to a consumer account must comply with the provisions of the Act.

Failure to comply with the provisions of this Act exposes a company and its employees to the following liabilities:

- Any actual damage sustained by the consumer.
- Amounts of not less than $100 and not greater than $1,000 for each act.
- Amounts of $500,000 or greater in class action suits.
- All costs of the court action and reasonable attorneys' fees.

Companies covered under this Act are subject to all the liabilities and all the resulting damages approximately caused by the failure to make an electronic funds transfer. The Act states that a company may not be liable under the Act if that company can demonstrate a certain set of circumstances. The company must show by a “preponderance of evidence” that its actions or failure to act were caused by “...an Act of God or other circumstances beyond its control, that it expressed reasonable care to prevent such an occurrence, and that it expressed such diligence as the circumstances required...”

Standard of Care.

Each of these three statutes mentioned in this section is based on the precept of standard of care, which is described by the legal publication entitled Corpus Juris Secundum, Volume 19, Section 491. The definition is that “... directors and officers owe a duty to the corporation to be vigilant and to exercise ordinary or reasonable care and diligence and the utmost good faith and fidelity to conserve the corporate property; and, if a loss or depletion of assets results from their willful or negligent failure to perform their duties, or to a willful or fraudulent abuse of their trust, they are liable, provided such losses were the natural and necessary consequences of omission on their part...”

Determining Liability

Courts determine liability by weighing the probability of the loss occurring compared to the magnitude of harm, balanced against the cost of protection. This baseline compels companies to implement a reasonable approach to disaster recovery in which the cost of implementation is in direct correlation to the expected loss. In other words, if a company stands to lose millions of dollars as a result of an interruption to its computerized processing, the courts would take a dim view of a recovery plan which lacked the capability to restore the computer systems in a timely manner.

Another precedent-setting case, referred to as the Hooper Doctrine, can be cited when courts are looking to determine a company's liability. This doctrine establishes that even though many companies do not have a disaster recovery plan, there are “precautions so imperative that even their universal disregard does not excuse their omission.” Simply put,

a company cannot use, as a defense, the fact that there are no specific requirements to have a disaster recovery plan and that many other companies do not have one.

Liability is not just related to corporations but extends to individuals who develop disaster recovery plans as well. In 1989, in Diversified Graphics v. Ernst & Whinney, the United States Eighth Circuit Court of Appeals handed down a decision finding a computer specialist guilty of professional negligence. In this case, professional negligence was defined as a failure to act reasonably in light of special knowledge, skills and abilities.

If the directors and officers of a corporation can be held accountable for not having a disaster recovery plan, then this case provides the precedent for individuals who are certified disaster recovery planners to be held personally accountable for their company's disaster recovery plan.

Insurance as a Defense

Directors and officers (D&O) of companies have a fiduciary responsibility to ensure that any and all reasonable efforts are made to protect their companies. D&O insurance does exist, but it only protects officers if they used good judgment and their decisions resulted in harm to their company or employees, or both. D&O insurance does not cover, however, a company officer who fails to exercise good judgment (e.g., by not implementing a disaster recovery plan).

Errors and omissions (E&O) insurance covers consequential damages that result from errors, omissions, or negligent acts committed in the course of business, or from all of these together. In a 1984 precedent-setting case heard in the District Court of Ohio, the court ruled, “Negligence is a failure to exercise the degree of care that a reasonably prudent person would exercise under the same circumstance.” With regard to a trade, practice, or profession, the court added that “the degree of care and skill required is that skill and knowledge normally possessed by members of that profession in good standing in similar communities.” Liability insurance does not prevent the organization from being brought to court, but it will pay toward the litigation and penalties incurred as a result.

Disaster recovery practitioners possess a unique expertise and subsequently could be held accountable for their actions and advice in the development of a disaster recovery plan. A word of caution here is that if the data center manager passes himself or herself off as an expert, he or she should expect to be held accountable as an expert.

Conclusion

Courts assess liability by determining the probability of loss, multiplying it by the magnitude of the harm, and balancing them against the cost of prevention. Ostensibly, should the data center manager's company end up in court, the burden of proof would be on the company to prove that all reasonable measures had been taken to mitigate the harm caused by the disaster. There are clearly enough legal precedents for the courts to draw on in determining if a standard of care was taken or if due diligence was exercised in mitigating the effects of the disaster on the company's critical business operations. Every business is governed by laws that dictate how it must conduct itself in the normal course of business. By researching these laws and statutes, the data center manager will eventually find where penalties for non-performance are stipulated. These penalties become the demarcation point for reverse engineering the business operations, thus finding the points of failure that could affect the company's ability to perform under the statutes that specifically govern the company's business.

State Control of Unsolicited E-mail: State of Washington *v.* Heckel

Edward H. Freeman

ONE OF THE MOST FREQUENT COMPLAINTS FROM INTERNET USERS CONCERNS THE ENDLESS FLOOD OF UNWANTED E-MAIL, ALSO KNOWN AS *SPAM*. These unsolicited messages attempt to sell everything from get-rich pyramid schemes to stop-smoking seminars, from Viagra to chain letters to hair-loss treatments. No Internet user is immune from this constant barrage of unsolicited e-mail. In the world of spamming, no claim is too preposterous and no promise is too fantastic.[1]

Bulk e-mail is very inexpensive for the sender, requiring only a basic personal computer and modem. For about $249, the sender can receive a CD-ROM containing over 11,000,000 e-mail addresses. There are no postage or printing costs and no reason for the sender to support a full-time staff to process orders or deal with customer inquiries.

Spammers transfer the costs associated with bulk e-mailing to the end user and to the Internet service provider (ISP). ISPs must provide additional bandwidth and storage devices to process and forward unsolicited e-mail messages. They must maintain additional storage to save messages for delivery to the intended recipient. These costs are eventually passed on to the e-mail user.

This column deals with attempts by the State of Washington to enforce tough ordinances against spam. It discusses the *Commerce Clause* of the U.S. Constitution and how individual states can and cannot limit commercial activities among residents and corporations of different states. Actual court cases are used throughout to highlight specific points.

THE STATE OF WASHINGTON'S ANTI-SPAM LAW

In March 1998, the Washington Legislature unanimously passed the Unsolicited Electronic Mail Act [The Act]. It stated:

1. No person, corporation, partnership, or association may initiate the transmission of a commercial electronic mail message from a computer located in Washington or to an electronic mail address that the sender knows, or has reason to know, is held by a Washington resident that:
   — uses a third party's Internet domain name without permission of the third party, or otherwise misrepresents any information in identifying the point of origin or the transmission path of a commercial electronic mail message
   — contains false or misleading information in the subject line.
2. For purposes of this section, a person, corporation, partnership, or association knows that the intended recipient of a commercial electronic mail message is a Washington resident if that information is available, upon request, from the registrant of the Internet domain name contained in the recipient's electronic mail address.[2]

Fines for violation of the act ranged from $100 to $1000 per e-mail.

As originally proposed, the Act would have completely prohibited sending unsolicited e-mail messages to Washington residents. The Legislature eliminated the concept of a total ban during preliminary deliberations because of challenges from the ACLU and other free-speech advocates. Opponents felt that the Act contained an "exceedingly broad definition of unsolicited commercial speech."[3] These challenges convinced the Legislature to regulate spam indirectly by prohibiting false or misleading commercial e-mail. The Legislature felt that such restrictions were more consistent with First Amendment concerns.[4]

The Act specifically banned two practices commonly used by spammers:

- It prohibited messages containing misleading or incorrect information about its point of origin or return e-mail address.
- It also prohibited false or misleading information in the subject line. Spammers will frequently use a subject line such as "You have just won $1000" or "Employment opportunities in your field" to encourage curious users to open their messages rather than delete them without reading. If an e-mail had such a subject line and then promoted a pyramid marketing scheme, the e-mail violated the Washington law.

Because the Act was state law, its scope was limited geographically to Washington. A spammer could violate the Act only if his computer was physically located in Washington or if the sender knew that the recipient

was located there. As defined in the Act, the sender was considered to know that the receiving party was located in Washington if "that information is available, upon request, from the registrant of the Internet domain contained in the recipient's electronic mail address."[5]

The Attorney General and the Washington Association of Internet Service Providers (WAISP) co-sponsored a statewide registry of e-mail accounts held by Washington residents. Washington e-mail subscribers could register their accounts by accessing the WAISP Registry Page at hyperlink http://registry.waisp.org. According to the Act, spammers were expected to check potential recipients against the WAISP listing to determine whether the user resided in Washington and to remove the user if the e-mail message violated the terms of the Act.

THE FACTS OF THE CASE

At the time of the litigation, Jason Heckel, in his mid-20s, was the sole proprietor of Natural Instincts in Salem, Oregon. In 1997, Heckel developed and printed a 46-page booklet called "How to Profit from the Internet." The booklet sold for $39.95.

To market the booklet, Heckel used a software package called Extractor Pro. The package finds e-mail addresses on the Internet and automatically sends e-mail to each of those addresses. Heckel sent up to 1,000,000 unsolicited e-mails monthly to promote his booklet. These messages went to Internet users all over the world, including users in Washington. The suit claimed that he sold about 40 booklets each month.

Heckel's methods of marketing his pamphlet were typical for spammers:

- He sent his messages on an indirect, circuitous path all over the Internet, making it impossible to determine the origin of the message.
- He gave recipients no way to reply to his messages. The e-mail address cited in the "sender" field did not exist. If recipients complained about his messages, the complaints were returned to the sender as undeliverable because of an invalid e-mail address. If a user wanted to purchase Heckel's pamphlet, he would have to use regular mail along with a credit card number.
- He used a deceptive subject line, such as "Do I have the right address?" This fooled users into opening the e-mail, thinking that the message was from a long-lost friend or associate.

The Washington Attorney General's office received several complaints about Heckel. They sent a warning letter to Heckel, asking him to discontinue sending his messages to Washington residents. When he refused to comply, they sued Heckel in Washington Superior Court, charging that he had violated the terms of the Act.

At trial, Heckel's attorney asked that the court dismiss the case, claiming that the Act violated the Commerce Clause of the U.S. Constitution.[6] The Commerce Clause limits the rights of individual states to restrict interstate commerce if the burden imposed on interstate commerce is excessive.

On March 10, 2000, Judge Parker Robinson of the King County Superior Court granted Heckel's motion and dismissed the case, ruling that the Act was unconstitutional. According to Judge Robinson, the Act was "unduly restrictive and burdensome." It placed a burden on business that clearly outweighed the benefits to consumers. In cyberspace, it is difficult to determine the state in which each e-mail recipient resides. This would subject "someone like Mr. Heckel to potentially 50 different standards of commerce, which I think is a problem in terms of the commerce clause."[7]

On April 10, 2000, the Attorney General's office filed an appeal of Judge Robinson's ruling to the State Supreme Court. As of July 2000, the higher court had not yet reached a decision.[8]

THE INTERSTATE COMMERCE CLAUSE

At the end of the American Revolution, individual states attempted to regulate interstate and international commerce with only their own interests in mind. The Confederation Congress, which represented the states until the adoption of the U.S. Constitution, had no authority to regulate commerce among the states. With each state guarding its own unique interests, 13 conflicting systems of commercial regulation and tax policies governed trade in the new country. This led to conflicts among the states as states retaliated against each other with different markets, tariffs, and industries.[9]

In January 1786, the Virginia Legislature called for a national convention to consider a uniform system of commerce regulation. At the Constitutional Convention in 1787, Congress was empowered to "regulate commerce with foreign nations, and among the several states, and with the Indian tribes." This congressional power, known as the Commerce Clause, gave Congress the power to regulate economic life in the nation and to promote the free flow of interstate commerce, including action within state borders that interfered with that flow.[10] This reduced the potential for economic warfare among the states.

There is a natural conflict between a state's right to control and regulate its own activities and the federal government's desire to maintain control over interstate commerce. The terms of the Commerce Clause have led to numerous Supreme Court decisions. The Court interprets the Commerce Clause as granting virtually complete power to Congress to regulate the economy and business. A court may invalidate state legislation under the Commerce Clause after balancing several factors:

- the necessity and importance of the state regulation upon interstate commerce
- the burden it imposes upon interstate commerce
- the extent to which it discriminates against interstate commerce in favor of local concerns

The states do have certain powers to make laws governing matters of local concern. The courts use a three-part test to determine whether states can regulate a specific form of interstate commerce:[11]

- Does the law discriminate against another state?
- Does the substance of the law require national or uniform regulation?
- Do the interests of the state outweigh the federal government's right to regulate interstate commerce?

The courts usually analyze these factors on a case-by-case basis. In discussing this analysis, the Supreme Court summarized this method. "Where the statute regulates even-handedly to effectuate a legitimate local public interest, and its effects on interstate commerce are only incidental, it will be upheld unless the burden imposed on such commerce is clearly excessive in relation to the putative local interest."[12]

An example of this analytical method arose in a classic 1949 Supreme Court decision. H.P. Hood was a Massachusetts milk distributor that purchased milk from farmers in New York state. Hood brought the milk to its Massachusetts plants and then sold it in Boston. Hood applied to the New York Commissioner of Agriculture and Markets for permission to open another receiving station. The Commissioner denied Hood's request on the ground that the proposed plant would divert milk from the New York market and thereby cause milk prices to rise in New York.

The Supreme Court ruled that New York could not curtail interstate commerce to keep prices lower for New York purchasers. This action would have set up a barrier to free trade among the states. A state may not use the power to tax or use its police powers to establish an economic barrier to competition with the products of another state. Such actions were a violation of the Commerce Clause and were therefore unconstitutional.[13]

The courts will continue to refine the Commerce Clause in future decisions. It is possible that the Supreme Court will eventually decide *Heckel* or a similar case in another state.

ANALYSIS OF *HECKEL*

As previously noted, Judge Robinson's decision stated that the Act was unconstitutional because it violated the Commerce Clause. The decision has drawn generally negative reviews in the cyberspace community. These criticisms were based on three major factors:

- Some critics felt that spam does not rise to the level of interstate commerce protected by the Commerce Clause. No commercial transaction has occurred between the spammer and the recipient, merely an unsolicited and usually unwanted e-mail.
- Judge Robinson felt that it would be "burdensome" for Heckel to determine which recipients live in Washington. Critics have noted that allowing Heckel to send his spam places a burden on both the ISPs and e-mail recipients. Heckel's "right" to send out his messages means that ISPs must provide additional hard drive space to store messages. Users must spend time deleting such messages. Clearly, Heckel's spam constituted a burden to ISP's and e-mail users, both in productivity and in added hardware costs.
- States long ago enacted consumer-protection measures, such as restricting out-of-state telemarketers and junk faxes. There is no real difference between these unwanted methods of advertising and spam.

A higher court will ultimately decide these issues.

CONCLUSION

Experts agree that spam is here to stay. Most Internet users dislike unsolicited, sometimes offensive messages. Spam has become an inexpensive method of advertising and of sending messages throughout the world. Unfortunately, it will continue to attract unscrupulous, fraudulent operators selling every product imaginable as well as some products that are not imaginable.

Legislators, attorneys, civil libertarians, and cyberspace experts will continue to search for a constitutionally acceptable method of reducing unsolicited e-mail, especially when theft, fraud, or abusive conduct is involved. The courts will decide what level of protection from spam is constitutionally sound under the Commerce Clause.

Exhibit 41-1. Bally's logo.

FACTS OF *BALLY V. FABER*

Bally Total Fitness (see Exhibit 41-1) is a New York Stock Exchange corporation with its international headquarters in Chicago. Bally is the largest commercial operator of fitness centers in North America, with nearly 4,000,000 members and 360 facilities in 27 states and Canada.[1]

Andrew Faber, a Washington, D.C. photographer and Web designer, had a dispute with Bally. When he could not resolve the dispute to his satisfaction, Faber created and maintained a Web site called "Bally Sucks." The site was devoted to consumer complaints about Bally and contained instructions on how members could cancel their membership.[2] Faber's site encouraged other dissatisfied customers to tell their stories. When a Web surfer visited the site, Bally's distinctive trademark (Exhibit 41-1) appeared with the word "Sucks" superimposed on it. At the bottom of the screen were the words "Bally Total Fitness Complaints! Un-authorized" [sic].

In February 1998, Bally sued Faber in federal court in California. Bally asked that Faber stop using its trademark on his Web site. Bally claimed that Faber's Web site was in violation of laws prohibiting trademark infringement, unfair competition, and trademark dilution. In April, the court denied Bally's motion for a temporary restraining order against Faber.

In November, the court granted Faber's motion for summary judgment against Bally. Summary judgment is a device used by the courts when "there is no genuine issue as to any material fact and … the moving party is entitled to a judgment as a matter of law."[3] By granting the motion for summary judgment, the court held that even if all of Bally's claims were true, they would not prove Bally's case. Bally appealed the lower court's verdict, but the parties agreed to a settlement before the higher court reached a decision. As part of the settlement, Faber removed the Bally Sucks Web site.

AN OVERVIEW OF TRADEMARK LAW

A trademark is a distinctive picture or word that a seller adds to a product to identify its origin and to distinguish the product from other products. Trademark law grants protection to many forms of identification, including:

- Invented words such as Kodak and Exxon
- Distinctive and unique packaging such as the Heinz Ketchup glass bottle
- Unique color combinations (yellow and red for Kodak film)
- Building designs (McDonald's golden arches)
- Unique logos or symbols (the IBM symbol or the red K used by Kellogg's)

In 1946, Congress passed the Lanham Act[4] (the Act) to regulate trademarks. Congress enacted the Act under its constitutional right to regulate interstate commerce.[5] A trademark registered under the Act is given federal protection. Parties may register actual or planned trademarks with the Patent and Trademark Office. If examiners initially approve a trademark, it is published in the Official Gazette of the Trademark Office. This is done to notify other parties pending final approval. A full set of legal options is available to resolve trademark disputes.

The Act also discusses certain marks that may not be legally registered as trademarks. They include:

- Generic or geographic product names. (As an example, "Maine Potatoes" cannot be registered as a trademark by any one person. The phrase does not distinguish one person's product, but describes all potatoes grown in Maine. "Johnson's Maine Potatoes" could be registered as a trademark.)
- The name, portrait, or signature of a living person without his or her consent.
- State or municipal flags.[6]

Although the owner of a trademark is guaranteed "exclusive use" of the trademark, that right has certain limitations. These limitations are known as *fair use* and allow others to use the trademark as a descriptive term. The fair use doctrine allowed the use of Bally's trademark as an exhibit in this chapter. If I wanted to sell my 1985 Chevrolet Celebrity, I could advertise that it is a Chevrolet Celebrity although I did not get permission from General Motors to use the name. A competitor may use another person's registered trademark in a comparison of goods. For example, an ad for Coca-Cola can say that it tastes better than Pepsi Cola, although Pepsi did not authorize the use of its trademark.

People and organizations rely on trademarks to make intelligent decisions about product purchases. According to the Act, infringement has occurred when use of the trademark by another party is "likely to cause confusion, or cause mistakes, or to deceive."[7] The court may issue injunctions, compensate the owner for damages, take away profits from the infringer or award attorney fees.[8] The court may even confiscate and destroy goods with the illegal trademark (a frequent occurrence used against illegal vendors at rock concerts).

The owner of a trademark has the exclusive right to use it on its product and on related products, such as T-shirts and lunchboxes. A recognized and respected trademark can be one of an organization's most valuable assets and often has cash value when the company is sold or liquidated.

Trademark dilution takes place when the unauthorized use of a trademark would reduce its value to the owner. Dilution must be commercial in nature and can occur even when there is no direct business competition between the parties.[9] In one recent case,[10] American Express, the worldwide credit card organization, sued the American Express Limousine Service after the limousine service used the same name. Although there was no competition between the two companies (credit cards and limousine service), the court found that the "defendant's use of the AMERICAN EXPRESS mark would 'whittle away' the distinct quality of plaintiff's mark."

ANALYSIS: TRADEMARK INFRINGEMENT

Bally claimed that Faber's Web site constituted both trademark infringement and trademark dilution. By granting summary judgment, the court held that Faber's actions were not a violation of trademark law, even if all of the charges claimed by Bally were true. According to the Act, the court would have to find that Faber's use of the Bally trademark created a likelihood of confusion.[11] Only then could the court find that trademark infringement had occurred.

A major factor in determining whether there is a likelihood of confusion is the similarity of goods produced by the two parties.[12] The more related

the goods are, the more likely it is that the court will find that trademark infringement actually took place. "Related goods are those goods which, though not identical, are related in the minds of consumers."[13] Courts have considered the following pairs of items to be related goods:

- Shirts and pants[14]
- Beer and whiskey[15]
- Locks and flashlights[16]

Bally and Faber did not market similar goods (health club memberships as opposed to Web page design) so there was little likelihood of confusion through related goods. The court then held that:

> No reasonable consumer comparing Bally's official Web site with Faber's site would assume Faber's site 'to come from the same source or thought to be affiliated with, connected with, or sponsored by, the trademark owner.' Therefore, Bally's claim for trademark infringement fails as a matter of law.[17]

ANALYSIS: TRADEMARK DILUTION

The court also granted Faber's motion for summary judgment against Bally's claim of trademark dilution. To show dilution, the defendant's use of the trademark must lessen the capacity of the plaintiff's trademark to identify and distinguish its goods and services and must be commercial in nature. For a dilution claim, Bally had to show that Faber's use of its famous trademark was commercial in nature. Bally also had to show that Faber's use diluted the value of the trademark by lessening the capacity of the mark to identify and distinguish goods and services.[18]

Faber's use of the Bally trademark was noncommercial. He did not use the trademark for the benefit of his own business, and Bally could not show that Faber's use had tarnished the trademark. Faber's site could not confuse consumers, and the court granted the motion for summary judgment.

RECOMMENDATIONS TO ORGANIZATIONS

For even the most stable organization, gripe sites can be an embarrassing nuisance. Potential customers and employees do look at these sites. www.walmartsucks.com has received over 1,000,000 hits through the past three years. Here are some recommendations that may prevent problems.

Some organizations actually purchase the names of potential gripe sites, thereby making them unavailable for outsiders. For example, Chase Manhattan bought the Web site rights to several Web sites, including IhateChase.com, ChaseStinks.com, ChaseSucks.com, ChaseBlows.com, and several others not appropriate for this journal.[19] That did not stop a disgruntled

customer from setting up his own gripe site at chasebanksucks.com. It may make it more difficult for potential customers to find the gripe site.

Organizations would be wise to read their gripe sites regularly. Because of the freewheeling nature of the Internet, there is no real control over the contents of any Web site. A single unhappy person can spread false rumors that could be detrimental to employee morale or even the corporation's reputation.

Lastly, an organization should keep its perspective on gripe sites. Most gripe sites are simply one unhappy customer or ex-employee letting off steam harmlessly. Most of these sites can be safely ignored, unless they threaten personnel or present confidential documents obtained through an internal security leak.

Dissatisfied customers have the free speech right to criticize organizations publicly on the Internet. *Bally v. Faber* allows individuals to use the trademarked logos on such sites as long as there is no reasonable chance of confusion. As the Internet continues to grow, gripe sites will become more common. Organizations should evaluate these sites and learn from them about their relationship with their customers and employees.

Computer Crime Investigations: Managing a Process without Any Golden Rules

George Wade, CISSP

Security is often viewed as an "after-the-fact" service that sets policy to protect physical and logical assets of the company**.** In the event that a policy is violated, the security organization is charged with making a record of the violation and correcting the circumstances that permitted the violation to occur. Unfortunately, the computer security department (CSD) is usually viewed in the same light and both are considered cost-based services. To change that school of thought, security must become a value-added business partner, providing guidance before and after incidents occur.

The Security Continuum

Each incident can be managed in five phases, with each phase acting as a continuation of the previous phase, and predecessor of the next. Exhibit 145.1 displays the continuum.

Flowing in a clockwise, circular fashion, the security continuum begins with the report of an incident or a request for assistance from the CSD business partner (also known as "the customer"). Strong documentation during this initial report phase is the first building block of an ever-evolving incident response plan. Strong documentation will also be used to determine whether or not an investigation is opened, as not every anomaly requires a full investigation. The report phase flows into the investigative phase where intelligence gathering and monitoring begins and documentation continues. At this point, the CSD investigator (CSDI) should understand and be able to define what has occurred so that a determination can be made to begin a full investigation. The investigative phase will flow into the assessment phase, although there may not be a strong demarcation point. The investigative phase and the assessment phase may run concurrently, depending on the incident. Time spent during the assessment phase is dedicated to determining the current state of the business, identifying additional problem areas, and continued documentation. The assessment phase documentation will provide input into the corrective action phase, with this phase beginning as the investigative phase is completed. Intelligence gained during the investigative and assessment phases of the continuum is used to build the corrective action plan. Execution of the correction action plan can be coordinated with the final steps of the investigative phase, in that system holes are plugged as the suspect is being arrested by law enforcement or interviewed by a CSDI. Following the completion of the four previous phases, the proactive phase can begin. This phase should be used to educate management and the user community about incident particulars.

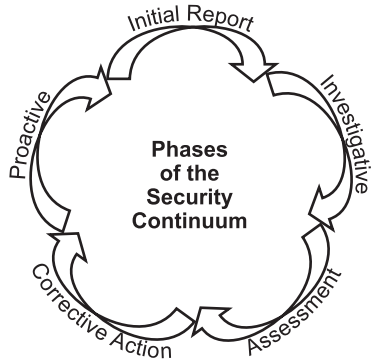

EXHIBIT 145.1 The security continuum.

Education in the form of security awareness presentations will lead to a greater consciousness of the CSD being a value-added business partner that will generate new reports and lead the CSD back into the report phase.

The Initial Report Phase

Before any investigation can begin, the CSD needs to receive a report of an anomaly. One of the best ways to advertise the services of the CSD is through a comprehensive awareness program that includes the methods to report incidents. The CSD should have the ability to receive reports over the phone, via e-mail, and via the World Wide Web (WWW), and each of these methods should permit anonymous reporting. Additionally, the CSD should make the initial report process as painless as possible for the reporter. Because anomalies in computers and networks do not just occur from 9 to 5, convenient 24-hour coverage should be provided. This may be provided by a well-trained guard staff, an internal helpdesk, an external answering service that receives calls after a designated time, or a simple recording that provides a 24-hour reach number such as a pager. It is important that the CSD personnel designated to receive initial reports be well-versed in the structure of the business, have an understanding of common computer terminology, and have excellent customer service skills. They must also understand that all reports must remain confidential because confidentiality is an important aspect of all investigative issues. Without confidentiality, investigative efforts will be hampered, and employees may be wrongfully accused of policy violation or illicit acts.

The CSD Receives an Incident Report

Whether the reports come into the CSD help desk or directly to a CSDI, the same questions need to be asked when receiving the initial report. By asking the "who, what, where, when, why, and how" questions, the CSD trained personnel receiving the initial report should be able to generate a somewhat thorough overview of the anomaly and record this information in a concise, easy-to-read format. An incident is classified as an anomaly at this point because, without initial review, the action or incident may be nothing more than the reporter's misunderstanding of standard business events or practices. The best method to compile and record this information is by using an initial report form (Exhibit 145.2).

Using a form will ensure that each incident is initially handled in the same manner and the same information is recorded. As the types of incidents change, this form can be updated to ensure that the most relevant questions are being asked. It will provide a comprehensive baseline for the CSDI when investigative work begins and can be included as part of the incident case file. Should it be determined during the investigative phase that the anomaly will not be pursued, the form will act as a record of the incident.

An important point to remember is that no question is too trivial to ask. What may seem apparent to CSD personnel may or may not be apparent to the reporter, and vice versa. The person receiving the initial report for the CSD must also be trained to recognize what is and what is not an urgent issue. An urgent issue is a system administrator calling to report watching an unauthorized user peruse and copy files, not a customer calling to report a PC, normally turned off at night, was found on in the morning. Asking key questions and obtaining relevant and pertinent information will accomplish this task.

EXHIBIT 145.2 The Initial Report Form

<Company Name >- Proprietary□

The "who" questions should cover the reporter, witnesses, and victims. The victims are the application owner, user group, and system administrators. Contact information should be obtained for each. The reporter should also be queried as to who has been notified of the incident. This will help the CSDI determine the number of people aware of the issue.

"What" is comprised of two parts: the "anomaly what" and the "environment what." The "anomaly what" should include a description of the conditions that define the anomaly and the reporter's observations. The "environment what" is comprised of questions that identify the operating hardware and software in the impacted environment. Is the system running a UNIX variant such Linux or Solaris, a DOS variant such as Windows 95/98, or Windows NT? The operating system version number should be obtained, as well as the latest release or software patch applied. The reporter should also be queried about the application's value to business. Although all reporters will most likely consider their systems critical, it is important to determine if this is a mission-critical system that will impact revenue stream or shareholder value if the anomaly is confirmed to be a security breech.

The "where" questions cover the location of the incident, the location of the system impacted (these may not be in the same physical location), and the reporter's location. It is very common in logical security incidents that the reporter may be an application user in one location and the system may reside in another location.

"When" should cover the time of discovery and when the reporter suspects the anomaly occurred. This could be the time the system was compromised, a Web page was changed, or data was deleted. If the reporter is utilizing system logs as the basis of the report, the CSD personnel should determine the time zone being used by the system.

"Why" is the reporter's subjective view of the events. By asking why the reporter believes the anomaly occurred, the reporter may provide insight as to ongoing workplace problems, such as layoffs or a disgruntled employee with access to the system. Insight such as this might provide the CDSI with initial investigative direction.

Finally, "how" is the reporter's explanation for how the anomaly occurred. Be sure to ask how the reporter arrived at this conclusion, as this line of questioning will draw out steps the reporter took to parse data. Should the anomaly be confirmed as an incident requiring investigation, these actions would require further understanding and documentation.

When considering logical security incidents, be sure to cover the physical security aspect during the initial report as well. Questions about the physical access to the compromised machine and disaster recovery media (operating system and application data backups) should be covered during the initial report.

The Investigative Phase

Before any monitoring or investigation can take place, the company must set a policy regarding use of business resources. This policy should be broad enough to cover all uses of the resources, yet specific enough so as not to be ambiguous. A policy covering the use of noncompany-owned assets (laptop and desktop computers) should also be considered. This will become important during the evidence-gathering portion of the investigative phase. Once the policies are established, thorough disclosure of the corporate policies must take place. Each employee, contractor, and business partner must be required to read the policies and initial a document indicating that the policy was reviewed, and the document should be kept in the employee's personnel folder. A periodic re-review of the policy should also be required.

In addition to the policy on use of resources, a warning banner should be included in the log-on process and precede access to all systems. The banner should advise the user that activity must adhere to the policy, that activity can be monitored, and any activity deemed illegal can be turned over to law enforcement authorities. The following is an example of a warning message:

> This system is restricted solely to <company name> authorized users for legitimate business purposes only. The actual or attempted unauthorized access, use, or modification of this system is strictly prohibited by <company name>. Unauthorized users are subject to company disciplinary proceedings and/or criminal and civil penalties under state, federal, or other applicable domestic and foreign laws. The use of this system may be monitored and recorded for administrative and security reasons. Anyone accessing this system expressly consents to such monitoring and is advised that if monitoring reveals possible evidence of criminal activity, <company name> might provide the evidence of such activity to law enforcement officials. All users must comply with <company name> Company Instructions regarding the protection of <company name> information and assets.

This warning banner should precede entry into all corporate systems and networks, including stand-alone (nonnetworked) computers and FTP sites. When confronted with the banner, the users should be given the option to exit the log-on process if they do not agree with the policy.

The investigations undertaken by the CSD can be classified into two broad categories: reactive and proactive. Some of the more common reactive reports include unauthorized or suspected unauthorized access to company resources, nonbusiness use of resources, the release of proprietary material, threatening or harassing activity, and activity that creates a hostile work environment. From the reactive cases being generated, the CSD should identify opportunities for prevention of the reactive cases. For example, if the CSD is receiving a large amount of unauthorized access cases, what are the similarities in each? Can a companywide solution be devised and an awareness campaign started to eliminate the vulnerability? Proactive activities can include intelligence-gathering activities such as the monitoring of company access to WWW and newsgroup sites known to hacking tools, offensive, or illegal material. Monitoring of financial message boards may reveal premature proprietary information release or include anticompany postings that are a precursor to workplace violence. Review and monitoring of traffic to free, WWW-based e-mail sites may identify proprietary information being transferred to a competitor. Periodic review of postings to Internet newsgroups could reveal stolen equipment being resold.

Beyond the Initial Report

From the Incident Report Form, the CSDI can begin developing a plan of action. Each investigation will contain two initial steps; anomaly validation and investigation initiation. The first step determines if the anomaly is actually an incident worth investigating. Not every anomaly is the result of a criminal or dishonest act, and not every anomaly warrants a full-scale investigation. An anomaly that presents itself to be unauthorized access to a system with data deletion, may have been an honest mistake caused by the wrong backup tape being loaded. In this instance, a short report of the incident should be recorded. If several similar reports are received in the same area of the company, steps to initiate better data control should be taken. If a Windows 9x system, in an open area, that does not contain sensitive data or support network access is entered, the CSDI must decide if the action justifies full investigation. In this example, it may be prudent to record the incident without further investigative effort and dedicate resources to more mission-critical tasks. Through proactive review of anomaly report records, a decision might be made to conduct an investigation into recurring incidents.

After it is determined that the anomaly requires further investigation, logs supporting the anomaly or logs that may have been altered at the time of the anomaly need to be collected and analyzed. The CSDI must be careful not to view the anomaly with tunnel vision, thereby overlooking important pieces of information. Additionally, more thorough interviews of the reporter and witnesses need to be conducted. These secondary fact-finding interviews will help the CSDI further document what has occurred and what steps the victim or reporter may have taken during the identification of the anomaly. The CSDI should request and obtain from the reporter, and other witnesses, detailed statements of what steps were taken to identify the anomaly. For example, a system administrator (SA) of a UNIX-based system may have examined system logs from the victim system while logged into the victim system using the root ID. In this example, the CSDI should obtain a detailed written statement from the SA, that describes the steps taken and why they were taken. This statement should clearly state why data might have been added or deleted. In addition to the statement, the CSDI should obtain a copy of the shell history file for the ID used, print a copy of the file, and have the SA annotate the listing. The SA's notes should clearly identify which commands were entered during the review and when the commands, to the best of the SA's recollection, were entered. The written statement should be signed by the SA, and placed, along with the annotated version of the shell history, in an investigative case file.

The written statement and data capture (this will be dealt with in more detail later) should be received by the CSDI as soon as possible after the initial report. It is important that witnesses (in this example, the SA) provide written statements while the steps taken are still fresh in their minds. Should it be determined that the anomaly is actually unauthorized activity, the written statements will help to close potential loopholes in any civil or criminal action that may come at the conclusion of the activity.

Intelligence Gathering

It behooves the CSDI to understand as much as possible about the suspect. Understanding the equipment being used, the physical location from which the suspect is initiating the attacks, the time at which the attacks occur, and human factors such as the suspect's persona, all help the CSDI fully understand the tasks at hand.

Initially, the CSDI will want to gather information about the machine being used. By running commands such as nbtstat, ping, trace route, etc., the CSDI can obtain the IP address being used, user ID and machine name being used, and the length of the lease if DHCP is being used.

Following the identification of the machine being used, the CSDI will want to identify where the machine is physically located. If the investigation involves an insider threat, the CSDI could perform physical surveillance on the suspect's office or perform after-business-hours visits to the suspect's office. Before visiting the office, the CSDI should determine the normal business hours at the location, and the ability to gain after-business-hours access. In addition to the physical facility information, the CSDI should determine the type of equipment the suspect utilizes. Once again, if the suspect utilizes a laptop computer to execute the attacks, a late-night visit to the suspect's office may prove fruitless.

If possible, try to gain intelligence about the suspect's work habits in addition to the intelligence gained from the anomalies and initial queries. The suspect may spend the day attacking systems to avoid detection from after-business hours attacks and spend evenings catching up on this work so that management is not aware of his daily activity. In a situation such as this, the CSDI may run into the suspect during a late-night visit. By gathering intelligence, the CSDI can better plan on what equipment will be needed when visiting the suspect's workspace, what actions may need to be taken, and how long the action may take.

No Longer an Anomaly

From the intelligence gathered during the fact-finding interviews and log review, the CSDI should be able to identify the anomaly as an actual incident of unauthorized activity. One of the most important decisions to make while building the action plans is to decide if the activity will be stopped immediately or monitored while additional evidence is gathered. There are several factors to consider before making this decision — most importantly, the impact to the business should the activity continue. The CSDI must be sure that value of identifying the perpetrator outweighs the potential impact to the business. If the CSDI is assured of being able to accurately monitor the activities of the perpetrator, and there is no potential damage such as additional proprietary information being lost or data deleted, the CSDI should proceed with monitoring and build additional evidence. If the perpetrator cannot be controlled or accurately monitored, the activity should be stopped by shutting down the perpetrator's access. In either case, the CSDI must be sure to obtain CSD management approval of the action plan. The selling point to management for continued monitoring is that it buys the CSDI more time to determine what damage may have been done, identify more areas compromised, record new exploits as they occur, and most importantly, identify areas of entry not yet identified.

Active Monitoring

If the activity will be monitored, the first step in the monitoring process is to set up a recording device at the point of entry. If the activity is originating from an office within the CSDI's company, monitoring may consist of a keystroke monitor on the computer being used or a sniffer on the network connection. The traffic captured by the sniffer should be limited to the traffic to and from the machine under electronic surveillance. In addition, video surveillance should be considered — if the environment and law permits. Video surveillance will help confirm the identity of the person sitting at the keyboard. If video surveillance is used, the time on the video recorder should be synchronized to match the time of the system being attacked. Synchronizing the time on the video recorder to that of the system being attacked will confirm that the keystrokes of the person at the keyboard are those reaching the system being attacked. Although this may seem obvious, the attacker could actually be using the machine being monitored as a stepping stone in a series of machines. To do this, the attacker could be in another office and using something as simple as Telnet to access the system in the office being monitored to get to the system being attacked. It is the task of the CSDI to prove that the system attack is originating from the monitored office.

When using video surveillance, the CSDI needs to be aware that the law only permits video — not audio — and that only certain areas can be monitored. Areas that provide a reasonable expectation of privacy, such as a bathroom, cannot be surveyed. Luckily, there are not that many instances of computing environments being set up in bathrooms. Employee offices do not meet that exception and may be surveyed, although the CSDI should only use video surveillance as a means of building evidence during an investigation.

The next step in the monitoring process is to confirm a baseline for the system being attacked. The goal is to identify how the system looked before any changes occur. If the company's disaster recovery plan requires a full system backup once a week, the CSDI, working with the systems administrator (SA), should determine which full backup is most likely not to contain tainted data. This full backup can be used as the baseline. Because the CSDI cannot be expected to understand each system utilized within the company, the CSDI must rely on the SA for assistance. The SA is likely to be the person who knows the system's normal processes and can identify differences between the last-known good backup and the current system. Ideally, the system backup will be loaded on a similar machine so that subtle differences can be noted. However, this is not usually the case. In most instances, the baseline is used for comparison after monitoring has been completed and the attacker repelled.

While monitoring activity, the SA and CSDI should take incremental backups, at a minimum once a day. The incremental backups are then used to confirm changes to the system being attacked on a daily basis.

As the monitoring progresses, the CSDI and the SA should review the captured activity to identify the attacker's targets and methods. As the activity is monitored, the CSDI should begin building spreadsheets and charts to identify the accounts attacked and the methods used to compromise the accounts. The CSDI should also note any accounts of interest that the attacker was unable to compromise. The CSDI must remember that the big picture includes not only what was compromised, but also what was targeted and not compromised.

The Project Plan

In building a picture of the attack, the CSDI should also begin to identify when to begin the assessment, the corrective action phase, when to end monitoring, and when to bring in law enforcement or interview the employee involved. This should be part of the dynamic project plan maintained by the CSDI, and shared with CSD management. As the plan evolves, it is important to get the project plan approved and reapproved as changes are made. Although it is always best to keep those who are knowledgeable or involved in the investigation to a minimum, the CSDI may not be able to make informed decisions about the impact of the unauthorized activity to the victim business unit (BU). With this in mind, the CSDI needs to inform management of the BU impacted by the attack and the company legal team, and keep both apprised of project plan changes. The project plan should include a hierarchy of control for the project, with CSD management at the top of the hierarchy providing support to the CSDI. The CSDI, who controls the investigation will offer options and solutions to the victim BU, and the victim BU will accept or reject the project plan based on its level of comfort.

Legal Considerations

As the investigation progresses, the CSDI should have a good understanding of which laws and company policies may have been violated. Most states now have laws to combat computer crime, but to list them here would take more room than available for this chapter. However, there are several federal laws defined in the United States Code (USC) with which the CSDI should be familiar. Those laws include:

- *18 USC Sec. 1029.* Fraud and related activities in connection with access devices. This covers the production, use, or trafficking in, unauthorized access devices. Examples include passwords gleaned from a targeted computer system. This also provides penalties for violations.
- *18 USC Sec. 1030. The Computer Fraud and Abuse act of 1986.* Fraud and related activity in connection with computers. This covers trespass, computer intrusion, unauthorized access, or exceeding authorized access. It includes and prescribes penalties for violations.
- *The Economic Espionage Act of 1996.* Provides the Department of Justice with sweeping authority to prosecute trade secret theft whether it is in the United States, via the Internet, or outside the United States. This act includes:
  - *18 USC Sec. 1831.* Covers offenses committed while intending or knowing that the offense would benefit a foreign government, foreign instrumentality, or foreign agent.
  - *18 USC Sec. 1832.* Covers copyright and software piracy, specifically those who convert a trade secret to their own benefit or the benefit of others intending or knowing that the offense will injure any owner of the trade secret.
- *The Electronic Communications Privacy Act of 1986.* This act covers the interception or access of wire, oral, and electronic communications. Also included is the unauthorized access of, or intentionally exceeded authorized access, to stored communications. This act includes:
  - *18 USC Sec. 2511.* Interception and disclosure of wire, oral, or electronic communications.
  - *18 USC Sec. 2701.* Unlawful access to stored communications.
- *The No Electronic Theft (NET) Act.* The NET Act amends criminal copyright and trademark provisions in 17 USC and 18 USC. Prior to this act, the government had to prove financial benefit from the activity to prosecute under copyright and trademark laws. This act amended the copyright law so that an individual risks criminal prosecution when there is no direct financial benefit from the reproduction of copyright material. This act is in direct response to *United States v. La Macchia,* 871 F. Supp 535 (D. Mass. 1994), in which an MIT student loaded copyrighted materials onto the Internet and invited others to download this material, free of charge. In *La Macchia,* because the student received no direct financial benefit from his activity, the court held that the criminal provisions of the copyright law did not apply to his infringement.

In addition, those dealing with government computer systems should be familiar with:

- *Public Law 100-235.* The Computer Security Act of 1987. This bill provides for a computer standards program, setting standards for government-wide computer security. It also provides for training of

persons involved in the management, operation, and use of federal computer systems, in security matters.

Evidence collection

Evidence collection must be a very methodical process that is well-documented. Because the CSDI does not know at this point if the incident will result in civil or criminal prosecution, evidence must be collected as if the incident will result in prosecution.

Evidence collection should begin where the anomaly was first noted. If possible, data on the system screen should be captured and a hardcopy and electronic version should be recorded. The hardcopy will provide the starting point in the "series of events" log, a log of activities and events that the CSDI can later use when describing the incident to someone such as a prosecutor, or management making a disciplinary decision. Because CSDIs will be immersed in the investigation from the beginning, they will have a clear picture of the anomaly, the steps taken to verify the anomaly were actually an unauthorized act, the crime committed or policy violated, the actions taken by the suspect, and the damage done. Articulating this event to someone, particularly someone not well-versed in the company's business and who has never used a computer for more than word processing, may be a challenge bigger than the investigation. The series of events log, combined with screen prints, system flows, and charts explaining the accounts and systems compromised and how compromised, will be valuable tools during the education process.

In addition to screen prints, if the system in which the unauthorized access was noted is one of the systems targeted by the suspect or used by the suspect, photographs should be taken. The CSDI should diagram and photograph the room where the equipment was stored to accurately depict the placement of the equipment within the room. Once the room has been photographed, the equipment involved and all of its components should be photographed. The first step is to take close-up photographs of the equipment as it is placed within the room. If possible, photographs of the screen showing the data on the screen should be taken. Be sure to include all peripheral equipment, remembering it may not be physically adjacent to the CPU or monitor. Peripheral equipment may include a printer, scanner, microphone, storage units, and an uninterrupted power supply component. Bear in mind that with the advent of wireless components, not all components may be physically connected to the CPU. The next step is to photograph the wires connected to the CPU. Photographs should include a close-up to allow for clear identification of the ports being used on the machine. The power supply should also be included.

Once the equipment has been photographed, attention should turn to the surrounding area. Assuming one has permission to search the office, one should begin looking for evidence of the activity. It is important to note the location of diskettes and other storage media in relation to the CPU. Careful review of the desktop may reveal a list of compromised IDs or systems attacked, file lists from systems compromised, printouts of data from files compromised, and notes of the activity. Each of these items should be photographed as they are located.

Confiscating and Logging Evidence

After the items have been located, evidence collection should begin. It is important for the CSDI to be familiar with the types of equipment owned and leased by the company. If the CSDI is presented with a machine that is not standard issue, the CSDI must consider the possibility that the machine is privately owned. Without a policy covering privately owned equipment and signed by the employee, the CSDI can not search or confiscate the machine without permission from the owner. Once the CSDI has confirmed company ownership, evidence collection may begin. For each piece of evidence collected, the CSDI needs to identify where and when it was obtained and from whom it was obtained. The best method to accomplish this is a form used to track evidence (Exhibit 145.3).

As the evidence is collected, the CSDI will fill out the form and identify each item using serial numbers and model numbers, if applicable, and list unique features such as scratch marks on a CPU case. Each item should be marked, if possible, with the CSDI's initials, the date the item was collected, and the case number. If it is not possible to mark each item, then each item should be placed in a container and the container sealed with evidence tape. The evidence tape used should not allow for easy removal without breakage. The CSDI should then sign and date the evidence tape. The CSDI should always mark evidence in the same manner because the

EXHIBIT 145.3 The Evidence Form

Evidence/Property Custody Document				
District/Office:			Serial Number:	
Location:			Investigator Assigned To:	
Name and Title of Person from whom received Owner Other			Investigator's Address (include zip code)	
Address from where obtained (including zip code)			Reason Obtained	Date:

		SIGNATURE NAME,GRADE OR TITLE	SIGNATURE NAME,GRADE OR TITLE	
		SIGNATURE NAME,GRADE OR TITLE	SIGNATURE NAME,GRADE OR TITLE	

<Company> - Proprietary

CSDI may be asked to testify that he is the person identified by the marking. By marking items in the same fashion, the CSDI can easily identify where the markings were placed.

Evidence Storage

After the evidence has been collected, it must be transported to and stored in a secure location. During transport, special care must be taken to ensure that custody can be demonstrated from the point of departure until the evidence arrives at, and is logged into, the storage facility. While in custody of the CSD, the evidence must be protected from damage caused by heat, cold, water, fire, magnetic fields, and excessive vibration. Hard drives should be stored in static-free bags and packed in static-free packaging within the storage container. The CSD must take every precaution to ensure the evidence is protected for successful prosecution and eventual return to the owner. Should the confiscated items be damaged during transport, storage, or examination, the owner of the material may hold the CSD liable for the damage.

Evidence Custodian

When the evidence arrives at the storage location, it is preferable that an evidence custodian logs it into the facility. It will be the job of the evidence custodian to ensure safe storage for the material as described above. Using an evidence custodian, as opposed to each CSDI storing evidence from their cases, ensures that the evidence, property owned by others until the case is adjudicated, is managed with a set of checks and balances. The evidence custodian will be responsible for confirming receipt of evidence, release of evidence, and periodic inventory of items in evidence. After the case has been adjudicated, the evidence will need to be removed from evidence storage and returned to the owner. The evidence form should then be stored with the case file.

Business Continuity during Evidence Collection

The CSDI must remember that his responsibility is to the company and shareholders. The CSDI must find the balance between performing an investigation and protecting the business, thereby maintaining shareholder value. If the unauthorized activity required the computer be shut down during the length of an investigation, then an attacker need not gain entry and destroy files if the purpose of the attack is to disrupt business. Simply causing a machine to reboot or drop a connection would, in itself, be enough to disrupt the business.

When an investigation requires the CDSI to obtain evidence from a computer's hard drive or from drives that support a network, the CSDI cannot stop the business for an extended period of time by placing the hard drive into evidence. By performing a forensic backup of the hard drives in question, the CSDI can ensure evidence preservation and allow the business to get up and running in a short amount of time. A forensic image of a hard drive preserves not only the allocated file space, but also the deleted files, swap space, and slack space. The forensic image is the optimal answer to gathering evidence. Once a forensic image has been obtained, a new disk can be placed in the target computer and data loaded from a backup. If data loss is a concern, then the forensic image can be restored to the new disk, allowing the business to proceed as the investigation continues.

Although it is not recommended, the CSDI may not be able to stop the business long enough for a forensic image to be taken. In situations involving a system that cannot be brought down (for example, a production control systems or systems that accept customer orders), the CSDI may be presented with the task of gathering evidence while the system is continuing to process data. In situations such as these, the CSDI may be able to gather some evidence by attaching removable storage media to the machine and copying pertinent files to the removable media. In these situations, the CSDI must remember that the data gathered is not the best evidence to prosecute the case. However, just because the evidence may not be optimal for prosecution, it should not be overlooked. Evidence such as this may be used to support the CSDI's theories and may provide the CSDI with insight to other unauthorized activities not identified thus far.

Gathering Evidence through Forensic Imaging

This section provides a cursory overview of forensic imaging. Forensic imaging of a hard drive is a subject deserving a chapter in itself, so this section only attempts to provide the CSDI with an overview of what steps are taken and what equipment is needed to produce a forensic image.

Once the computer has been accurately photographed, the system can be removed to an area where the forensic image will be made or the CPU box opened so that a forensic image can be taken on site. One problem with performing an on-site image is that without an evidence review machine on hand, in which to load and review the forensic image, the CSDI must trust that the image was successful. Assuming removal of the machine would not compromise the investigation, it is best to remove the machine to an examination area. Once in the examination area, a forensic image can be obtained using a DOS boot diskette, forensic imaging software, and tape backup unit. The suspect machine will be booted using the DOS diskette to ensure that no advanced operating system software tools are loaded. The forensic imaging software (there are many packages on the consumer market) is loaded and run from DOS. Output is then directed to the tape backup unit via the system's SCSI port.

In systems without a SCSI port, the hard drive (called the original drive or suspect drive) will have to be removed and installed as a slave drive in another computer. This exercise should not be taken lightly, as there is much opportunity to damage the suspect's drive and lose or overwrite data. In situations such as this, the equipment used to obtain an image may vary; but in all cases, the target for the image must be as large or

larger than the original disk. Targets for the image may be either magnetic tape or a second hard drive. The first step in creating the image is to physically access the original drive and remove it from the system housing. Next, the original drive must be connected to a secondary machine, preferably as a slave drive. Once this original drive has been connected to the secondary machine, the data can be copied from the slave drive to the backup media.

As electronics get smaller, laptop computers present challenges that are unique in, and of, themselves. When performing a forensic image of a laptop computer hard drive that does not provide a SCSI port or PCMCIA adapter access, special interface cables are needed to ensure power to the original drive and data connectivity from the original to the imaging media. If a PCMCIA socket is available, special adapter cards can be obtained to allow the data transfer through the socket to a SCSI device. In this case, drivers for the PCMCIA card are loaded, in addition to the DOS and imaging software.

Once the forensic image has been obtained, the acquired data needs to be reviewed. There are several commercially available packages on the consumer market that support forensic data review. There are also shareware tools available that claim to perform forensic image review without data alteration. It is best to use a package purchased from a company that has a history of providing expert testimony in court about the integrity of its product. The CSD does not want an investigation challenged in court due to evidence gathering and review methods. Unless a vendor is willing to provide expert testimony as to the technical capabilities of its program, the CSD would be well-advised to steer away from that vendor.

During a review of the acquired hard drive, efforts should be made to recover deleted files, examine slack space, swap space, and temporary files. It is not uncommon for evidence of the unauthorized activity to be found in these areas. Additionally, files with innocuous names should be verified as being unaltered by, or in support of, the unauthorized activity. There are some commercially available products on the market that provide hash values for the more commonly used programs. This will allow the CSDI to automate a search for altered files by identifying those that do not match the hash.

Law Enforcement Now or Later?

Throughout the investigation, the CSDI must continually weigh the options and advantages of involving law enforcement in the investigation. There are several advantages and disadvantages to bringing in law enforcement and there is no golden rule as to when law enforcement should be contacted. Although cases involving outsider threats are a little more apparent, insider threat cases are not as obvious.

When law enforcement is brought into an investigation, the dynamics of that investigation change. Although the CSDI can control information dissemination prior to law enforcement involvement, once law enforcement becomes involved, the CSDI no longer has control due to the Freedom of Information Act. Unless the law enforcement agency can prove the need to seal case information, for reasons such as imminent loss of life due to the information release, they do not have the ability to seal the case once arrests have been made. If law enforcement is being brought into an investigation, the CSDI must notify the company's public relations team as soon as possible. Additionally, any steps taken by the CSDI after law enforcement enters the case could be a violation of the Fourth Amendment to the Constitution of the United States. For example, during an insider threat case, the CSDI would normally search the suspect's office for evidence as part of the normal course of the investigation. Because the CSDI is not a sworn law enforcement officer and an employee of the company, the CSDI is permitted by law to conduct the search and not subject to the rules and laws governing search and seizure. However, this does not hold true when:

- The CSDI performs a search in which law enforcement would have needed a search warrant to conduct
- The CSDI performs that search to assist law enforcement
- Law enforcement is aware of the CSDI's actions and does not object to them

When the above conditions are true, the CSDI is acting as an agent of law enforcement and is in violation of the Fourth Amendment.

As stated above, outsider threat cases will not amount to much unless outside assistance through the courts or law enforcement is sought. The most direct way to receive assistance is to contact law enforcement in the event the anomaly can be proven to be intentional and provide them with evidence of the activity. Law enforcement has the power to subpoena business records from Internet service providers (ISPs), telephone companies, etc. in support of their investigation. A less-used tactic is for the CSDI's company to begin a third-party, "John Doe" lawsuit to assist the company in identifying the suspect. These civil remedies will allow the

CSDI to gather information not normally available. For example, the anomaly detected was confirmed as unauthorized access from a local ISP known to the CSDI as the ISP utilized by an employee under suspicion. By filing the lawsuit, the company and the CSDI will be able to obtain subscriber information not normally available. The CSDI needs to be aware that some ISPs will inform the user when a subpoena from a lawsuit is received.

Regardless of when the CSDI chooses to bring law enforcement into the investigation, it should not be the first meeting between the CSDI and law enforcement agent. It is important for the CSDI to establish ties with local, state, and various branches of federal law enforcement (FBI, Secret Service, Customs, etc.) before incidents occur. One of the best methods to establish the relationship early is by participating in training offered by professional service organizations such as the American Society of Industrial Security (www.asisonline.org) and the High Technology Crime Investigation Association (www.htcia.org). Both international organizations not only provide training, but also provide important networking opportunities before incidents occur.

Assessment Phase

The assessment is the phase where the CSDI knows, or has an idea of what has been done, but needs to determine what other vulnerabilities exist. The assessment phase helps reduce investigative tunnel vision by providing the CSDI with insight as to additional vulnerabilities or changes that may have been made. The assessment phase can run in conjunction with an active investigation and should be run as soon as possible after the unauthorized activity is defined. An exception to this is when active monitoring and recording of the activity is taking place. There are two reasons for this. First, the attacker is already in the company's system so one does not want the attacker to see processes running that would not normally be run. These new processes might give the attacker insight as to other system vulnerabilities or alert the attacker to the investigation. Second, the CSDI needs to be able to distinguish between the vulnerability tests performed by the automated process and the tests performed by the attacker. Once it is determined safe to execute the test, the automated tools should be run and the results removed from the system immediately.

Closing the Investigation

One of the largest management challenges during a computer-related incident is bringing the investigation to a close when a suspect has been identified. The CSDI must orchestrate a plan that might include the participation of law enforcement, systems administrators, BU management, public relations, and legal departments.

By now, the decision has most likely been made to pursue criminal or civil charges, or handle the incident internally. Aiding in this decision will be the amount of damage done and potential business loss, as quantified by high-level management in the victim BU.

The Interview

One of the questions that should be paramount in the CSDI mind is why the suspect engaged in the unauthorized activity. This question can frequently be answered during an interview of the suspect. If involved, law enforcement personnel will usually work with the CSDI to ensure that their questions and the CSDI questions are answered during the interview. If law enforcement is not involved, then it is up to the CSDI to interview the suspect and obtain answers to some very important questions. Other than why the suspect took the actions, the CSDI will want to have the suspect explain the steps taken to perform the unauthorized activity, actions taken before and after the unauthorized activity was noted and reported to the CSD, and what additional unauthorized activity may have occurred. For example, if the activity was unauthorized access to a system, the CSDI should have the suspect explain when the access was first attempted, when access was accomplished, what accounts were accessed, and how the system was accessed. The CSDI should have the suspect identify any changes made to the system (i.e., modified data, deleted data, backdoors planted, etc.), and what gains were achieved as a result of the activity. During the interview, the CSDI should not make any promises as to the outcome of the suspect's employment or potential for criminal or civil prosecution, unless first concurring with CSD management and the company legal team. The CSDI should strive for the suspect to detail the discussion in a written statement and sign and date the statement at the completion of the interview. The CSD should utilize a standard form for written statements that includes a phrase about the company being allowed to use the written statement as the company sees fit and that no promises are made in exchange for the written

statement. This will ensure that the suspect does not later attempt to say that any employment promises were made in exchange for the written statement or that the suspect was promised the statement would not be used in disciplinary, criminal, or civil proceedings.

The Corrective Action Phase

After the assessment has been completed, the corrective action phase can begin. This phase should be coordinated with investigative efforts so as not to interrupt any final investigative details. Optimally, the corrective action phase begins as the suspect is being arrested by law enforcement or interviewed by the CSDI. Once it has been determined that the phases can run concurrently or the investigative efforts have been completed, the target machines should be brought down and a forensic image should be acquired. After a forensic image of the machine is acquired, the operating system should be loaded from original disks and all software patches applied. If possible, all user IDs should be verified in writing. If this is not possible, all user passwords should be changed and all users forced to change their passwords at next log-on. Careful documentation should be kept to identify those IDs not used within a selected timeframe; for example, 30 days from the time the system is reloaded. Any ID not claimed by a user should be documented and removed from the system. This documentation should be kept as a supplement to the investigative case file in the event it is determined that the unclaimed ID was a product of the attacker's work. The CSDI should note any attempted use of any unclaimed IDs. If a suspect has been identified and either arrested or blocked from the system, attempted use of one of the unclaimed IDs may indicate a further problem not previously identified.

The validity of application programs and user data is at best a shot in the dark, unless the CSDI and system administrator can identify the date the system was compromised. To be absolutely sure backdoors placed by the attacker are not reloaded, BU management may have to fall back to a copy of the last application software load to ensure future system security.

Once the system has been restored and before it is brought back online, a full automated assessment should be run once again to identify any existing vulnerability. Any vulnerability identified should be corrected or, if not corrected, identified and signed off on as an acceptable risk by the BU manager. After all vulnerabilities have been corrected or identified as acceptable risks, the victim system can once again be brought back online.

Proactive Phase

After the investigation and corrective phases have been completed, a post-mortem meeting should be conducted to initiate the proactive phase. Problems encountered, root cause determination, and lessons learned from the incident should be documented in this meeting. The meeting should be led by the CSDI and attended by all company personnel involved in the incident. If the CSDI can show cost savings or recovered loss, these facts should be documented and provided to management. An overview of the incident and the lessons learned should be incorporated into the CSD security awareness presentations and presented to employees throughout the company. Timely reporting of incidents to the CSD should be stressed during the presentations. As this incident and others are presented throughout the company, the CSD is advertised as a value-added business partner, thereby generating more business for the CSD.

Summary

Although there are no golden rules to follow when investigating computer crime, following a structured methodology during investigations will provide a means for the CSDI to guarantee thorough investigations. Using the security continuum as a shell for a dynamic project plan, the CSDI will ensure a comprehensive examination of each incident. A strong project plan, coupled with traditional investigative skills and a good understanding of forensics and emerging technology, will provide the CSDI with the tools needed to confront an ever-changing investigative environment.

147

Operational Forensics

Michael J. Corby, CISSP

The increased complexities of computer systems today make it difficult to determine what has happened when a malfunction occurs or a system crashes**.** Sometimes, it is difficult to even make the basic identification of whether the cause was accidental or intentional. If the cause was intentional, legal action may be in order; if the cause was operational, the reason must be identified and corrected. Both require a planned and measured response.

Unfortunately, with today's emphasis on immediate recovery in the networked environment, and with the obligation to get back online as quickly as possible, determining the cause may be impossible. The tendency to restart, or reboot, may remove information that could be valuable in ascertaining cause or providing evidence of criminal wrongdoing.

Operational forensics is a two-phased approach to resolving this problem. The first phase is the proper collection of operational information such as data logs, system monitoring, and evidence-tracking methods. The appropriate attention to this phase makes it much easier to identify the problem in the second phase, the recovery.

At recovery time, the information at hand can be used to decide whether a formal intrusion investigation needs to be initiated and evidence collected needs to be preserved. By responding in prescribed ways, which can include repair/replacment of the equipment, correction of a software weakness, or identification of human-caused error(s) that resulted in the disruption, the system can be returned to operation with a much reduced probability of the same event occurring in the future.

Related Business Requirements

Technology has been more than an efficiency enhancement to the organization. It has become the lifeblood of the successful enterprise and the sole product of the networked application service provider. As such, the maximum availability of this essential resource is critical. When a failure occurs or the system is not operating at expected levels, proper procedures should be used to accurately identify and correct the situation. Failing to do so will result in unpredictable operations, inefficiencies and possibly lost revenue, tarnished image, and failure to thrive. The business case for investing in the time, procedures, and the relatively small cost of computer hardware or software components seems clear.

Why then, do companies not have operational forensics (or the same functions by other names) programs in place? Well, for two reasons: People have started with the assumption that computers are perfectly reliable and therefore will only fail under rare circumstances if programs are well-written. Why waste resources in pointing the finger at something that should never occur? Second, the topic of methodical, procedural investigations is new to other than law enforcement, and only recently has come into the foreground with the advent of computer crimes, cyber terrorism, and the relationship of vengeance and violence linked to some computer "chat rooms," e-mail, and personal private data intrusions.

The good news is that operational forensics is not an expensive option. There is some additional cost needed to properly equip the systems and the process for secure log creation; but unless the need is determined for a full-scale criminal investigation and trial preparation, the process is almost transparent to most operations.

The business objectives of implementing an operational forensics program are threefold:

1. Maintain maximum system availability (99.999 percent or five-nines "uptime").
2. Quickly restore system operations without losing information related to the interruption.
3. Preserve all information that may be needed as evidence, in an acceptable legal form, should court action be warranted.

The acceptable legal form is what calls for the operational forensics process to be rigorously controlled through standard methods and a coordinated effort by areas outside the traditional IT organization.

Justification Options

The frequent reaction to a request to start an operational forensics program is one of financial concerns. Many stories abound of how forensic investigations of computer crimes have required hundreds or thousands of hours of highly paid investigators pouring over disk drives with a fine-tooth comb — all of this while the business operation is at a standstill. These stories probably have indeed occurred, but the reason they were so disruptive, took so long, or cost so much, was because the operational data or evidence had to be reconstructed. Often, this reconstruction process is difficult and may be effectively challenged in a legal case if not prepared perfectly.

Operational forensics programs can be justified using the age-old 80-20 rule: an investigation cost is 80 percent comprised of recreating lost data and 20 percent actually investigating. An effective operational forensics program nearly eliminates the 80 percent data recreation cost.

A second way in which operational forensics programs have been justified is as a positive closed-loop feedback system for making sure that the investment in IT is effectively utilized. It is wise investment planning and prudent loss reduction. For example, an operational forensics program can quickly and easily determine that the cause of a server crashing frequently is due to an unstable power source, not an improperly configured operating system. A power problem can be resolved for a few hundred dollars, whereas the reinstallation of a new operating system with all options can take several days of expensive staff time, and actually solve nothing.

No matter how the program is justified, organizations are beginning to think about the investment in technology and the huge emphasis on continuous availability, and a finding ways to convince management that a plan for identifying and investigating causes of system problems is a worthwhile endeavor.

Basics of Operational Forensics

Operational forensics includes developing procedures and communicating methods of response so that all flexibility to recover more data or make legal or strategic decisions is preserved. Briefly stated, all the procedures in the world and all the smart investigators that can be found cannot reverse the course of events once they have been put into action. If the Ctrl-Alt-Delete sequence has been started, data lost in that action is difficult and expensive, if not impossible to recover. Operational forensics, therefore, starts with a state of mind. That state of mind prescribes a "think before reacting" mentality. The following are the basic components of the preparation process that accompany that mentality.

For all situations:

- Definition of the process to prioritize the three key actions when an event occurs:
  - — Evidence retention
  - — System recovery
  - — Cause identification
- Guidelines that provide assistance in identifying whether an intrusion has occurred and if it was intentional
- Methods for developing cost-effective investigative methods and recovery solutions
- Maintenance of a secure, provable evidentiary chain of custody

For situations where legal action is warranted:

- Identification or development of professionally trained forensic specialists and interviewers/interrogators, as needed
- Procedures for coordination and referral of unauthorized intrusions and activity to law enforcement and prosecution, as necessary
- Guidelines to assist in ongoing communication with legal representatives, prosecutors, and law enforcement, as necessary
- Instructions for providing testimony, as needed

Notice that the evidence is collected and maintained in a form suitable for use in cases where legal action is possible, even if the event is purely an operational failure. That way, if after the research begins, it is determined that what was thought initially to be operational, turns out to warrant legal action, all the evidence is available.

Consider the following scenario. A Web server has stopped functioning, and upon initial determination, evidence shows that the building had a power outage and when the server rebooted upon restoration, a diskette was left in the drive from a previous software installation. Initial actions in response include purchasing a new UPS (uninterruptable power supply) capable of keeping the server functioning for a longer time, and changing the boot sequence so that a diskette in the drive will not prevent system recovery. All set? Everybody thinks so, until a few days after the recovery, someone has discovered that new operating parameters have taken effect, allowing an intruder to install a "trap door" into the operating system. That change would take effect only after the system rebooted. Is the data still available to identify how the trap door was installed, whether it posed problems prior to this event, and who is responsible for this act of vandalism?

An operational forensics program is designed to identify the risk of changes to the system operation when it is rebooted and conduct baseline quality control, but also to preserve the evidence in a suitable place and manner so that a future investigation can begin if new facts are uncovered.

Building the Operational Forensics Program

Policy

To start building an operational forensics program, the first key element, as in many other technical programs, includes defining a policy. Success in developing this process must be established at the top levels of the organization. Therefore, a policy endorsed by senior management must be written and distributed to the entire organization. This policy both informs and guides.

This policy informs everyone that the organization has corporate endorsement to use appropriate methods to ensure long-term operational stability, and thus ensure that the means to accurately identify and correct problems will be used. It should also inform the organization that methods will be used to take legal action against those who attempt to corrupt, invade, or misuse the technology put in place to accomplish the organization's mission. There is a subtle hint here meant to discourage employees who may be tempted to use the system for questionable purposes (harassing, threatening, or illegal correspondence and actions), that the organization has the means and intent to prosecute violators.

The policy guides in that it describes what to do, under what circumstances, and how to evaluate the results. With this policy, the staff responsible for operating the system components, including mainframes, servers, and even workstations, as well as all other peripherals, will have a definition of the process to prioritize the three key actions when an event occurs:

1. Evidence retention
2. System recovery
3. Cause identification

In general, this policy defines a priority used for establishing irrefutable data that identifies the cause of an interruption. That priority is to first ensure that the evidence is retained; then recover the system operation; and, finally, as time and talent permits, identify the cause.

Guidelines

As a supplement to these policies, guidelines can be developed that provide assistance in identifying whether an intrusion has occurred and if it was intentional. As with all guidelines, this is not a specific set of definitive rules, but rather a checklist of things to consider when conducting an initial response. More detailed guidelines are also provided in the form of a reminder checklist of the process used to secure a site for proper evidence retention. The suggested method for publishing this guideline is to post it on the wall near a server, firewall, or other critical component. Items on this reminder checklist can be constructed to fit the specific installation, but typical entries can include:

Before rebooting this server:

1. Take a photograph of the screen (call Ext xxxx for camera).
2. Verify that the keyboard/monitor switches are set correctly.
3. Record the condition of any lights/indicators.
4. Use the procedure entitled "*Disabling the disk mirror.*"
5. …
6. …
7. etc.

Accompanying these posted instructions are a series of checklists designed to help record and control the information that can be collected throughout the data collection process.

Log Procedures

Policies and guidelines can help provide people with the motivation and method to act thoughtfully and properly when responding to an event, but they are insufficient by themselves to provide all that is needed. Most operating system components and access software (modem drivers, LAN traffic, Internet access software, etc.) provide for log files to be created when the connection is used, changed, or when errors occur. The catch is that usually these logs are not enabled when the component is installed. Furthermore, the log file may be configured to reside on a system device that gets reset when the system restarts. To properly enable these logs, they must be:

- Activated when the service is installed
- Maintained on a safe device, protected from unauthorized viewing or alteration
- Set to record continuously despite system reboots

Additional third-party access management and control logs can and should be implemented to completely record and report system use in a manner acceptable for use as legal evidence. This includes data that can be independently corroborated, non-repudiated, and chain-of-custody maintained.

Configuration Planning

The operational forensics program also includes defining methods for maximizing the data/evidence collection abilities while providing for fast and effective system recovery. That often can be accomplished by planning for operational forensics when system components are configured. One technique often used is to provide a form of disk mirroring on all devices where log files are stored. The intent is to capture data as it exists as close as possible to the event. By maintaining mirrored disks, the "mirror" can be disabled and removed for evidence preservation while the system is restarted. This accomplishes the preservation of evidence and quick recovery required in a critical system.

The process for maintaining and preserving this data is then to create a minimum of three copies of the mirrored data:

1. One copy to be signed and sealed in an evidence locker pending legal action (if warranted)
2. One copy to be used as a control copy for evidence/data testing and analysis
3. One copy to be provided to opposing attorney in the discovery phase, if a criminal investigation proceeds

Linking Operational Forensics to Criminal Investigation

The value of a well-designed operational forensics program is in its ability to have all the evidence necessary to effectively develop a criminal investigation. By far, the most intensive activity in preparing for a legal opportunity is in the preparation of data that is validated and provable in legal proceedings. Three concepts are important to understanding this capacity:

1. Evidence corroboration
2. Non-repudiation
3. Preservation of the chain of custody

Evidence Corroboration

If one is at all familiar with any type of legal proceeding, from the high profile trials of the 1990s to the courtroom-based movies, television programs, or pseudo-legal entertainment of judicial civil cases, evidence that is not validated through some independent means may by inadmissible. Therefore, to provide the maximum potential for critical evidence to be admitted into the record, it should be corroborated through some other means. Therefore, based on the potential for legal action, several log creation utilities can be employed to record the same type of information. When two sources are compared, the accuracy of the data being reported can be assured. For example, access to a system from the outside reported only by a modem log may be questioned that the data was erroneous. However, if the same information is validated by access to the system from system login attempt, or from an application use log, the data is more likely to be admitted as accurate.

Non-Repudiation

A second crucial element necessary for a smooth legal process is establishing evidence in a way that actions cannot be denied by the suspect. This is called "non-repudiation." In many recent cases of attempted system intrusion, a likely suspect has been exonerated by testifying that it could not have been his actions that caused the violation. Perhaps someone masqueraded as him, or perhaps his password was compromised, etc. There is no way to definitely make all transactions pass the non-repudiation test; but in establishing the secure procedures for authenticating all who access the system, non-repudiation should be included as a high-priority requirement.

Preservation of the Chain of Custody

Finally, the last and perhaps most important legal objective of operational forensics is to preserve the chain of custody. In simple terms, this means that the data/evidence was always under the control of an independent source and that it could not have been altered to support one side of the case. This is perhaps the most easily established legal criterion, but the least frequently followed. To establish a proper chain of custody, all data must be properly signed-in and signed-out using approved procedures, and any chance of its alteration must be eliminated — to a legal certainty. Technology has come to the rescue with devices such as read-only CDs, but there are also some low-technology solutions like evidence lockers, instant photography, and voice recorders to track activity related to obtaining, storing, and preserving data.

For all legal issues, it is wise and highly recommended that the organization's legal counsel be included on the forensic team, and if possible, a representative from the local law enforcement agency's (Attorney General, Prosecutor or FBI/state/local police unit) high-tech crime unit. In the case of properly collecting evidence when and if a situation arises, prior planning and preparation is always a good investment.

Linking Operational Forensics to Business Continuity Planning

What makes operational forensics an entity unto itself is the ability to use the time and effort spent in planning for benefits other than prosecuting criminals. The key benefit is in an organization's ability to learn something

from every operational miscue. Countless times, systems stop running because intruders who only partially succeed at gaining access have corrupted the network connections. In most instances, all the information that could have been used to close access vulnerabilities goes away with the Ctrl-Alt-Delete keys. Systems do not crash without cause. If each cause were evaluated, many of them could be eliminated or their probability of reoccurring significantly reduced.

In the current age of continuous availability, maximum network uptime is directly linked to profit or effectiveness. Implementing an operational forensics program can help establish an effective link to business continuity planning risk reduction and can raise the bar of attainable service levels.

Although evidence collected for improving availability does not need to pass all legal hurdles, an effective method of cause identification can help focus the cost of prevention on *real* vulnerabilities, not on the whole universe of possibilities, no matter how remote. Cost justification of new availability features is more readily available, and IT can begin to function more like a well-defined business function than a "black art."

Summary and Conclusion

When a system interruption occurs, operational forensics is a key component of the recovery process and should be utilized to identify the nature and cause of the interruption as well as collecting, preserving, and evaluating the evidence. This special investigation function is essential because it is often difficult to conclusively determine the nature, source, and responsibility for the system interruption. As such, to improve the likelihood of successfully recovering from a system interruption, certain related integral services, such as establishing the data/activity logs, monitoring system, evidence collection mechanisms, intrusion management, and investigative management should be established prior to a system interruptions occurrence. This is the primary benefit of operational forensics. One will see much more of this in the near future.

Computer Crime Investigation and Computer Forensics

Thomas Welch

Incidents of computer-related crime and telecommunications fraud have increased dramatically over the past decade, but due to the esoteric nature of this crime there have been very few prosecutions and even fewer convictions. The same technology that has allowed for the advancement and automation of many business processes has also opened to the door to many new forms of computer abuse. While some of these system attacks merely use contemporary methods to commit older, more familiar types of crime, others involve the use of completely new forms of criminal activity that have evolved along with the technology.

Computer crime investigation and computer forensics are also evolving sciences which are affected by many external factors: continued advancements in technology, societal issues, legal issues, etc. There are many gray areas that need to be sorted out and tested through the courts. Until then, the system attackers will have a clear advantage and computer abuse will continue to increase. We, as computer security practitioners, must be aware of the myriad of technological and legal issues that affect our systems and its users, including issues dealing with investigations and enforcement.

This chapter will take the security practitioner and investigator through each of the areas of computer crime investigation and computer forensics, so that they are better prepared to respond to both internal and external attacks.

COMPUTER CRIME

According to the American Heritage Dictionary a "crime" is any act committed or omitted in violation of the law. This definition causes a perplexing problem for law enforcement when dealing with computer-related crime, since much of today's computer-related crime is without violation of any formal law. This may seem be a contradictory statement, but traditional criminal statutes, in most states, have only been modified throughout the years to reflect the theories of modern criminal justice. These laws generally envision applications to situations involving traditional types of criminal activity, such as burglary, larceny, fraud, etc. Unfortunately, the modern criminal has kept pace with the vast advancements in technology and he has found ways to apply such innovations as the computer to his criminal ventures. Unknowingly and probably unintentionally, he has also revealed the difficulties in applying older traditional laws to situations involving "computer related crimes."

In 1979 the United States Department of Justice established a definition for "computer crime," stating that "a computer crime is any illegal act for which knowledge of computer technology is essential for its perpetration, investigation, or prosecution." This definition was too broad and has since been further refined by new or modified, state and federal criminal statutes.

Criminal Law

Criminal law identifies a crime as being a wrong against society. Even if an individual is victimized, under the law, society is the victim. A conviction under criminal law normally results in a jail term or probation for the defendant. It could also result in a financial award to the victim as restitution for the crime. The main purpose for prosecuting under criminal law is punishment for the offender. This punishment is also meant to serve as a deterrent against future crime. The deterrent aspect of punishment only works if the punishment is severe enough to discourage further criminal activity. This is certainly not the case in the United States, where very few computer criminals ever go to jail. In other areas of the world there are very strong deterrents. For example, in China in 1995, a computer hacker was executed after being found guilty of embezzling $200,000 from a National bank. This certainly will have a dissuading value for other hackers in China!

To be found guilty of a criminal offense under criminal law, the jury must believe, beyond a reasonable doubt, that the offender is guilty of the offense. The lack of technical expertise, combined with the many confusing questions posed by the defense attorney, may cause doubt for many jury members, thus rendering a "not guilty" decision. The only short-term solution to this problem, is to provide simple testimony in layman terms and to use demonstrative evidence whenever possible. Even with this, it will be difficult for many juries to return a guilty verdict.

Criminal conduct is broken down into two classifications depending on severity. A felony is the more serious of the two, normally resulting in a jail term of more than one year. Misdemeanors are normally punishable by a fine or a jail sentence of less than a year. It is important to understand that if we wish to deter future attacks, we must push for the stricter sentencing, which only occurs under the felonious classification. The type of attack and/or the total dollar loss has a direct relationship to the crime classification. As we cover investigation procedures, we will see why it is so important to account for all time and money spent on the investigation.

Criminal law falls under two main jurisdictions: Federal and State. Although there is a plethora of federal and state statutes which may be used against traditional criminal offenses, and even though many of these same statutes may apply to computer related crimes with some measure of success, it is clear that many cases fail to reach prosecution or fail to result in conviction because of the gaps which exists in the Federal Criminal Code and the individual state criminal statutes.

Because of this, every state in the United States, with the exception of one, along with the Federal government, have adopted new laws specific to computer related abuses. These new laws, which have been redefined over the years to keep abreast of the constant changes in the technological forum, have been subjected to an ample amount of scrutiny due to many social issues, which have been impacted by the proliferation of computers in society. Some of these issues, such as privacy, copyright infringement, and software ownership are yet to be resolved, thus we can expect many more changes to the current collection of laws. Some of the computer related crimes, which are addressed by the new state and federal laws, are

- Unauthorized access
- Exceed authorized access
- Intellectual property theft or misuse of information
- Child Pornography
- Theft of services
- Forgery
- Property theft (i.e. Computer hardware, chips, etc.)
- Invasion of privacy
- Denial of services
- Computer fraud
- Viruses
- Sabotage (Data alteration or malicious destruction)
- Extortion
- Embezzlement
- Espionage
- Terrorism

All but one state, Vermont, have created or amended laws specifically to deal with computer-related crime. Twenty-five of the states have enacted specific computer crime statutes, while the other twenty-four states have merely amended their traditional criminal statutes to confront computer crime issues. Vermont has announced legislation under Bill H.0555, which deals with theft of computer services. The elements of proof, which define the basis of the criminal activity, vary from state to state. Security practitioners should be fully cognizant of their own state laws, specifically the elements of proof. Additionally, traditional criminal statutes, such as theft, fraud, extortion and embezzlement, can still be used to prosecute computer crime.

Just as there has been numerous new legislation at the State level, there have also been many new federal policies, such as the:

- Electronic Communications Privacy Act
- Electronic Espionage Act of 1996
- Child Pornography Prevention Act of 1996
- Computer Fraud and Abuse Act of 1986, 18 U.S.C. 1001

These laws and policies have been established, precisely to deal with computer and telecommunications abuses at the Federal level. Additionally, many modifications and updates have been made to the Federal Criminal Code, Sections 1029 and 1030, to deal with a variety of computer related abuses. Even though these new laws have been adopted for use in the prosecution of a computer-related offense, some of the older, proven federal laws, identified below, offer a "simpler" case to present to judges and juries:

- Wire Fraud
- Mail Fraud
- Interstate Transportation of Stolen Property
- Racketeer Influenced & Corrupt Organizations (RICO)

The Electronic Communications Privacy Act (ECPA) is being tested more today than ever before. The ECPA prohibits all monitoring of wire, oral, and electronic communications unless specific statutory exceptions apply. This includes monitoring of e-mail, network traffic, keystrokes, or telephone systems. The ECPA was not meant to prohibit network providers from monitoring and maintaining their networks and connections, thus the ECPA provides an exception for monitoring network traffic for legitimate businesses purposes. Additionally, the ECPA also allows monitoring when the network users are notified of the monitoring process.

The two new Acts enacted in 1996, the Child Pornography Prevention Act (CPPA) and the Electronic Espionage Act (EEA) have proved that the legislative process is working, albeit a bit slower than one would like. The

CPPA is especially impressive in that it eradicates many of the loopholes afforded by newer technology. The CPPA was enacted specifically to combat the use of computer technology to produce pornography that conveys the impression that children were used in the photographs or images, even if the participants are actually adults. The Court held that any child pornography, including simulated or morphed images, stimulate the sexual appetites of pedophiles and that the images themselves may persuade a child to engage in sexual activity by viewing other children. The CPPA was contested by the Freedom of Speech Coalition (FSC), but was upheld by the Court in FSC v. Reno.

The EEA hopefully will curtail some of the industrial espionage that is going on today, but it will also have an impact on how business is conducted in the United States, especially intelligence gathering. According to the EEA, it is a criminal offense to take, download, receive, or possess trade secret information obtained without the owner's authorization. Penalties can reach $10 Million in fines, up to 15 years in prison, and forfeiture of property used in the commission of the crime. This could have tremendous, far-reaching consequences for businesses should an employee improperly use information gained from any previous employment.

Civil Law

Civil law (or tort law) identifies a tort as a wrong against an individual or business, which normally results in damage or loss to that individual or business. The major differences between criminal and civil law, are the type of punishment and the level of proof required to obtain a guilty verdict. There is no jail sentence under the civil law system. A victim may receive financial or injunctive relief as restitution for their loss. An injunction against the offender will attempt to thwart any further loss to the victim. Additionally, a violation of the injunction may result in a Contempt of Court order, which would place the offender in jeopardy of going to jail. The main purpose for seeking civil remedy is for financial restitution, which can be awarded as follows:

- Compensatory Damages
- Punitive Damages
- Statutory Damages

In a civil action, if there is no culpability on the part of the victim, the victim may be entitled to compensatory (restitution), statutory, and punitive damages. Compensatory damages are actual damages to the victim and include attorney fees, lost profits, investigation costs, etc. Punitive damages are just that — damages set by the jury, with the intent to punish the offender. Even if the victim is partially culpable, an award may be made on the victim's behalf, but may be lessened due to the victim's culpable

negligence. Statutory damages are damages determined by law. Mere violation of the law entitles the victim to a statutory award.

Civil cases are much easier to convict under because the burden of proof required for a conviction is much less. To be found guilty of a civil wrong, the jury must believe, based only upon the preponderance of the evidence, that the offender is guilty of the offense. It is much easier to show that the majority (51%) of the evidence is pointing to the defendant's guilt.

Finally, just as a Search Warrant is used by law enforcement as a tool in the criminal investigation, the Court can issue an Inpoundment Order or Writ of Possession, which is a court order to take back the property in question. The investigator should also keep in mind that the criminal and civil case could take place simultaneously, thus allowing items seized during the execution of the Search Warrant to be used in the civil case.

Insurance

An insurance policy is generally part of an organization's overall risk mitigation/management plan. The policy offsets the risk of loss to the insurance company in return for an acceptable level of loss (the insurance premium). Since many computer-related assets (software and hardware) account for the majority of an organization's net worth, they must be protected by insurance. If there is a loss to any of these assets, the insurance company is usually required to pay out on the policy. One important factor to bear in mind, is the principle of culpable negligence. This places part of the liability on the victim if the victim fails to follow a "standard of due care" in the protection of identified assets. If a victim organization is held to be culpably negligent, the insurance company may be required to pay only a portion of the loss. Also, an insurance company can attempt to deny coverage, arguing that an employee's "dishonest" acts caused the damage.

Two important insurance issues related to the investigation are prompt notification of the loss and understanding that the insurance company has a duty to defend. Regarding prompt notification, insurance companies may deny coverage by arguing that the claim was received too late. Some states even allow insurance companies to void its insurance obligations if the notice or claim is proven to be late.

RULES OF EVIDENCE

Before delving into the investigative process and computer forensics, it is essential that the investigator have a thorough understanding of the Rules of Evidence. The submission of evidence in any type of legal proceeding generally amounts to a significant challenge, but when computers are involved, the problems are intensified. Special knowledge is needed to locate and collect evidence and special care is required to preserve and

transport the evidence. Evidence in a computer crime case may differ from traditional forms of evidence inasmuch as most computer-related evidence is intangible—in the form of an electronic pulse or magnetic charge.

Before evidence can be presented in a case, it must be competent, relevant and material to the issue and it must be presented in compliance with the rules of evidence. Anything which tends to prove directly or indirectly, that a person may be responsible for the commission of a criminal offense may be legally presented against him. Proof may include the oral testimony of witnesses or the introduction of physical or documentary evidence.

By definition, **evidence** is any species of proof or probative matter, legally presented at the trial of an issue, by the act of the parties and through the medium of witnesses, records, documents, objects, etc., for the purpose of inducing belief in the minds of the court and jurors as to their contention. In short, evidence is anything offered in court to prove the truth or falsity of a fact at issue. This section will cover each of the Rules of Evidence as they relate to computer crime investigations.

Types of Evidence

There are many types of evidence that can be offered in court to prove the truth or falsity of a given fact. The most common forms of evidence are direct, real, documentary and demonstrative. Direct evidence is oral testimony, whereby the knowledge is obtained from any of the witness's five senses and is, in itself, proof or disproof of a fact in issue. Direct evidence is called to prove a specific act (i.e. Eye Witness Statement). Real Evidence, also known as associative or physical evidence, is made up of tangible objects that prove or disprove guilt. Physical evidence includes such things as tools used in the crime, fruits of the crime, perishable evidence capable of reproduction, etc. The purpose of the physical evidence is to link the suspect to the scene of the crime. It is this evidence which has material existence and can be presented to the view of the court and jury for consideration. Documentary evidence is evidence presented to the court in the form of business records, manuals, printouts, etc. Much of the evidence submitted in a computer crime case is documentary evidence. Finally, demonstrative evidence is evidence used to aid the jury. It may be in the form of a model, experiment, chart, or an illustration offered as proof.

It should be noted that in order to aid the court and the jury in their quest to understand the facts at issue, demonstrative evidence is being used more often, especially in the form of simulation and animation. It is very important to understand the difference between these two types of evidence because the standard of admissibility is affected. A computer simulation is a prediction or calculation about what will happen in the future given known facts. A traffic reconstruction program is a perfect example of

computer simulation. There are many mathematical algorithms used in this type of program, that must be either stipulated to, or proven to the court to be completely accurate. It is generally more difficult to admit a simulation as evidence, because of the substantive nature of the process.

Computer animation, on the other hand, is simply a computer-generated sequence, illustrating an expert's opinion. Animation does not predict future events. It merely supports the testimony of an expert witness through the use of demonstrations. An animation of a hard disk spinning, while the read/write heads are reading data, can help the court or jury understand how a disk drive works. There are no mathematical algorithms that must be proven. The animation solely aids the court and jury through visualization. The key to having animation admitted as evidence is in the strength of the expert witness. Under Rule 702, the expert used to explain evidence must be qualified to do so through skill, training or education.

When seizing evidence from a computer-related crime, the investigator should collect any and all physical evidence, such as the computer, peripherals, notepads, documentation, etc. in addition to computer-generated evidence. There are four types of computer-generated evidence. They are

- Visual output on the monitor
- Printed evidence on a printer
- Printed evidence on a plotter
- Film recorder — Includes magnetic representation on disk, tape or cartridge, and optical representation on CD

Best Evidence Rule

The Best Evidence Rule, which had been established to deter any alteration of evidence, either intentionally or unintentionally, states that the court prefers the original evidence at the trial, rather than a copy, but they will accept a duplicate under the following conditions:

- Original lost or destroyed by fire, flood or other acts of God. This has included such things as careless employees or cleaning staff.
- Original destroyed in the normal course of business
- Original in possession of a third party who is beyond the court's subpoena power

This rule has been relaxed to now allow duplicates unless there is a genuine question as to the original's authenticity, or admission of the duplicate would under the circumstances be unfair.

Exclusionary Rule

Evidence must be gathered by law enforcement in accordance with court guidelines governing search and seizure or it will be excluded (Fourth

Amendment). Any evidence collected in violation of the Fourth Amendment is considered to be "Fruit of the Poisonous Tree," and will not be admissible. Furthermore, any evidence identified and gathered as a result of the initial inadmissible evidence will also be held to be inadmissible. Evidence may also be excluded for other reasons, such as violations of the Electronic Communications Privacy Act (ECPA) or violations related to provisions of Chapters 2500 and 2700 of Title 18 of the United States Penal Code.

Private citizens are not subject to the Fourth Amendment's guidelines on search and seizure, but are exposed to potential exclusions for violations of the ECPA or Privacy Act. Therefore, internal investigators, private investigators, and Computer Emergency Response Team (CERT) team members should take caution when conducting any internal search, even on company computers. For example, if there were no policy in place explicitly stating the company's right to electronically monitor network traffic on company systems, then internal investigators would be well advised not to set up a sniffer on the network to monitor such traffic. To do so may be a violation of the ECPA.

Hearsay Rule

A legal factor of computer-generated evidence is that it is considered hearsay. Hearsay is second-hand evidence; evidence which is not gathered from the personal knowledge of the witness but from another source. Its value depends on the veracity and competence of the source. The magnetic charge of the disk or the electronic bit value in memory, which represents the data, is the actual, original evidence. The computer-generated evidence is merely a representation of the original evidence.

Under the US Federal Rules of Evidence, all business records, including computer records, are considered "hearsay" because there is no firsthand proof that they are accurate, reliable, and trustworthy. In general, hearsay evidence is not admissible in court. However, there are some well-established exceptions (Rule 803) to the hearsay rule for business records. In Rosenberg v. Collins, the court held that if the computer output is used in the regular course of business, then the evidence shall be admitted.

Business Record Exemption to the Hearsay Rule

US Federal Rules of Evidence 803(6) allows a court to admit a report or other business document made at or near the time by, or from information transmitted by, a person with knowledge, if kept in the course of regularly conducted business activity, and if it was the regular practice of that business activity to make the [report or document], all as shown by testimony of the custodian or other qualified witness, unless the source of information or the method or circumstances of preparation indicate lack of trustworthiness.

To meet Rule 803 (6) the witness must:

- Have custody of the records in question on a regular basis
- Rely on those records in the regular course of business
- Know that they were prepared in the regular course of business

Audit trails would meet the criteria if they were produced in the normal course of business. The process to produce the output will have to be proven to be reliable. If computer-generated evidence is used and admissible, the court may order disclosure of the details of the computer, logs, maintenance records, etc. in respect to the system generating the printout, and then the defense may use that material to attack the reliability of the evidence. If the audit trails are not used or reviewed (at least the exceptions — i.e., failed log-on attempts) in the regular course of business, then they may not meet the criteria for admissibility.

US Federal Rules of Evidence 1001 (3) provides another exception to the Hearsay Rule. This rule allows a memory or disk dump to be admitted as evidence, even though it is not done in the regular course of business. This dump merely acts as statement of fact. System dumps (in binary or hexidecimal) would not be hearsay because it is not being offered to prove the truth of the contents, but only the state of the computer.

Chain of Evidence (Custody)

Once evidence is seized, the next step is to provide for its accountability and protection. The Chain of Evidence, which provides a means of accountability, must be adhered to by law enforcement when conducting any type of criminal investigation, including a computer crime investigation. It helps to minimize the instances of tampering. The Chain of Evidence must account for all persons who handled or who had access to the evidence in question.

The Chain of Evidence shows:

- Who obtained the evidence
- Where and when the evidence was obtained
- Who secured the evidence
- Who had control or possession of the evidence

It may be necessary to have anyone associated with the evidence testify at trial. Private citizens are not required to maintain the same level of control of the evidence as law enforcement although they would be well advised to do so. Should an internal investigation result in the discovery and collection of computer-related evidence, the investigation team should follow the same, detailed chain of evidence as required by law enforcement. This will help to dispel any objection by the defense, that the evidence is unreliable, should the case go to court.

Admissibility of Evidence

The admissibility of computer-generated evidence is, at best, a moving target. Computer-generated evidence is always suspect because of the ease with which it can be tampered—usually without a trace! Precautionary measures must be taken in order to ensure that computer-generated evidence has not been tampered with, erased, or added to. In order to ensure that only relevant and reliable evidence is entered into the proceedings, the judicial system has adopted the concept of admissibility.

- *Relevancy of Evidence* — evidence tending to prove or disprove a material fact. All evidence in court must be relevant and material to the case.
- *Reliability of Evidence* — The evidence and the process to produce the evidence must be proven to be reliable. This is one of the most critical aspects of computer-generated evidence.

Once computer-generated evidence meets the Business Record Exemption to the hearsay rule, is not excluded for some technicality or violation, follows the Chain of Custody, and is found to be both relevant and reliable, then it is held to be admissible. The defense will attack both the relevancy and reliability of the evidence, so great care should be taken to protect both.

Evidence Life Cycle

The Evidence Life Cycle starts with the discovery and collection of the evidence. It progresses through the following series of states until it is finally returned to the victim or owner:

- Collection and Identification
- Analysis
- Storage, Preservation and Transportation
- Presented in Court
- Returned to Victim (Owner)

Collection and Identification. As the evidence is obtained or collected, it must be properly marked so that it can be identified as being the particular piece of evidence gathered at the scene. The collection must be recorded in a logbook identifying the particular piece of evidence, the person who discovered it, and the date, time and location discovered. The location should be specific enough for later recollection in court. All other types of identifying marks, such as make, model or serial number, should also be logged. It is of paramount importance to list any type of damage to the particular piece of evidence. This is not only for identification purposes, but it will also limit any potential liability should a claim be made later on that you damaged the evidence. When marking evidence, the following guidelines should be followed:

- Mark the actual piece of evidence if it will not damage the evidence, by writing or scribing your initials, the date and the case number if known. Seal this evidence in the appropriate container and again, mark the container by writing or scribing your initials, the date and the case number, if known.
- If the actual piece of evidence cannot be marked, then seal the evidence in an appropriate container, then mark the container by writing or scribing your initials, the date and the case number, if known.
- The container should be sealed with evidence tape and your marking should write over the tape, so that if the seal is broken it can be noticed.
- Be extremely careful not to damage the evidence while engraving or marking the piece.

When marking glass or metal, a diamond scriber should be used. For all other objects, a felt tip pen with indelible ink is recommended. Dependent on the nature of the crime, the investigator may wish to preserve latent fingerprints. If so, static free gloves should be used if working with computer components, instead of standard latex gloves.

Try to always mark evidence the same way, because you will be asked to testify to the fact that you are the person identified by the evidence markings. Keep in mind, that the defense is going to try to discredit you as a witness or try some way to keep the evidence out of court, so something as simple as quick, positive identification of your mark is largely beneficial to the your case.

Storage, Preservation, and Transportation. All evidence must packed and preserved to prevent contamination. It should be protected against heat, extreme cold, humidity, water, magnetic fields, and vibration. The evidence must be protected for future use in court and for return to the original owner. It the evidence is not properly protected, the person or agency responsible for the collection and storage of the evidence may be held liable for damages. Therefore, the proper packing materials should be used whenever possible. Documents and disks (hard, floppy, optical, tapes, etc.) should be seized and stored in appropriate containers to prevent their destruction. For example, hard disks should be packed in a sealed, static-free bag, within a cardboard box with a foam container. The box should be sealed with evidence tape and an Electromagnetic Field (EMF) warning label should be affixed to the box. It may be wise to defer to the system administrator or a technical advisor on how to best protect a particular type of system, especially mini-systems or mainframes.

Finally, evidence should be transported to a location where it can be stored and locked. Sometimes the systems are too large to transport, thus the forensic examination of the system may need to take place on site.

Presented in Court. Each piece of evidence that is used to prove or disprove a material fact needs to be presented in court. After the initial seizure, the evidence is stored until needed for trial. Each time the evidence is transported to and from the courthouse for the trial, it needs to be handled with the same care as with the original seizure. Additionally, the Chain of Custody must continue to be followed. This process will continue until all testimony related to the evidence is completed. Once the trail is over, the evidence can be returned to the victim (owner).

Returned to Victim (Owner). The final destination of most types of evidence is back with its original owner. Some types of evidence, such as drugs or paraphernalia (i.e. contraband) are destroyed after the trial. Any evidence gathered during a search, even though maintained by law enforcement, is legally under the control of the courts. Even though a seized item may be yours and may even have your name on it, it may not be returned to you unless the suspect signs a release or after a hearing by the court. Unfortunately, many victims don't want to go to trial. They just want to get their property back.

Many investigations merely need the information on a disk to prove or disprove a fact in question, thus there is no need to seize the entire system. Once a schematic of the system is drawn or photographed, the hard disk can be removed and then transported to a forensic lab for copying. Mirror copies of the suspect disk are obtained using forensic software and then one of those copies can be returned to the victim so that business operations can resume.

COMPUTER CRIME INVESTIGATION

The computer crime investigation should start immediately following the report of any alleged criminal activity. Many processes ranging from reporting and containment to analysis and eradication need to be accomplished as soon as possible after the attack. An Incident Response Plan should be formulated and a Computer Emergency Response Team (CERT) should be organized prior to the attack. The Incident Response Plan will help set the objective of the investigation and will identify each of the steps in the investigative process.

The use of a Corporate CERT Team is invaluable. Due to the numerous complexities of any computer-related crime, it is extremely advantageous to have a single group that is acutely familiar with the Incident Response Plan to call upon. The CERT team should be a technically astute group, that is knowledgeable in the area of legal investigations, the Corporate Security Policy (especially the Incident Response Plan), the severity levels of various attacks, and the company position on information dissemination and disclosure.

The Incident Response Plan should be part of the overall Corporate Computer Security Policy. The plan should identify reporting requirements, severity levels, guidelines to protect the crime scene and preserve evidence, etc. The priorities of the investigation will vary from organization to organization but the issues of containment and eradication are reasonably standard, that is to minimize any additional loss and resume business as quickly as possible. The following sections describe the investigative process starting with the initial detection.

Detection and Containment

Although intrusion detection is covered elsewhere in this manual, it must be mentioned that before any investigation can take place, the system intrusion or abusive conduct must first be detected. The closer the detection is to the actual intrusion event will not only help to minimize system damage, but will also assist in the identification of potential suspects.

To date, most computer crimes have either been detected by accident or through the laborious review of lengthy audit trails. While audit trails can assist in providing user accountability, their detection value is somewhat diminished because of the amount of information that must be reviewed and because these reviews are always post-incident. Accidental detection is usually made through observation of increased resource utilization or inspection of suspicious activity, but again, is not effective due to the sporadic nature of this type of detection.

These types of reactive or passive detection schemes are no longer acceptable. Proactive and automated detection techniques need to be instituted in order to minimize the amount of system damage in the wake of an attack. Real-time intrusion monitoring can help in the identification and apprehension of potential suspects and automated filtering techniques can be used to make audit data more useful.

Once an incident is detected it is essential to minimize the risk of any further loss. This may mean shutting down the system and reloading clean copies of the operating system and application programs. It should be noted, that failure to contain a known situation (i.e. system penetration) might result in increased liability for the victim organization. For example, if a company's system has been compromised by an external attacker and the company failed to shut down the intruder, hoping to trace him, the company may be held liable for any additional harm caused by the attacker.

Report to Management

All incidents should be reported to management as soon as possible. Prompt internal reporting is imperative in order to collect and preserve

potential evidence. It is important that information about the investigation be limited to as few people as possible. This should be done on a need-to-know basis. This limits the possibility of the investigation being leaked. Additionally, all communications related to the incident should be made via an out-of-band method to ensure the intruder does not intercept any incident-related information. In other words, do not use e-mail to discuss the investigation on a compromised system. Based on the type of crime and type of organization it may be necessary to notify:

- Executive Management
- Information Security Department
- Physical Security Department
- Internal Audit Department
- Legal Department

Preliminary Investigation

A preliminary internal investigation is necessary for all intrusions or attempted intrusions. At a minimum, the investigator must ascertain if a crime has occurred; and if so, he must identify the nature and extent of the abuse. It is important for the investigator to remember that the alleged attack or intrusion may not be a crime at all. Even if it appears to be some form of criminal conduct, it could merely be an honest mistake. Most internal losses occur from errors, not from overt criminal acts. There is no quicker way to initiate a lawsuit than to mistakenly accuse an innocent person of criminal activity.

The preliminary investigation usually involves a review of the initial complaint, inspection of the alleged damage or abuse, witness interviews, and, finally, examination of the system logs. If during the preliminary investigation, it is determined that some alleged criminal activity has occurred, the investigator must address the basic elements of the crime to ascertain the chances of successfully prosecuting a suspect either civilly or criminally. Additionally, the investigator must identify the requirements of the investigation (dollars and resources). If it is believed that a crime has been committed, neither the investigator nor any other company personnel should confront or talk with the suspect. Doing so would only give the suspect the opportunity to hide or destroy evidence.

Determine if Disclosure is Required

It must be determined if a disclosure is required or warranted, due to laws or regulations. Disclosure may be required by law or regulation or may be required if the loss affects a corporation's financial statement. Even if disclosure is not required, it is sometimes better to disclose the attack to possibly deter future attacks. This is especially true if the victim organization

prosecutes criminally and/or civilly. Some of the following attacks would probably result in disclosure:

- Large Financial Loss of a Public Company
- Bank Fraud
- Public Safety Systems (i.e. Air Traffic Control)

The Federal Sentencing Guidelines also require organizations to report criminal conduct. The stated goals of the Commission were to "provide just punishment, adequate deterrence, and incentives for organizations to maintain internal mechanisms for preventing, detecting, and reporting criminal conduct." The Guidelines also state that organizations have a responsibility to "maintain internal mechanism for preventing, detecting, and reporting criminal conduct." The Federal Sentencing Guidelines do not prevent an organization from conducting preliminary investigations to ascertain if, in fact, a crime has been committed. One final note of the Federal Sentencing Guidelines, is that they were designed to punish computer criminals for acts of recidivism and using their technical skills and talents to engage in criminal activity.

If the decision is made to disclose an alleged incident or intrusion, be sure to be especially careful when dealing with the media. The media has a history of sensationalizing these types of events and can easily distort the facts that could portray the victim organization as the "Goliath," using the "David v. Goliath" analogy. Make sure that you have all the facts and provide the media with the "slant" that best serves your purposes. Do not lie to the media! A "No Comment" is better then lying.

Investigation Considerations

Once the preliminary investigation is complete and the victim organization has made a decision related to disclosure, the organization must decide on the next course of action. The victim organization may decide to do nothing or they may attempt to eliminate the problem and just move on. Deciding to do nothing is not a very good course of action as the organization may be held to be culpably negligent should another attack or intrusion occur. The victim organization should at least attempt to eliminate the security hole that allowed the breach, even if they do not plan to bring the case to court. If the attack is internal, the organization may wish to conduct an investigation that might only result in the dismissal of the subject. If they decide to further investigate the incident, they must also determine if they are going to prosecute criminally or civilly, or are they merely conducting the investigation for insurance purposes. If an insurance claim is to be submitted, a police report is usually necessary.

When making the decision to prosecute a case, the victim must clearly understand the overall objective. If the victim is looking to make a point by

punishing the attacker, then a criminal action is warranted. This is one of the ways to deter potential future attacks. If the victim were seeking financial restitution or injunctive relief, then a civil action would be appropriate. Keep in mind that a civil trial and criminal trial can happen in parallel. Information obtained during the criminal trial can be used as part of the civil trial. The key is to know what you want to do at the outset, so all activity can be coordinated.

The evidence or lack thereof, may also hinder the decision to prosecute. Evidence is a significant problem in any legal proceeding, but the problems are compounded when computers are involved. Special knowledge is needed to locate and collect the evidence while special care is required to preserve the evidence.

There are many factors to consider when deciding upon whether or not to further investigate an alleged computer crime. For many organizations, the primary consideration will be the cost associated with an investigation. The next consideration will probably be the impact to operations or the impact to business reputation. The organization must answer the following questions:

- Will productivity be stifled by inquiry process?
- Will the subject system have to be shut down to conduct an examination of the evidence or crime scene?
- Will any of the system components be held as evidence?
- Will proprietary data be subject to disclosure?
- Will there be any increased exposure for failing to meet a "standard of due care"?
- Will there be any adverse publicity related to the loss?
- Will a disclosure invite other perpetrators to commit similar acts or will an investigation and subsequent prosecution deter future attacks?

The answers to these questions may have an impact on how the investigation is handled and who is called in to conduct the investigation. Furthermore, these issues must be addressed early on, so that the proper authorities can be notified if required. Prosecuting an alleged criminal offense is a very time consuming task. Law enforcement and the prosecutor will expect a commitment of time and resources for the following:

- Interviews to prepare crime reports and search warrant affidavits
- Engineers or computer programmers to accompany law enforcement on search warrants
- Assistance of the victim company to identify and describe documents, source code, and other found evidence
- A company expert who may needed for explanations and assistance during the trial

- Discovery — Documents may need to be provided to the defendant's attorney for discovery. They may ask for more than you want to provide. Your attorney will have to argue against broad ranging discovery. Defendants are entitled to seek evidence they need for their defense.
- You and other company employees will be subpoenaed to testify.

Who Should Conduct the Investigation?

Based upon the type of investigation (i.e. civil, criminal, insurance, or administrative) and extent of the abuse, the victim must decide who is to conduct the investigation. This used to be a fairly straightforward decision, but high-technology crime has altered the decision making process. Inadequate and untested laws combined with the lack of technical training and technical understanding, has severely hampered the effectiveness of our criminal justice system when dealing with computer-related crimes.

In the past, society would adapt to change, usually at the same rate of that change. Today, this is no longer true. The information age has ushered in dramatic technological changes and achievements, which continue to evolve at exponential rates. The creation, the computer itself, is being used to create new technologies or advance existing ones. This cycle means that changes in technology will continue to occur at an ever-increasing pace. What does this mean to the system of law? It means we have to take a look at how we establish new laws. We must adapt the process to account for the excessive rate of change. Unfortunately, this is going to take time! In the mean time, if they are to launch an investigation, the victim must choose from the following options:

- Conduct an internal investigation
- Bring in external private consultants/investigations
- Bring in local/state/federal law enforcement

Exhibit 1 identifies each of the tradeoffs.

Law enforcement officers have greater search and investigative capabilities than private individuals, but they also have more restrictions than private citizens. For law enforcement to conduct a search, a warrant must first be issued. No warrant is needed if the victim or owner of compromised system gives permission to conduct the search. Issuance of the search warrant is based upon probable cause (reason to believe the something is true). Once probable cause has been identified, law enforcement officers have the ability to execute search warrants, subpoenas and wire taps. The warrant process was formed in order to protect the rights of the people. The Fourth Amendment to the Constitution of the United States established the following:

Group	Cost	Legal Issues	Information Dissemination	Investigative Control
Internal Investigators	Time/People Resources	Privacy Issues Limited Knowledge of Law and Forensics	Controlled	Complete
Private Consultants	Direct Expenditure	Privacy Issues	Controlled	Complete
Law Enforcement Officers	Time/People Resources	Fourth Amendment Issues Jurisdiction Miranda Privacy Issues	Uncontrolled Public Information (FOIA)	None

Exhibit 1. Tradeoffs for Three Options Compensating for Rate of Change

---

The right of the people to be secure in their persons, houses, papers, and effects, against unreasonable searches and seizures, shall not be violated, and no Warrants shall issue, but upon probable cause, supported by oath or affirmation, and particularly describing the place to be searched, and the persons or things to be seized.

There are certain exceptions to this. The "exigent circumstances" doctrine allows for a warrantless seizure, by law enforcement, when the destruction of evidence is impending. In United States v. David, the court held that "When destruction of evidence is imminent, a warrantless seizure of that evidence is justified if there is probable cause to believe that the item seized constitutes evidence of criminal activity."

Internal investigators (non-government) or private investigators, acting as private citizens, have much more latitude in conducting a warrantless search, due to a ruling by the Supreme Court, in Burdeau v. McDowell. In this case, the Supreme Court held that evidence obtained in a warrantless search, could be presented to a grand jury by a government prosecutor, because there was no unconstitutional government search and hence no violation of the fourth amendment.

Normally, a private (party) citizen is not subject to the rules and laws governing search and seizure, but a private citizen becomes a police agent, and the Fourth Amendment applies, when:

- the private party performs a search which the government would need a search warrant to conduct;
- the private party performs that search to assist the government, as opposed to furthering its own interest; and
- the government is aware of that party's conduct and does not object to it.

The purpose of this doctrine is to eliminate the opportunity for government to circumvent the warrant process by eliciting the help of a private citizen. If a situation required law enforcement to obtain a warrant, due to the subject's expectations of privacy, and the government knowingly allowed a private party to conduct a search in order to disclose evidence, the court would probably rule that the private citizen acted as a police agent. A victim acting to protect its property by assisting police to prevent or detect a crime does not become a police agent.

Law enforcement personnel are not alone in their ability to obtain a warrant. A private party can also obtain a warrant, albeit a civil one, to search and seize specifically identified property which they make claim to. This civil warrant, also known as a Writ of Possession, allows the plaintiff to seize property that is rightfully theirs. In order to obtain such a court order, the plaintiff much prove to a judge or magistrate that the property in question is theirs and that an immediate seizure is essential to minimizing any collateral monetary loss. Additionally, the plaintiff must also post a bond, double the value of the property in question. This places an enormous burden on the plaintiff, should they be unsuccessful in their endeavor, but it also protects individuals and businesses against frivolous requests made to the court.

The biggest issues affecting the decision on who to bring in (in order of priority) are information dissemination, investigative control, cost, and the associated legal issues. Once an incident is reported to law enforcement, information dissemination becomes uncontrolled. The same holds true for investigative control. Law enforcement controls the entire investigation, from beginning to end. This is not always bad, but the victim organization may have a different set of priorities. Cost is always a concern and the investigation costs only add to the loss initially sustained by the attack or abuse. Even law enforcement agencies, which are normally considered "free," add to the costs because of the technical assistance they require during the investigation.

Another area that affects law enforcement is jurisdiction. Jurisdiction is the geographic area where the crime had been committed and any portion

of the surrounding area over, or through which the suspect passed, is enroute to, or going away from, the actual scene of the crime. Any portion of this area adjacent to the actual scene over which the suspect, or the victim, might have passed, and where evidence might be found, is considered part of the crime scene. When a system is attacked remotely, where did the crime occur? Most courts submit that the crime scene is the victim's location. But what about "enroute to"? Does this suggest that a crime scene may also encompass the telecommunications path used by the attacker? If so, and a theft occurred, is this interstate transport of stolen goods? There seem to be more questions than answers but only through cases being presented in court can precedence be set. It will take time for the answers to shake out.

There are advantages and disadvantages to each of the groups identified above. Internal investigators will know your systems the best, but may lack some of the legal and forensic training. Private investigators, who specialize in high-technology crime, also have a number of advantages, but usually result in higher costs. Private security practitioners and private investigators are also private businesses and may be more sensitive to business resumption than law enforcement. If you elect to retain the services of a private investigator or computer consultant, it is best if your corporate counsel retains them. This protects the victim organization from unwarranted or untimely disclosure. All communications are treated as privileged communications, under the Attorney-Client Privilege. Additionally, all work product is protected by the same privilege and is protected from disclosure. This includes details of the investigation, witness interviews, forensic analysis, etc. It also includes any past criminal activity, by the victim organization, which may be uncovered during the investigation.

Should you decide to contact your local police department, call the detective unit directly. Chances are you will get someone who is more experienced and knowledgeable and someone who can be more discrete. If you call 911, a uniformed officer will arrive on your doorstep and possibly alert the attacker. Furthermore, the officer must create a report of the incident that will become part of a public log. Now the chances for a discretionary dissemination of information and a covert investigation are gone.

Ask the detective to meet with you in plain clothes. When they arrive at your business have them announce themselves as consultants. If you decide that you would like Federal authorities to be present, do so, but you should inform the local law enforcement authorities. Be aware that your local law enforcement agency may not be well equipped to handle high-tech crime. The majority of law enforcement agencies have limited budgets and, as such, place an emphasis on problems related to violent crime and drugs. Also, with technology changing so rapidly, most law enforcement

officers lack the technical training to adequately investigate an alleged intrusion.

The same problems hold true for the prosecution and the judiciary. To successfully prosecute a case, both the prosecutor and the judge must have a reasonable understanding of high-tech laws and the crime in question. This is not always the case. Additionally, many of the current laws are woefully inadequate. Even though an action may be morally and ethically wrong, it is still possible that no law is violated (i.e. LaMacchia case). Even when there is a law that has been violated, many of these laws remain untested and lack precedence. Because of this many prosecutors are reluctant to prosecute high-tech crime cases.

Many recent judicial decisions have indicated that judges are lenient towards techno-criminal just as with other white-collar criminals. Furthermore, the lack of technology expertise may cause "doubt," thus rendering "not guilty" decisions. Since many of the laws concerning computer crime are new and untested, many judges have a concern with setting precedence, which may later be overturned in an appeal. Some of the defenses that have been used, and accepted by the judiciary, are

- If you have no system security or lax system security, then you are implying that there is no company concern. Thus there should be no court concern.
- If a person is not informed that access is unauthorized, then it can be used as a defense.
- If an employee is not briefed and does not acknowledge understanding of policy and procedures, then they can use it as a defense.

The Investigative Process

As with any type of criminal investigation the goal of the investigation is to know who, what, when, where, why, and how. It is important that the investigator logs all activity and account for all time spent on the investigation. The amount of time spent on the investigation has a direct impact on the total dollar loss for the incident. This may result in greater criminal charges and, possibly, stiffer sentencing. Finally, the money spent on investigative resources can be reimbursed as compensatory damages in a successful civil action.

Once the decision is made to further investigate the incident, the next course of action for the investigative team is to establish a detailed investigative plan, including the search and seizure plan. The plan should consists of an informal strategy that will be employed throughout the investigation, including the search and seizure:

- Identify any potential suspects
- Identify potential witnesses
- Identify what type of system is to be seized
- Identify the Search and Seizure Team Members
- Obtain a Search Warrant (if required)
- Determine if there is risk of the suspect destroying evidence or causing greater losses

Identify Any Potential Suspects. The type of crime and the type of attacker will set the stage for the overall investigation. Serious attacks against government sites, military installations, financial centers, or a telecommunications infrastructure must be met with the same fervor as that of a physical terrorist attack. Costs will not be the issue. On the other hand, when an organization plans to conduct an investigation pertaining to unauthorized access or a violation of company policy all the factors should considered. This includes the anticipated cost and the chances of success. In either case, there will always be the usual suspects: insiders and outsiders.

Insiders are usually trusted users who abuse their level of authorized access to the system. They are normally the greatest source of loss. They know the value of your assets! They are usually motivated by greed, need (i.e. drug habit, gambling problem, divorce, etc.), or perceived grievance. Most importantly that have the access and the opportunity. Outsiders, as the name implies, attack your systems and networks from the outside. They attack systems for a variety of reasons, with attacks increasing at alarming rates because of advancements such as the Internet. Some examples of Outsiders are as follows:

- Hackers and Crackers
- Organized Crime
- Terrorists
- Pedophiles
- Industrial/Corporate Spies

While, individually, each of these groups continue to be a problem, it is especially disturbing to realize the potential for collaboration between any two or more of the groups. When organized crime groups or terrorist factions gain access to the technical expertise provided by hackers and crackers, the potential for widespread harm and exorbitant financial losses is intensified. Albert Einstein said it best when he said, "Technological progress is like an axe in the hands of a pathological criminal."

When commencing with the investigation, it is important to understand how and why a system is being attacked. The how will provide you with information pertaining to technical expertise required to conduct the

attack. The why will potentially indicate motive. The how and why together, along with the when and the where, may provide the who.

Identify Potential Witnesses. It is important to identify potential witnesses early on in the investigation. It is just as important not to alert the suspect to the investigation, therefore selecting whom will be interviewed and when may have an impact on the investigation. The key to obtaining good witness statements is to ascertain the facts in the case, not opinions. Also, it is wise not to ask leading questions. Sources of information may be staff members, expert witnesses, associates, etc. Interviews are not the same as interrogations and great care should go into not confusing the two. If a hostile witness does not want to be interviewed, then the process should cease immediately. If a witness or potential witness is detained against their will, there may be criminal and/or civil liability to the individuals and business responsible for the investigation. Never intimidate, coerce, or harass a potential witness.

Technically competent personnel should conduct interviews of technical witnesses or suspects. A potential suspect, who is technically competent, will have a field day if interviewed by a non-technical investigator. Many times these individuals are arrogant to start with. If they feel that they have the upper hand, because of their "esoteric knowledge," they may be less inclined to provide a truthful statement. Also, it is sometimes better to interview a technical suspect (i.e. programmer) first, before seizing his system. If you advise the suspect that you will be seizing his systems if he does not cooperate, he may assist in the investigation.

One final note on conducting interviews. It is always a good idea to have the witness write out and sign their statement, in their own handwriting. This statement can then be types for better readability, but you can always point to the original. This helps to counter statements made by the witness in court, that that is not what they meant.

Identify the Type of System That Is to Be Seized. It is imperative to learn as much as possible about the target computer system(s). If possible, obtain the configuration of the system, including the network environment (if any), hardware, and software. The following data should be acquired prior to the seizure:

- Identify system experts. Make them part of the team.
- Is a security system in place on the system, If so, what kind? Are passwords used? Can a root password be obtained?
- Where is the system located? Will simultaneous raids be required?
- Obtain the required media supplies in advance of the operation
- What law has been violated? Discuss the elements of proof. These should be the focus of the search and seizure.

- What is your Probable Cause? Obtain a warrant if necessary.
- Determine if the analysis of the computer system will be conducted on site or back in the office or forensics lab.

Identify the Search and Seizure Team Members. There are different rules for Search and Seizure based upon who's conducting the search. Under the Fourth Amendment, law enforcement must obtain a warrant, which must be based on probable cause. Regardless of who's conducting the Search and Seizure, a team should be identified and should consist of the following members:

- Lead Investigator
- Information Security Department
- Legal Department
- Technical Assistance — System Administrator as long as he is not a suspect

If a Corporate CERT Team is already organized, then this process is already complete. A Chain of Command needs to be established and it must be determined who is to be in charge. This person is responsible for delegating assignments to each of the team members. A media liaison should be identified if the attack is to be disclosed. This will control the flow of information to the media.

Obtaining and Serving Search Warrants. If it is believed that the suspect has crucial evidence at his home or office, then a search warrant will be required to seize the evidence. If a search warrant is going to be needed, then it should be done as quickly as possible before the intruder can do further damage. The investigator must establish that a crime has been committed and that the suspect is somehow involved in the criminal activity. He must also show why a search of the suspect's home or office is required. The victim may be asked to accompany law enforcement when serving the warrant to identify property or programs.

If you must take along documents with you when serving the Search Warrant, consider coping them onto a colored paper to prevent the defense from inferring that what you might have found was left by you.

Is the System at Risk. Prior to the execution of the plan, the investigative team should ascertain if the suspect, if known, is currently working on the system. If so, the team must be prepared to move swiftly, so that evidence is not destroyed. The investigator should determine if the computer is protected by any physical or logical access control systems and be prepared to respond to such systems. It should also be decided early on, what will be done if the computer is on at the commencement of the seizure. The goal

of this planning is to minimize any risk of evidence contamination or destruction.

Executing the Plan

The first step in executing the plan is to secure and control the scene. This includes securing the power, network servers, and telecommunications links. If the suspect is near the system, it may be necessary to physically remove him. It may be best to execute the search and seizure after normal business hours to avoid any physical confrontation. Keep in mind, that even if a search is conducted after hours, the suspect may still have remote access to the system via a LAN-based modem connection, PC-based modem connection, wireless modem connection, or Internet connection. Many times it is required to seize a disk from the suspects computer, mirror image a copy of the disk and then replace the original with a copy of the disk, all without the suspect knowing what is happening. This allows the investigative team to protect the evidence and continue with the investigation, while retaining secrecy of the investigation.

Enter the area slowly so as not to disturb or destroy evidence. Evaluate the entire situation. In no other type of investigation, can evidence be destroyed more quickly. Do not touch the keyboard as this may invoke a Trojan Horse or some other rogue or malicious program. Do not turn off the computer unless it appears to be active (i.e. formatting the disk, deleting files, initiating some I/O process, etc.). Look for the disk activity light and listen for disk usage. If you must turn off the computer, pull the plug from the wall, rather than using the on/off switch. Look for notes, documentation, passwords, encryption codes, etc. The following questions must be answered in order to effectively control the scene:

- Is the subject system turned on?
- Is there a modem attached? If so,
  - Check for internal and wireless modems
  - Check for telephone lines connected to the computer
- Is the system connected to a LAN?

The investigator may wish to videotape the entire evidence collection process. There are two schools of thought on this. The first is that if you videotape the search and seizure, any mistakes can nullify the whole operation. The second school of thought is that if you videotape the evidence collection process, many of the claims by the defense can be silenced. In either case, be careful what you say if the audio is turned on!

Sketch and photograph the crime scene before touching anything. Sketches should be drawn to scale. Take still photographs of critical pieces of evidence. At a minimum, the following should be captured:

- The layout of desks and computers (Include dimensions and measurements)
- The configuration of the all computers on the network
- The configuration of the suspect computer, including network connections, peripheral connections, internal and external components, and system backplane
- The suspect computer display

A drawing package, such a Visio — Technical Edition, is excellent for these types of drawings. Visio allows the investigator to sketch the scene using a drag and drop graphical user interface (GUI). Most computer and network graphics, desk and furniture graphics, etc., are included with the application. The output is a professional product that is made part of the report and can be used later to recreate the environment or to present the case in court.

If the computer is on, the investigator should capture what is on the monitor. This can be accomplished by video taping what is on the screen. The best way to do this, without getting the "scrolling effect" caused by the video refresh, is to use a National Television Standards Committee (NTSC) adapter. Every monitor has a specific refresh rate (i.e. Horizontal: 30-66 KHz, Vertical: 50-90 Hz), which identifies how frequently the screen's image is redrawn. It is this redrawing process that causes the videotaped image to appear as if the vertical hold is not properly adjusted. The NTSC adapter is connected between the monitor and the monitor cable, and directs the incoming signal into the camcorder directly. The adapter converts the computer's analog signal (VGA) to a NTSC format. Still photos are a good idea too. Do not use a flash, because it can "white out" the image. Even if the computer is off, check the monitor for burnt-in images. This does not happen as much with the new monitors, but it may still help in the discovery of evidence.

Once you have reviewed and captured what's on the screen, pull the plug on the system. This is for PC-based systems only. Mini-systems or mainframes must be logically power-downed. It is best to conduct a forensic analysis (technical system review with a legal basis focused on evidence gathering) on a forensic system, in a controlled environment. If necessary, a forensic analysis can be conducted on site, but never using the suspect system's operating system or system utilities. See the section on forensic analysis for the process that should be followed.

Once the computer is turned off, remove the cover and photograph and sketch the inside of the computer. The analyst or investigator should use a static-dissipative grounding kit when working inside of the computer. You should note any peculiarities, such as booby traps. Identify each drive and its logical ID (i.e. C: drive) by tracing the ribbon cables to the I/O board.

Also identify any external drives. Once this has been completed, remove, label and pack all drives. Check the floppy drives for any media. If a disk is in the drive, remove the disk, and mark on the evidence label where it was found. Next, place a blank diskette into the floppy drive(s). Place evidence tape over the floppy drives and the on/off switch, once it is placed in the off position.

Identify, mark and pack all evidence according to the collection process under the Rules of Evidence. Identify and label all computer systems, cables, documents, disks, etc. The investigator should also seize all diskettes, backup tapes, PCMCIA disks, magnetic cartridges, optical disks, and printouts. All diskettes should be write protected. Make an entry for each in the evidence log. Check the printer. If it uses ribbons, make sure it (or at least the ribbon) is taken as evidence. Keep in mind that many of the peripheral devices may contain crucial evidence in their memory and/or buffers. Some items to consider are LAN servers, routers, printers, etc. You must check with the manufacturer on how to output the memory buffers for each device. Also, keep in mind that most buffers are stored in volatile memory. Once the power is cut, the information may be lost.

Additionally, check all drawers, closets and even the garbage for any forms of magnetic media (i.e. hard drives, floppy diskettes, tape cartridges, optical disks, etc.) or documentation. It seems that many computer literate individuals conduct most of their correspondence and work product on a computer. This is an excellent form of leads, but take care to avoid an invasion of privacy. Even media that appears to be destroyed can turn out to be quite useful. One case involved an American serviceman, who contracted to have his wife killed and wrote the letter on his computer. In an attempt to destroy all the evidence, he cut up the floppy disk, containing the letter, into 17 pieces. The Air Force Office of Special Investigations (AFOSI)was able to reconstruct the diskette and read almost all the information.

Don't overlook the obvious, especially hacker tools and any ill-gotten gains (i.e. password or credit card lists). This will help your case when trying to show motive and opportunity. The State of California has equated hacker tools to that of burglary tools; the mere possession constitutes a crime. Possession of a Red Box, or any other telecommunications instrument that has been modified with the intent to defraud, is also prohibited under U.S.C. Section 1029. Some of the hacker tools that you should be aware of are:

- Password crackers
- Network sniffers
- Automated probing tools (i.e. SATAN)
- Anonymous remailers
- War dialers
- Encryption and Steganography tools

Finally, phones, answering machines, desk calendars, day-timers, fax machines, pocket organizers, electronic watches, etc. are all sources of potential evidence. If the case warrants, seize and analyze all sources of data, both, electronic and manual. Document all activity in an Activity Log and if necessary secure the crime scene.

Surveillance

There are two forms of surveillance used in computer crime investigations. They are physical surveillance and computer surveillance. The physical surveillance can be generated at the time of the abuse, via CCTV security camera, or after the fact. When done after the fact, physical surveillance is usually performed undercover. It can be used in an investigation to determine a subject's personal habits, family life, spending habits, or associates.

Computer surveillance is achieved in a number of ways. It is done passively through audit logs or actively by way of electronic monitoring. Electronic monitoring can be accomplished via keyboard monitoring, network sniffing, or line monitoring. In any case, it generally requires a warning notice and/or explicit statement in the security policy, indicating that the company can and will electronically monitor any and all system or network traffic. Without such a policy or warning notice, a warrant is normally required.

Before you conduct electronic monitoring, make sure you review Chapters 2500 & 2700 of the Electronic Communications Privacy Act, Title 18 of the US Code as it relates to keystroke monitoring or system administrators looking into someone's account. If you do not have a banner or if the account holder has not been properly notified, the system administrator and the company can be guilty of a crime and liable for, both, civil and criminal penalties. Failure to obtain a warrant could result in the evidence being suppressed or worse yet, litigation by the suspect for invasion of privacy or violation of the ECPA.

One other method of computer surveillance that is used are "sting operations." These operations are established so as to continue to track the attacker, on-line. By baiting a trap or setting up "Honey Pots," the victim organization lures the attacker to a secured area of the system. This is what was done in the Cuckoo's Egg. The system attackers were enticed into accessing selected files. Once these files or their contents are downloaded to another system, their mere presence can be used as evidence against the suspect. This enticement is not the same as entrapment as the intruder is already predisposed to commit the crime. Entrapment only occurs when a law enforcement officer induces a person to commit a crime that the person had not previously contemplated.

It is very difficult to track and identify a hacker or remote intruder, unless there is a way to trace the call (i.e. Caller ID, wire tap, etc.). Even with these resources, many hackers meander through communication networks, hopping from one site to the next, via a multitude of telecommunications gateways and hubs, such as the Internet! Bill Cheswick, author of Firewalls and Internet Security, refers to this a "connection laundering." Additionally, the organization can not take the chance of allowing the hacker to have continued access to their system and potentially cause any additional harm.

Telephone traps require the equivalent of a search warrant. Additionally, the victim will be required to file a criminal report with law enforcement and must show probable cause. If sufficient probable cause is shown, a warrant will be issued and all incoming calls can be traced. Once a trace is made, a pen register is normally placed on the suspects phone to log all calls placed by the suspect. These entries can be tied to the system intrusions based upon the time of the call and the time the system was accessed.

Investigative and Forensic Tools

Exhibit 2, although not exhaustive, identifies some of the investigative and forensic tools that are commercially available. The first table identifies the hardware and software tools that should be part of the investigator's toolkit, while the second table identifies forensic software and utilities.

Other Investigative Information Sources

When conducting an internal investigation it is important to remember that the witness statements and computer-related evidence are not the only sources of information useful to the investigation. Personnel files provide a wealth of information related to an employee's employment history. It may show past infractions by the employee or disciplinary action by the company. Telephone and fax logs can possibly identify any accomplices or associates of subject. At a minimum they will identify the suspects most recent contacts. Finally, security logs, time cards, and check-in sheets will determine when a suspected insider had physical access to a particular system.

Investigative Reporting

The goal of the investigation is to identify all available facts related to the case. The investigative report should provide a detailed account of the incident, highlighting any discrepancies in witness statements. The report should be a well organized document that contains a description of the incident, all witness statements, references to all evidentiary articles, pictures of the crime scene, drawings and schematics of the computer and the computer network (if applicable), and finally, a written description of the forensic analysis. The report should state final conclusions, based solely

Investigative Tools	
Investigation and Forensic Toolkit Carrying Case	Static Charge Meter
Cellular Phone	EMF/ELF Meter (Magnetometer)
Laptop Computer	Gender Changer (9 Pin and 25 Pin)
Camcorder w/NTSC adapter	Line Monitor
35mm Camera (2)	RS232 Smart Cable
Wide Angle & Telephoto Lens	Nitrile Anti-static Gloves
Night Vision Adapter for Camera and Camcorder	Alcohol Cleaning Kit
Polaroid Camera	CMOS Battery
Tape Recorder (VOX)	Extension Cords
Scientific Calculator	Power Strip
Label Maker	Keyboard Key Puller
Crime Scene/Security Barrier Tape	Cable Tester
PC Keys	Breakout Box
IC Removal Kit	Transparent Static Shielding Bags (100 Bags)
Compass	Anti-Static Sealing Tape
Diamond Tip Engraving Pen Extra Diamond Tips	Serial Port Adapters (9 Pin 25 Pin & 25 Pin 9 Pin)
Felt Tip Pens	Foam-Filled Carrying Case
Evidence Seals (250 Seals/Roll)	Static-Dissipative Grounding Kit w/Wrist Strap
Plastic Evidence Bags (100 Bags)	Foam-Filled Disk Transport Box
Evidence Labels (100 Labels)	Computer Dusting System (Air Spray)

on the facts. It should not include the investigator's opinions, unless he is an expert. Keep in mind that all documentation related to the investigation is subject to discovery by the defense, so be careful about what is written down!

COMPUTER FORENSICS

Computer forensics is the study of computer technology as it relates to the law. The objective of the forensic process is to learn as much about the

suspect system as possible. This generally means analyzing the system using a variety of forensic tools and processes. Bear in mind that the examination of the suspect system may lead to other victims and other suspects. The actual forensic process will be different for each system analyzed, but the following guidelines should help the investigator/analyst conduct the forensic analysis.

There are many tools available to the forensic analyst to assist in the collection, preservation and analysis of computer-based evidence. The make-up of a forensic system will vary from lab to lab, but at a minimum, each forensic system must have the ability to:

- Conduct a Disk Image Backup of the Suspect System
- Authenticate the File System
- Conduct Forensic Analysis in a Controlled Environment
- Validate Software and Procedures

Before analyzing any system it is extremely important to protect the systems and disk drives from static electricity. The analyst should always use an anti-static or static-dissapative wristband and mat before conducting any forensic analysis.

Conduct a Disk Image Backup of the Suspect System

A disk image backup is different from a file system backup in that it conducts a bit level copy of the disk, sector-by-sector, rather then merely copying the system files. This process provides the capability to back up deleted files, unallocated clusters and slackspace. The backup process can be accomplished by using either disk imaging hardware, such as the ImageMaster 1000, or through a variety of software programs. Most of these programs run under DOS or Windows and will back up most any type of hard disk or floppy disk, regardless of the operating system. The image backup process is conducted as depicted in Exhibit 3.

Authenticate the File System

File system authentication helps to ensure the integrity of the seized data and the forensic process. Before actually analyzing the suspect disk, a message digest is generated for all system directories, files and disk sectors. A message digest is a signature that uniquely identifies the content of a file or disk sector. It is created using a one-way hashing algorithm. In the past a 32-bit CRC32 algorithm was used, but due to the advancements in cryptographic research and along with more powerful machines, two more advanced, one-way hashing algorithms are now being used. MD5 is a 128-bit hash, while SHA is a 160-bit hash. These strong cryptographic hashing algorithms virtually guarantee the integrity of the processed data. Doing

Step	Disk Image Backup Procedure
1	Remove the internal hard disk(s) from suspect machine and label (if not already done). Make a note of which logical disk you are removing. Follow the ribbon cables from the disk to the I/O board to accomplish this task. It is a good idea to photograph the inside of the system including the connections to the I/O boards and disk drives.
2	Identify the type of disk (i.e. IDE or SCSI). Identify the make and model.
3	Identify the disk capacity. Make a note of cylinders, heads and sectors.
4	Place each disk, one at a time, in a clean forensic examination machine as the next available drive. Beware that the suspect disk may have a virus (keep only the minimal amount of software on the forensic examination machine). Note, if you are using a hardware-based disk duplication method (i.e. ImageMaster 1000), then this step is not necessary.
5	Backup (Disk Image) the suspect disk(s) to tape—Make at least 4 copies of each suspect disk
6	Check the disk image backup logs to make sure that there were no errors during the backup process.
7	Place the original suspect disk(s), along with one of the backup tapes, and backup logs, in the appropriate container. Seal, mark and log into evidence.
8	Return a copy of the original disk to the victim (if applicable)
9	Use the last two copies for the forensic analysis (one is used for file authentication)

Exhibit 3. Image Backup Process

this now will help refute any argument by the defense, that the evidence was tampered with.

The concept of a one-way hash, using MD5 for example, is that a file is read into memory. The file is then processed, bit by bit, until it reaches the end of the file. The hashing process creates a 128-bit signature for the file that is based upon the file content. Even the change of a single bit will change the signature produced by the hashing algorithm. The significance of the one-way hash is that it only works one way. Knowledge of the hash value can not produce the file content itself.

The only problem with executing the authentication process is that it will change the file's last access time. The mere process of reading the file, to produce the hash value will change this time. That is why a separate backup is used for the authentication process.

Conduct Forensic Analysis in a Controlled Environment

After restoring at least one of the backup tapes to a disk, of equal capacity to the original disk (identical disk, if possible), the restored data should be analyzed. This should be done in a controlled environment on a forensic system. Everything on the system must be checked, starting with the file system and directory structure. The analyst should create an organizational chart of the disk file system and then inventory all files on the disk.

There are a number of commercially available utilities that allow the analyst to quickly create a directory tree, list system files, identify hidden files, and to conduct keyword searches. The analyst should make notes during each step in the process, especially when restoring hidden or deleted files, or modifying the suspect system (i.e. repairing a corrupted disk sector w/Norton Utilities). The analyst should also note that what may have happened on the system may have resulted from error or incompetence rather from than a malicious user. It is a good idea to check for viruses at this point to, first, note their existence, and secondly, to avoid potential contamination.

Since forensic analysis can be a laborious and time-consuming process, it is sometimes better to distribute the workload to, both, other analyst and case agents. Since it would be too costly to have multiple forensic systems and to have to replicate the suspect data on multiple hard drives, it may be more effective to make CD copies of the hard disk contents that can be distributed and analyzed by different individuals. This is certainly more cost effective and may possibly accelerate the analysis process.

When using CD-R or WORM (Write Once Read Many) technology, the data should be structured in way that will enhance the forensic process. One method of data organization that works quite well is to create a logical directory structure that will store and organize all data from the target disk. This should include all files and directories from the original file structure, deleted files, hidden files, data in slack space, data in unallocated space, compressed data, encrypted data and data generated from search results.

To initiate this process, the analyst should copy (file copy) the complete file structure, starting from the root directory, from the image copy to a newly created hard disk partition. This type of copy will not pick up deleted files, data in slack space, or data in unallocated space, therefor the analyst must manually copy this data from the target system to the new disk partition. Before copying this data, individual sub-directories must be created for each data type: DELETED, SLACK, UNALLOC. The file copy process will copy the swap file, but it may be best to move the file to a SWAP sub-directory. The next step in the process is to review the information in the original file system, looking for files with hidden file attributes, compressed files, encrypted files and files that meet the criteria of key-word searches. These, too, should be copied to specific directories, so that later it is understood where the data came from. The following directories should be created to store and organize this data: HIDDEN, COMPRESS, ENCRYPT, and SEARCH.

The final process is to use a disk editor utility to look for “BAD” clusters that have data in them and to run key-word searches at the disk editor level

(below the operating system). Any data found during this analysis should be copied to the newly created file system. A BAD sub-directory can be created under the HIDDEN sub-directory and an EDITOR sub-directory can be created under the SEARCH sub-directory. Once the new file system is populated with all the data, the information can be burnt into a CD-R or WORM drive. This information can then be made available to other forensic analysts or case agents. If damaging evidence is discovered upon review of the data stored on the CD-R or WORM drive, the original information can easily be recovered from the original image copy.

A quick background on file times should be given before continuing on. Most computer systems, including Windows 95, NT and UNIX store three values for file times: creation time, update time, last access time. Any or all of these file times may have an impact on the investigation. The access time is the one most susceptible to modification because any read to access to the file changes this time. The image backup will not change this time, but the file authentication process will! The creation time is the time the file was originally created. It is not accessible from the file manager or the DIR command. The update time is the time the file was last modified (written to). This is the time the file manager displays. The last access time is recorded whenever any other program or command, including read, copy, etc touches the file. This time is also not accessible from the file manager but can be seen in the under file properties.

When searching through files and directories, the first things to look for are file names or document content that have case-relevant names. For example, if the case you are working is an espionage or theft of trade secrets case, then look for file names with the word (or partial word) of the trade secret item itself. If trade secret was related to the release of a new, database software product, called SplitDB, then look for files with the name "split.xls," "db.doc," or "database.ppt." Another search may find the word "split," "db," or "database" in the body of a word processing document (i.e. a hidden file named sys.dll with the following phase, "For this database structure to work effectively..."). Another indicator that something is afoul, is when the file extension doesn't match the file signature. All files have a signature, which identify the type of file, somewhere in the first 50 characters of the file. This file signature normally correlates to a particular file extension. For example, a bitmap graphic file normally has a file extension of .bmp and a file signature of BM as the first two bytes of the file. If these two items do not match up, then it may mean that someone modified the file extension to hide the presence of the file. A pedophile can use this technique to hide a bitmap image containing child pornography in the c:\windows\system directory as system.dll. A cursory review of the system may miss this file completely, thinking that it is a Windows system file, when in fact it is damaging evidence.

Search Tools. There are many search tools that can assist the forensic analyst in his endeavor to locate damaging evidence. Most of these tools are commercial off-the-shelf (COTS) applications that were created for some other reason, other than forensics. It just so happens that these applications work well in a forensic environment. Norton Utilities, although not the end all, is a must for all forensic investigators. Norton provides file searching utilities, disk editor functions, data recovery, etc. Some other tools are listed below:

- Quick View Plus
- Expert Witness
- Computer Forensics Laboratory
- Drag and View
- Rescue Professional
- Super Sleuth
- Outside/In

Searching for Obscure Data. Once the basic analysis is complete, the next step is to conduct a more detail analysis of more obscure data. It may be necessary to use forensic data recovery techniques to locate and recover:

- Hidden files
  - Hidden by attributes
  - Hidden through steganography
  - Hidden in slack space
  - Hidden in good clusters marked as BAD
- Modifying the size of the file in the directory entry
- Hidden directories
- Erased or deleted files
- Reformatted media
- Encrypted data
- Overwritten (wiped) files

The fact that a file is hidden is a good indicator of its evidentiary value. If someone took the time to hide the file, it was probably hidden for a reason. The simplest way to hide a file is to alter the file attribute to Hidden, System, or Volume Label. Files with these attributes do not normally appear in a DIR listing or even in the Windows file manager. Simply changing the attribute back will make the file accessible. Files with the Hidden attribute set are usually further hidden in a hidden directory. An example of hidden directory would be the .directory in UNIX or creating a directory with the ALT 255 character in a Windows or DOS system. Many times these hidden directories are deeply nested to avoid discovery. The “chkdsk” utility will display the number of hidden files on the DOS system, while Norton Utilities will display a listing of the hidden file and its location.

A file can also be hidden in slack space. Slack space is the area left over in a cluster that is not utilized by a file. For example, if a 2K file is stored in a 32K cluster, then there is 30K of slack space, which may contain data from a previous file. This area can also be used to hide data. A cluster, which is the basic allocation unit, is the smallest unit of space that DOS uses for a file. The amount of slack space for a given file varies based upon the file size and cluster size. The cluster size usually expands as hard disk capacity increases.

Another, more elaborate way to hide data is to first, write data to a file in the normal way. When this is complete, the suspect can use a disk editor to ascertain the sector and cluster of the newly created file, go to that cluster and mark the cluster as BAD. When the operating system sees a BAD cluster, it simply ignores the area. The data is still present on the disk even though it can not be accessed. The analyst will need to locate the cluster by using a sector searching utility, then go to the specific cluster and remove the BAD label.

Files and directories can also be deleted. But when DOS or Windows deletes a file, it only changes the first character of the file name to 0xE5, which merely makes the file space available. The file is not actually removed. The data in the cluster previously allocated by the file is still available until overwritten by a new file. On DOS and Windows systems, the analyst can use the un-erase utility to recover deleted files. These utilities only recover the first cluster that the file occupied. If the file occupied multiple clusters, this data may be lost, as the cluster chain is no longer available. Cluster chains can be re-built although not reliably.

If the disk is formatted, the analyst can attempt to use the "un-format" command in the DOS or Windows environment. If the disk has been wiped, which is also known as shredding, the data is not easily recoverable. The cost of recovery is usually exorbitant, far exceeding the initial loss.

Steganography. Steganography is the art of hiding communications. Unlike encryption, which utilizes an algorithm and a seed value to scramble or encode a message in order to make it unreadable, Steganography makes the communication invisible. This takes concealment to the next level — that is to deny that the message even exists. If a forensic analyst were to look at an encrypted file, it would be obvious that some type of cypher process has been used. It is even possible to determine what type of encryption process was used to encrypt the file, based upon a unique signature. However, Steganography hides data and messages in a variety of picture files, sound files and even slack space on floppy diskettes. Even the most trained security specialist or forensic analyst may miss this type of concealment during a forensic review.

Steganography simply takes one piece of information and hides it within another. Computer files, such as images, sound recordings, and slack space contain unused or insignificant areas of data. For example, the least significant bits of a 24-bit bitmap image can be used to hide messages, usually without any material change in the original file. Only through a direct, visual comparison of the original and processed image can the analyst detect the possible use of Steganography. Since many times the suspect system only stores the processed image, the analyst has nothing to use as a comparison and generally has no way to tell that the image in question contains hidden data. There is research underway that will help in the forensic process when dealing with Steganography. New tools are being developed that will look at the file contents to determine if there is a Steganographic signature within the file. But with over 25 different types of Steganography being used today, this new research may take some time.

Review Communications Programs. A good source of contact and associate information can many times be found on-line. Since many technically competent individuals use technology for the same reasons businesses do, electronic Rolodexes, databases of contacts, and communication programs should be searched. Applications like Microsoft Outlook, ACT and others can be tremendously beneficial during an investigation to link your suspect to other individuals or businesses. Some computers store Caller ID files, while others may contain war dialer (or demon dialer) logs. Review communications programs, such as Procomm, to ascertain if any numbers are stored in the application.

Microprocessor Output. One final note, before moving on to the next step in the forensic process, is to understand that not all microprocessors are created equal. If a forensic analyst is forced to dump the contents of a file in binary or hexadecimal format, he must not only understand how to read these hieroglyphic notations, but must know the type of microprocessor that produced the output. For example, the Intel 30286 is a 16-bit, little endian processor. A 16-bit microprocessor is capable of working with binary numbers of up to 16 places or bits. That translates to the decimal number 65,536. The Intel 30486 and newer Pentium processors are 32-bit computers, capable of handling binary numbers of up 32 bits or up to the decimal number 4,294,967,296. The little endian attribute of the Intel chip signifies the byte, not bit, ordering sequence. In this case the bytes are reversed, where the high order byte(s) is stored low order byte location. A big endian processor does not reverse the byte order. It is important to understand that the same value dumped out on two different systems may produce different results.

Reassemble and Boot Suspect System (with Clean Operating System)

The next step in the process is to reassemble the suspect system, using one of the copies of the suspect disk. Place a clean copy of the forensic operating system (usually DOS or Windows) into the floppy drive. Start the boot process and enter the CMOS setup. Check the CMOS to make sure that the boot sequence looks to the floppy drive first, then the hard disk second. This will allow the investigator to boot from the clean operating system diskette. Also, if the system is password protected at the CMOS level, remove and reinstall or short out the CMOS battery. Continue with the boot process and pay particular attention to the Boot-up process, looking for a modified BIOS or EPROM.

It is very important to boot from a clean operating system, as the target system utilities may contain a Trojan Horse or Logic Bomb that will do other than what's intended. (e.g. Modified command.com—conducting a Delete with the Dir command). The first thing to do once the system is booted is to check the system time. This time, even if not accurate, will give the analyst or investigator a reference for all file times. After the system time is obtained, run a complete Systems Analysis Report. This report should, at a minimum, provide the following:

- System Summary—contains basic system configuration
- Disk Summary
- Memory Usage w/Task List
- Display Summary
- Printer Summary
- TSR Summary
- DOS Driver Summary
- System Interrupts
- CMOS Summary
- Listing of all environment variables as set by Autoexec.bat, config.sys, win.ini, system.ini, etc.

Audit trails can be viewed any time subsequent to the image backup, but before a through analysis can be completed, the analyst will need a time reference, which is obtained from booting the suspect system. Check the audit logs for system and account activity. Check with the victim organization to ascertain if the Audit logs are used in the normal course of business. The following questions must be asked:

- Is there a corporate security policy on how the logs are to be used? If so, has the policy been followed?
- What steps have been taken to ensure the integrity of the audit trail?
- Has the audit trail been tampered with? If so, when?

Boot Suspect System (with Original Operating System)

The next step in the forensic process is to boot the target system using the original, target system operating system. This is done to see if any rouge programs were left on the system. The analyst should let the system install all background programs (Set by autoexec.bat and config.sys). Once this has been done, the analyst should check what programs (including TSR's) are running and what system interrupts have been set. The goal is to learn if there are any Trojan Horses or other rouge programs, such as keystroke monitors, activated. Execute some of the basic operating system commands to see if the command.com file had been altered.

Searching Backup Media

Remember that if the data is not on the hard disk, it may be on backup tapes or some other form of backup media. Even if the data was recently deleted from the hard disk, there may be a backup that has all of the original data. Many times a "snapshot" of the system is taken on a weekly or monthly basis and saved in the long term archives for disaster contingency purposes. Search for PCMCIA flash disks, floppy diskettes, optical disks, Ditto tapes, Zip and Jazz cartridges, Kangaroo drives, or any other form of backup media. Restore and review all data. Many organizations store backups off-site, and although a warrant may be required to obtain the media, don't forget to ascertain if this practice is being done. Before analyzing floppy diskettes, always write-protect the media.

Searching Access Controlled Systems and Encrypted Files

During a search the investigator may be confronted with a system which is secured physically and/or logically. Some physical security devices, such as CPU key locks, prevent only a minor obstacle, whereas other types of physical access control systems may be harder to break.

Logical access control systems may pose a more challenging problem. The analyst may be confronted with a software security program that requires a unique user-name and password. Some of these systems can be simply bypassed by entering a control-c or some other interrupt command. The analyst must be cautious that any of these commands may invoke a Trojan horse routine that may destroy the contents of the disk. A set of "password cracker" programs should be part of the forensic tool-kit. The analyst can always try to contact the publisher of the software program in an effort to gain access. Most security program publishers leave a back door into their systems.

The investigator should look around the suspects work area for documents that may provide him with a clue to the proper user-name/password combination. Check desk drawers, the suspect's Rolodex, acquaintances,

friends, etc. It may be possible to compel a suspect to provide access information. It is a good idea to first ask the suspect for his password, before going through the process of compelling him to do so. The following cases set precedence for ordering a suspect, whose computer is in the possession of law enforcement, to divulge password or decryption key:

- Fisher v US (1976), 425 US 391, 48 LED2 39
- US v Doe (1983), 465 US 605, 79 LED2d 552
- Doe v US (1988), 487 US 201, 101 LED2d 184
- People v Sanchez (1994) 24 CA4 1012

The caveat is that the suspect might use this opportunity to command the destruction of potential evidence. The last resort may be that the system needs to be hacked. This can be done as follows:

- Search for passwords written down (It may be part of the evidence collected)
- Try words, names or numbers that are related to the suspect
- Call the software vendor and request their assistance (Some charge for this)
- Try to use password cracking programs which are readily available on the net
- Try a brute force or dictionary attack

LEGAL PROCEEDINGS

A brief description of the legal proceedings that occur subsequent to the investigation are necessary so the victim and the investigative team understand the full impact of their decision to prosecute. The post-incident legal proceedings generally result in additional cost to the victim, until the outcome of the case, at which time they may be reimbursed.

Discovery and Protective Orders

Discovery is the process whereby the prosecution provides all investigative reports, information on evidence, list of potential witnesses, any criminal history of witnesses, and any other information except how their going to present the case to the defense. Any property or data recovered by law enforcement will be subject to discovery if a person is charged with a crime. However, a protective order can limit who has access, who can copy, and the disposition of the certain protected documents. These protective orders allow the victim to protect proprietary or trade secret documents related to a case.

Grand Jury and Preliminary Hearings

If the defendant is held to answer in a preliminary hearing or the grand jury returns an indictment, a trial will be scheduled. If the case goes to trail,

interviews with witnesses will be necessary. The victim company may have to assign someone to work as the law enforcement liaison.

The Trial

The trail may not be scheduled for some time based upon the backlog of the court that has jurisdiction in the case. Additionally, the civil trial and criminal trial will occur at different times, although much of the investigation can be run in parallel. The following items provide tips on courtroom testimony:

- The prosecutor does not know what the defense attorney will ask.
- Listen to the questions carefully to get the full meaning and to determine that this is not a multiple part or contradictory question.
- Do not answer quickly; Give the prosecutor time to object to the defense questions that are inappropriate, confusing, contradictory or vague.
- If you do not understand the question, ask the defense attorney for an explanation, or answer the question by stating "I understand your question to be . . ."
- You can not give hearsay answers. This generally means that you can not testify to what someone has told you.
- Do not lose your temper and get angry as this may affect your credibility.
- You may need to utilize expert witnesses.

Recovery of Damages

To recover the costs of damages, such as reconstructing data, re-installing an uncontaminated system, repairing a system, or investigating a breach, you can file a civil law suit against the suspect in either Superior Court or Small Claims Court.

Post Mortem Review

The purpose of the Post Mortem review is to analyze the attack and close the security holes that led to the initial breach. In doing so, it may also be necessary to update the corporate security policy. All organizations should take the necessary security measures to limit their exposure and potential liability. The security policy should include an:

- Incident Response Plan
- Information Dissemination Policy
- Incident Reporting Policy
- Electronic Monitoring Statement
- Audit Trail Policy

- Inclusion of a Warning Banner—This should:
  - Prohibit unauthorized access and;
  - Give notice that all electronic communications will be monitored

One final note is that many internal attacks can be avoided by conducting background checks on potential employees and consultants.

SUMMARY

As you probably gleaned from this chapter, computer crime investigation is more an art than a science. It is a rapidly changing field that requires knowledge in many disciplines. But although it may seem esoteric, most investigations are based on traditional investigative procedures. Planning is integral to a successful investigation. For the internal investigator, an Incident Response Plan should be formulated prior to an attack. The Incident Response Plan will help set the objective of the investigation and will identify each of the steps in the investigative process. For the external investigator, investigative planning may have to happen post incident. It is also important to realize that no one person will have all the answers and that teamwork is essential. The use of a Corporate CERT Team is invaluable, but when no team is available, the investigator may have the added responsibility of building a team of specialists.

The investigator's main responsibility is to determine the nature and extent of the system attack. From there, with knowledge of the law and forensics, the investigative team may be able to piece together who committed the crime, how and why the crime was committed, and maybe more importantly, what can be done to minimize the potential for any future attacks. For the near term, convictions will probably be few, but as the law matures and as investigations become more thorough, civil and criminal convictions will increase. In the mean time, it is extremely important that investigations be conducted so as to better understand the seriousness of the attack and the overall impact to business operations

Finally, to be successful, the computer crime investigator must, at a minimum, have a thorough understanding of the law, the rules of evidence as they relate to computer crime, and computer forensics. With this knowledge, the investigator should be able to adapt to any number of situations involving computer abuse.

148

What Happened?

Kelly J. Kuchta, CPP, CFE

Envision coming across the dead bodies and the related carnage of a crime scene at night. It is a place of chaos and confusion, smoke, shadows, and debris. Victims wander around dazed and stumble into each other; bystanders and the curious mill around in anxious speculation and anticipation. No one really knows what happened, or even when. They just know that it has happened. The authorities are supposedly on the way. Then suddenly, someone runs up to you and puts you in charge. Why? Because you know the neighborhood.

This sounds like a nightmare and in reality, it is — especially when the crime scene is somewhere in your network and involves your information systems.

I use the crime scene analogy because forensics issues involving information systems are like a crime scene. From decades of watching TV cop shows (or the O.J. trial), most people know that you do not trample over evidence because valuable information and clues about the crime could be inadvertently destroyed or tainted. At the crime scene, we know to check to see whether there is anyone who needs medical assistance and then just pick up the phone and dial 911 — thereby letting those who have the requisite training, background, and expertise analyze the crime scene and work it.

What do you do when you find out later that something bad has happened in your network and you need information about an event in the past? If someone in your organization has the appropriate skills, that person will appreciate early notice about the incident and your efforts to leave the crime scene intact.

As emergency personnel will often tell you, the initial decisions made following an incident have the greatest impact on the outcome. Today's information systems usually do not leave many outward signs that something is terribly wrong. Actually, it is the people that using the system who will provide insight into incidents.

With increasing frequency, we are seeing theft of confidential data and other misuse of computers. The best advice I can give people and corporations in handling future incidents is to develop a "behavioral pattern matrix" (see Exhibit 148.1) of personnel security-related events that need closer scrutiny (more on this later) and when in doubt preserve the evidence by removing the hard drive of the victimized computer. Hard drives are inexpensive, and the amount of downtime from pulling a hard drive and installing a new hard drive with your organizations' standard loadset is minimal. The effort to do this can save the organization money and headaches.

Consider the employee who resigns after working in a sensitive area of your business. If anything illegal or unethical has taken place, you will probably not find out about it until 30 to 60 days after the employee has left, if ever. I suggest saving the hard drives from laptops or desktops of resigned and terminated employees for a minimum of 60 to 90 days and longer if possible. At the end of this period of time, cleanse the disk and put it back into production. Why? Because once the hard drive and the residing data is reformatted and placed back into circulation, the chances of recovering any usable information from that hard drive for forensic analysis will be next to impossible and limited by the amount of time and money you have to spend.

In most instances when evidence is tainted, it is through ignorance, not through intentional acts of deception. I have witnessed corporations and individuals who attempt to use their investigative skills after an incident by having the system administrator look for clues or evidence. In one case, they were able to find incriminating data; however, after finding the information, they opened the file and copied it to a floppy disk. This action modified the key dates and contaminated the electronic evidence, preventing its use in a court of law.

EXHIBIT 148.1 Sample of Behavioral Matrix

Employee	Risk Score **Yes = 1 No = 0**	Weight 100 (percent)	Weighted Score
Did the employee work with sensitive information?	1	5	0.05
Was the separation hostile?	0	20	0
Did the employee go to work for a competitor?	1	20	0.2
Could the employee have been involved in any unexplained events?	0	5	0
Was the separation unexpected?	0	10	0
Is there a chance that the employee's actions might be involved in litigation?	0	25	0
Has the entity been the target of intelligence gathering?	1	15	0.15
Evidence preservation score			40 percent

Guidelines for evidence preservation
0 to 24 percent no apparent need to preserve evidence
25 to 49 percent good reason to preserve evidence
>49 percent strong reason to preserve evidence
This is a sample behavioral matrix you can customize to your needs.

Computer forensic professionals view the system dates as vital pieces of information. Created, last written, and last access dates are used to establish a chain of events that give important insight into what happened in the past. Computer forensics methodology dictates that computer forensics professionals must not change any piece of evidence, including the dates. When reviewing the data on a suspected system, great lengths are taken to prevent the operating system from writing to the hard drive. Even if you are not a computer forensics professional, you owe your organization the opportunity to fight back by preserving the original evidence.

When a computer is started, right away the operating system changes or modifies a large number of file dates on the system. The actual number of files may vary depending on what type of system, anti-virus applications, or network protocols the organization is using. A typical Windows 98 machine will have over 12,000 files loaded on it. During the start-up process, hundreds of these files may be changed during the POST (power on self test) process. If the anti-virus application is set to inoculate any viruses found, having the malicious code removed will modify the file. This process will change the last access and last written dates.

To keep as many options available as possible, consider setting the hard drives aside for a reasonable amount of time. If you think that putting each hard drive in a probationary period will not work because of the potential expense, consider doing it on a limited basis. Earlier I mentioned developing a behavioral pattern matrix for exiting employees who might give you reason to preserve their hard drives. The objective is to find predictors that would indicate the future need to review the hard drive of the computer.

My experience has shown that human behavior is a key predictor that must be considered at a digital crime scene. Each organization will experience different behaviors that constitute a warning. Each organization will need to develop its own behavior pattern that fits its culture. In this case, past events can be good indicators of future events. The sources of information to consider should come from human resources, corporate investigations, information security, as well as the legal department and the business units themselves.

Some factors that might weigh into your behavioral pattern matrix are as follows: Did the employee work with sensitive data? Was the resignation a surprise? Is the termination likely to result in legal proceedings? Is the employee going to work for a competitor? Have there been any events that are of concern to the organization in which the employee might have been involved? Was the employee vague about why he or she was leaving? The answer "yes" to any of these questions should trigger at least considering saving the hard drive for a reasonable period of time.

I often hear, "I knew there was something suspicious about the person!" when working on employee or former employee issues. There are other signs that are frequently overlooked, but by considering all the facts,

organizations realize in retrospect that they missed the warning signs. The warnings are generally spread out over multiple areas, such as human resources, corporate investigations, business units, and information security.

Human resources and the business units hold the keys about the behavior of the individual and the possible reason for the departure of the employee. Corporate investigations might be able to provide insight on external events and intelligence information. This could include events under investigation but not publicly known, attempts by competitors to gain proprietary information, and other possible related matters. Information security might have some information about suspicious behavior the individual demonstrated recently. Examples of suspicious behavior could be linked to attempting access to restricted information, copying large amount of data, allegations of technology misuse, or browsing suspicious Internet sites.

The best process I have witnessed was to have the human resources personnel in charge of the employee exit process give notice to the three groups listed previously. They should give each group a reasonable amount of time to respond that they would like the hard drive held for the proscribed period of time or want immediate analysis relating to a specific event. Of course, Human Rresources personnel might make this request themselves based on their information.

Do not forget the importance of having an "acceptable use" policy to guide new employees. As exiting employees are getting ready to turn in their PCs, they should be instructed on what they can or cannot do. Depending on business needs and culture, you might establish a policy that restricts the employee's ability to use wipe utilities (especially nonstandard products) or other products that could sabotage forensics results. Although this is a difficult subject to deal with in corporate America, it is vitally important. On more than one occasion, I have seen cases in which a mildly disgruntled employee deliberately erased valuable client information and used a wipe utility to make the information unrecoverable. You should make a conscious decision about this issue, even if it is to have no policy on this issue!

To develop a process that is customized to your organization, consider getting input from the above-named individuals and your legal counsel. If the employee is part of a unionized labor force, special rules may apply. There may also be special considerations based on state law or if the organization fulfills government contracts. The preserved evidence is probably discoverable with a subpoena. Your legal counsel can help you determine what legal requirements you need to adhere to.

Assume that you have adopted a process similar to the one outlined. The organization has made the decision to preserve a hard drive. How do you go about it? The major concerns are establishing a chain of custody, documenting specific details, and securing the hard drive. Each of these areas is vitally important if there is a chance that the electronic evidence you have preserved will be presented in a court of law.

You must establish a chain of custody to prove authentication and refute allegations of evidence tampering. Many defense attorneys have successfully argued that if you cannot prove that the evidence has been under your control, you cannot prove that it has not been changed or modified to construct the incriminating evidence. To establish the chain of custody, you must document possession from the point of acquiring it until the matter is resolved. This includes an appeals process through the court system.

Part of the documentation process will be to identify as many details about the original PC that the evidence came from as possible. This is important because an analysis completed later will go much smoother if a few key pieces of information are known. You should document the following:

- What types of operating system are on the hard drive?
- What are other systems specifications (RAM, SCSI, or IDE; processor type)?
- Are any partitions likely to be found?
- What applications are known to be on the hard drive?
- What, if any, encryption was used?
- Is there a list of any known passwords, keys, or certificates?
- To what systems did the owner of the hard drive have access?
- What type of system did the hard drive come from (manufacturer, model)?
- Is there a history of hardware problems, including any maintenance logs?

Having the answers to these questions will make the forensics analysis a much faster and efficient process.

A master log should accompany the evidence from the time it is acquired. It should include date and time, a detailed description of the evidence, and who seized the evidence. The log should also include a transfer-of-custody section, which should include reason for transfer, method (hand-delivered or courier), released by and date (signature and date of person transferring custody), and received by and date (signature and date of

person taking custody). People listed as having custody of the evidence will need to demonstrate that the evidence was under their control and secured to prevent tampering.

A secured location is a lockable container that has limited access. It can be a file cabinet with locks, a safe, an evidence locker, or even a room with a lock. The best possible scenario is to have only one person with access to the evidence. If that is not possible, the evidence must be stored in a limited area and everyone with access to the area should be documented. The more persons with access to evidence will mean more people testifying that they did not modify the evidence. It is easier to provide a lockable container with single access than one with multiple access. If you will be securing evidence on a regular basis, consider purchasing an evidence locker. Your evidence locker should also include a master log of evidence it holds. When evidence is stored, it should be logged in. Each time it is removed, custody should be transferred out to the individual removing it. The design of the log outlined above can also be utilized here. The purpose of this log is to document each and every time the evidence locker is accessed as well as to provide supporting documentation about particular evidence.

If it is necessary to send evidence to another location, I recommend using a courier service that can provide documentation of its custody. This should include tracking forms and numbers. Most of the traditional delivery services provide this service. The senders should seal the package themselves and the recipients observe that the package has not been breached. For additional protection, it is suggested that the evidence is sealed in a container so that the recipient can attest that the document has not been tampered with. Reasonable steps should be taken to protect the evidence during shipping. The evidence will do little good if it has been damaged.

Taking these steps will increase the odds of determining what happened in the past. Understanding history to change the future is the ultimate goal. To understand the history we must have good information. To preserve information, you do not need to be a computer forensics professional — just understand the process and why it is important. Also, practice techniques that will work for your company and be prepared to have good information on "what happened."

Computer Abuse Methods and Detection

Donn B. Parker

This chapter describes 17 computer abuse methods in which computers play a key role. Several of the methods are far more complex than can be described here in detail; in addition, it would not be prudent to reveal specific details that criminals could use. These descriptions should facilitate a sufficient understanding of computer abuse for security practitioners to apply to specific instances. Most technologically sophisticated computer crimes are committed using one or more of these methods. The results of these sophisticated and automated attacks are loss of information integrity or authenticity, loss of confidentiality, and loss of availability or utility associated with the use of services, computer and communications equipment or facilities, computer programs, or data in computer systems and communications media. The abuse methods are not necessarily identifiable with specific statutory offenses. The methods, possible types of perpetrators, likely evidence of their use, and detection and prevention methods are described in the following sections.

EAVESDROPPING AND SPYING

Eavesdropping includes wiretapping and monitoring of radio frequency emanations. Few wiretap abuses are known, and no cases of radio frequency emanation eavesdropping have been proved outside government intelligence agencies. Case experience is probably so scarce because industrial spying and scavenging represent easier, more direct ways for criminals to obtain the required information.

On the other hand, these passive eavesdropping methods may be so difficult to detect that they are never reported. In addition, opportunities to pick up emanations from isolated small computers and terminals, microwave circuits, and satellite signals continue to grow.

One disadvantage of eavesdropping, from the eavesdropper's point of view, is that the perpetrators often do not know when the needed data will be sent. Therefore, they must collect relatively large amounts of data and search for the specific items of interest. Another disadvantage is that identifying and isolating the communications circuit can pose a problem for perpetrators. Intercepting microwave and satellite communications is even more difficult, primarily because complex, costly equipment is needed for interception and because the perpetrators must determine whether active detection facilities are built into the communications system.

Clandestine radio transmitters can be attached to computer components. They can be detected by panoramic spectrum analysis or second-harmonic radar sweeping. Interception of free-space radiation is not a crime in the United States unless disclosure of the information thus obtained violates the Electronic Communications Privacy Act of 1986 (the ECPA) or the Espionage Act. Producing radiation may be a violation of FCC regulations.

Intelligible emanations can be intercepted even from large machine rooms and at long distances using parametric amplifiers and digital filters. Faraday-cage shielding can be supplemented by carbon-filament adsorptive covering on the walls and ceilings. Interception of microwave spillage and satellite footprints is different because it deals with intended signal data emanation and could be illegal under the ECPA if it is proved that the information obtained was communicated to a third party.

Spying consists of criminal acquisition of information by covert observation. For example, shoulder surfing involves observing users at computer terminals as they enter or receive displays of sensitive information (e.g., observing passwords in this fashion using binoculars). Frame-by-frame analysis of video recordings can also be used to determine personal ID numbers entered at automatic teller machines.

Solutions to Eavesdropping and Spying

The two best solutions to eavesdropping are to use computer and communications equipment with reduced emanations and to use cryptography to scramble data. Because both solutions are relatively costly, they are not used unless the risks are perceived to be sufficiently great or until a new level of standard of due care is met through changes in practices, regulation, or law.

In addition, electronic shielding that uses a Faraday grounded electrical conducting shield helps prevent eavesdropping, and physical shielding helps prevent spying. Detecting these forms of abuse and obtaining evidence require that investigators observe the acts and capture the equipment used to perpetrate the crime.

Potential Perpetrators	Methods of Detection	Evidence
• Communications technicians and engineers • Communications employees	• Voice wiretapping methods • Observation • Tracing sources of equipment used	• Voice wiretapping evidence

Exhibit 1. Detection of Eavesdropping

Eavesdropping should be assumed to be the least likely method used in the theft or modification of data. Detection methods and possible evidence are the same as in the investigation of voice communications wiretapping. Exhibit 1 summarizes the potential perpetrators, detection, and evidence in eavesdropping acts.

SCANNING

Scanning is the process of presenting information sequentially to an automated system to identify those items that receive a positive response (e.g., until a password is identified). This method is typically used to identify telephone numbers that access computers, user IDs, and passwords that facilitate access to computers as well as credit card numbers that can be used illegally for ordering merchandise or services.

Computer programs that perform the automatic searching, called demon programs, are available from various hacker electronic bulletin boards. Scanning may be prosecuted as criminal harassment and perhaps as trespassing or fraud if the information identified is used with criminal intent. For example, scanning for credit card numbers involves testing sequential numbers by automatically dialing credit verification services. Access to proprietary credit rating services may constitute criminal trespass.

Prevention of Scanning

The perpetrators of scanning are generally malicious hackers and system intruders. Many computer systems can deter scanners by limiting the number of access attempts. Attempts to exceed these limits result in long delays that discourage the scanning process.

Identifying perpetrators is often difficult, usually requiring the use of pen registers or dialed number recorder equipment in cooperation with communication companies. Mere possession of a demon program may constitute possession of a tool for criminal purposes, and printouts from demon programs may be used to incriminate a suspect.

Potential Perpetrators	Methods of Detection	Evidence
• Authorized computer users • Hackers	• Audit log analysis • Password violations • Observation • Report by person impersonated	• Computer audit log • Notes and documents in possession of suspects • Pen register and records of number dialed • Witnesses • Access control package exception or violation reports

Exhibit 2. Detection of Masquerading

MASQUERADING

Physical access to computer terminals and electronic access through terminals to a computer require positive identification of an authorized user. The authentication of a user's identity is based on a combination of something the user knows (e.g., a secret password), a physiological or learned characteristic of the user (e.g., a fingerprint, retinal pattern, hand geometry, keystroke rhythm, or voice), and a token the user possesses (e.g., a magnetic-stripe card, smart card, or metal key). Masquerading is the process of an intruder's assuming the identity of an authorized user after acquiring the user's ID information. Anybody with the correct combination of identification characteristics can masquerade as another individual.

Playback is another type of masquerade, in which user or computer responses or initiations of transactions are surreptitiously recorded and played back to the computer as though they came from the user. Playback was suggested as a means of robbing ATMs by repeating cash dispensing commands to the machines through a wiretap. This fraud was curtailed when banks installed controls that placed encrypted message sequence numbers, times, and dates into each transmitted transaction and command.

Detection of Masquerading

Masquerading is the most common activity of computer system intruders. It is also one of the most difficult to prove in a trial. When an intrusion takes place, the investigator must obtain evidence identifying the masquerader, the location of the terminal the masquerader used, and the activities the masquerader performed. This task is especially difficult when network connections through several switched telephone systems interfere with pen register and direct number line tracing. Exhibit 2 summarizes the methods of detecting computer abuse committed by masquerading.

PIGGYBACK AND TAILGATING

Piggyback and tailgating can be done physically or electronically. Physical piggybacking is a method for gaining access to controlled access areas when control is accomplished by electronically or mechanically locked doors. Typically, an individual carrying computer-related objects (e.g., tape reels) stands by the locked door. When an authorized individual arrives and opens the door, the intruder goes in as well. The success of this method of piggybacking depends on the quality of the access control mechanism and the alertness of authorized personnel in resisting cooperation with the perpetrator.

Electronic piggybacking can take place in an online computer system in which individuals use terminals and the computer system automatically verifies identification. When a terminal has been activated, the computer authorizes access, usually on the basis of a secret password, token, or other exchange of required identification and authentication information (i.e., a protocol). Compromise of the computer can occur when a covert computer terminal is connected to the same line through the telephone switching equipment and is then used when the legitimate user is not using the terminal. The computer cannot differentiate between the two terminals; it senses only one terminal and one authorized user.

Electronic piggybacking can also be accomplished when the user signs off or a session terminates improperly, leaving the terminal or communications circuit in an active state or leaving the computer in a state in which it assumes the user is still active. Call forwarding of the victim's telephone to the perpetrator's telephone is another means of piggybacking.

Tailgating involves connecting a computer user to a computer in the same session as and under the same identifier as another computer user, whose session has been interrupted. This situation happens when a dial-up or direct-connect session is abruptly terminated and a communications controller (i.e., a concentrator or packet assembler/disassembler) incorrectly allows a second user to be patched directly into the first user's still-open files.

This problem is exacerbated if the controller incorrectly handles a modem's data-terminal-ready signal. Many network managers set up the controller to send data-terminal-ready signals continually so that the modem quickly establishes a new session after finishing its disconnect sequence from the previous session. The controller may miss the modem's drop-carrier signal after a session is dropped, allowing a new session to tailgate onto the old session.

In one vexing situation, computer users connected their office terminal hardwired cables directly to their personal modems. This allowed them to connect any outside telephone directly to their employer's computers

Potential Perpetrators	Methods of Detection	Evidence
• Employees and former employees • Vendor's employees • Contracted persons • Outsiders	• Access observations • Interviewing witnesses • Examination of journals and logs • Out-of-sequence messages • Specialized computer programs that analyze characteristics of on line computer user accesses	• Logs, journals, and equipment usage meters • Photographs and voice and video recordings • Other physical evidence

Exhibit 3. Detection of Piggybacking and Tailgating

through central data switches, thus avoiding all dial-up protection controls (e.g., automatic callback devices). Such methods are very dangerous and have few means of acceptable control.

Prevention of Piggybacking and Tailgating

Turnstiles, double doors, or a stationed guard are the usual methods of preventing physical piggybacking. The turnstile allows passage of only one individual with a metal key, an electronic or magnetic card key, or the combination to a locking mechanism. The double door is a double-doored closet through which only one person can move with one key activation.

Electronic door access control systems frequently are run by a microcomputer that produces a log identifying each individual gaining access and the time of access. Alternatively, human guards may record this information in logs. Unauthorized access can be detected by studying these logs and interviewing people who may have witnessed the unauthorized access. Exhibit 3 summarizes the methods of detecting computer abuse committed by piggybacking and tailgating methods.

FALSE DATA ENTRY

False data entry is usually the simplest, safest, and most common method of computer abuse. It involves changing data before or during its input to computers. Anybody associated with or having access to the processes of creating, recording, transporting, encoding, examining, checking, converting, and transforming data that ultimately enters a computer can change this data. Examples of false data entry include forging, misrepresenting, or counterfeiting documents; exchanging computer tapes or disks; keyboard entry falsifications; failure to enter data; and neutralizing or avoiding controls.

Potential Perpetrators	Methods of Detection	Evidence
• Transaction participants • Data preparers • Source data suppliers • Nonparticipants with access	• Data comparison • Document validation • Manual controls • Audit log analysis • Computer validation • Report analysis • Computer output comparison • Integrity tests (e.g., for value limits, logic consistencies, hash totals, crossfoot and column totals, and forged entry)	• Data documents: —Source —Transactions • Computer-readable output • Computer data media: —Tapes —Disks —Storage modules • Manual logs, audit logs, journals, and exception reports • Incorrect computer output • Control violation alarms

Exhibit 4. Detection of False Data Entry

Preventing False Data Entry

Data entry typically must be protected using manual controls. Manual controls include separation of duties or responsibilities, which force collusion among employees to perpetrate fraudulent acts.

In addition, batch control totals can be manually calculated and compared with matching computer-produced batch control totals. Another common control is the use of check digits or characters embedded in the data on the basis of various characteristics of each field of data (e.g., odd or even number indicators or hash totals). Sequence numbers and time of arrival can be associated with data and checked to ensure that data has not been lost or reordered. Large volumes of data can be checked with utility or special-purpose programs.

Evidence of false data entry is data that does not correctly represent data found at sources, does not match redundant or duplicate data, and does not conform to earlier forms of data if manual processes are reversed. Further evidence is control totals or check-digits that do not check or meet validation and verification test requirements in the computer.

Exhibit 4 summarizes the likely perpetrators of false data entry, methods of detection, and sources of evidence.

SUPERZAPPING

Computers sometimes stop, malfunction, or enter a state that cannot be overcome by normal recovery or restart procedures. In addition, computers occasionally perform unexpectedly and need attention that normal

access methods do not allow. In such cases, a universal access program is needed.

Superzapping derives its name from Superzap, a utility program used as a systems tool in most IBM mainframe centers. This program is capable of bypassing all controls to modify or disclose any program or computer-based data. Many programs similar to Superzap are available for micro-computers as well.

Such powerful utility programs as Superzap can be dangerous in the wrong hands. They are meant to be used only by systems programmers and computer operators who maintain the operating system and should be kept secure from unauthorized use. However, they are often placed in program libraries, where they can be used by any programmer or operator who knows how to use them.

Detection of Superzapping

Unauthorized use of Superzap programs can result in changes to data files that are usually updated only by production programs. Typically, few if any controls can detect changes in the data files from previous runs. Applications programmers do not anticipate this type of fraud; their realm of concern is limited to the application program and its interaction with data files. Therefore, the fraud is detected only when the recipients of regular computer output reports from the production program notify management that a discrepancy has occurred.

Furthermore, computer managers often conclude that the evidence indicates data entry errors, because it would not be a characteristic computer or program error. Considerable time can be wasted in searching the wrong areas. When management concludes that unauthorized file changes have occurred independent of the application program associated with the file, a search of all computer use logs might reveal the use of a Superzap program, but this is unlikely if the perpetrator anticipates the possibility. Occasionally, there may be a record of a request to have the file placed online in the computer system if it is not typically in that mode. Otherwise, the changes would have to occur when the production program using the file is being run or just before or after it is run.

Superzapping may be detected by comparing the current file with parent and grandparent copies of the file. Exhibit 5 summarizes the potential perpetrators, methods of detection, and sources of evidence in superzapping abuse.

SCAVENGING

Scavenging is a method of obtaining or reusing information that may be left after processing. Simple physical scavenging could involve searching

Potential Perpetrators	Methods of Detection	Evidence
• Programmers with access to Superzap programs • Computer operation staff with applications knowledge	• Comparison of files with historical copies • Discrepancies in output reports, as noted by recipients • Examination of computer usage logs	• Output report discrepancies • Undocumented transactions • Computer usage or file request logs

Exhibit 5. Detection of Superzapping

trash barrels for copies of discarded computer listings or carbon paper from multiple-part forms. More technical and sophisticated methods of scavenging include searching for residual data left in a computer, computer tapes, and disks after job execution.

Computer systems are designed and operators are trained to preserve data, not destroy it. If computer operators are requested to destroy the contents of disks or tapes, they most likely make backup copies first. This situation offers opportunities for both criminals and investigators.

In addition, a computer operating system may not properly erase buffer storage areas or cache memories used for the temporary storage of input or output data. Many operating systems do not erase magnetic disk or magnetic tape storage media because of the excessive computer time required to do this. (The data on optical disks cannot be electronically erased, though additional bits could be burned into a disk to change data or effectively erase them by, for example, changing all zeros to ones.).

In a poorly designed operating system, if storage were reserved and used by a previous job and then assigned to the next job, the next job might gain access to the same storage area, write only a small amount of data into that storage area, and then read the entire storage area back out, thus capturing data that was stored by the previous job.

Detection of Scavenging

Exhibit 6 lists the potential perpetrators of, methods of detection for, and evidence in scavenging crimes.

TROJAN HORSES

The Trojan horse method of abuse involves the covert placement or alteration of computer instructions or data in a program so that the computer will perform unauthorized functions. Typically, the computer still allows the program to perform most or all of its intended purposes.

Potential Perpetrators	Methods of Detection	Evidence
• Users of the computer system • Persons with access to computer or backup facilities and adjacent areas	• Tracing of discovered proprietary information back to its source • Testing of an operating system to reveal residual data after job execution	• Computer output media • Type font characteristics • Proprietary information produced in suspicious ways and appearing in computer output media

Exhibit 6. Detection of Scavenging

Trojan horse programs are the primary method used to insert instructions for other abusive acts (e.g., logic bombs, salami attacks, and viruses). This is the most commonly used method in computer program-based frauds and sabotage.

Instructions may be placed in production computer programs so that they will be executed in the protected or restricted domain of the program and have access to all of the data files that are assigned for the program's exclusive use. Programs are usually constructed loosely enough to allow space for inserting the instructions, sometimes without even extending the length or changing the checksum of the infected program.

Detecting and Preventing Trojan Horse Attacks

A typical business application program can consist of more than 100,000 computer instructions and data items. The Trojan horse can be concealed among as many as 5 or 6 million instructions in the operating system and commonly used utility programs. It waits there for execution of the target application program, inserts extra instructions in it for a few milliseconds of execution time, and removes them with no remaining evidence.

Even if the Trojan horse is discovered, there is almost no indication of who may have done it. The search can be narrowed to those programmers who have the necessary skills, knowledge, and access among employees, former employees, contract programmers, consultants, or employees of the computer or software suppliers.

A suspected Trojan horse might be discovered by comparing a copy of the operational program under suspicion with a master or other copy known to be free of unauthorized changes. Although backup copies of production programs are routinely kept in safe storage, clever perpetrators may make duplicate changes in them. In addition, programs are frequently changed for authorized purposes without the backup copies being updated, thereby making comparison difficult.

A program suspected of being a Trojan horse can sometimes be converted from object form into assembly or higher-level form for easier examination or

Potential Perpetrators	Methods of Detection	Evidence
• Programmers with detailed knowledge of a suspected part of a program and its purpose as well as access to it • Employee technologists • Contracted programmers • Vendor programmers • Computer operators	• Program code comparison • Testing of suspected programs • Tracing of unexpected events or possible gain from the act to suspected programs and perpetrators • Examination of computer audit logs for suspicious programs or pertinent entries	• Unexpected results of program execution • Foreign code found in a suspected program • Audit logs • Uncontaminated copies of suspected programs

Exhibit 7. Detection of Trojan Horses and Viruses

comparison by experts. Utility programs are usually available to compare large programs; however, their integrity and the computer system on which they are executed must be verified by trusted experts.

A Trojan horse might be detected by testing the suspect program to expose the purpose of the Trojan horse. However, the probability of success is low unless exact conditions for discovery are known. (The computer used for testing must be prepared in such a way that no harm will be done if the Trojan horse is executed.) Furthermore, this testing may prove the existence of the Trojan horse but usually does not identify its location. A Trojan horse may reside in the source language version or only in the object form and may be inserted in the object form each time it is assembled or compiled — for example, as the result of another Trojan horse in the assembler or compiler. Use of foreign computer programs obtained from untrusted sources (e.g., shareware bulletin board systems) should be restricted, and the programs should be carefully tested before production use.

The methods for detecting Trojan horse frauds are summarized in Exhibit 7. The Exhibit also lists the occupations of potential perpetrators and the sources of evidence of Trojan horse abuse.

COMPUTER VIRUSES

A computer virus is a set of computer instructions that propagates copies of versions of itself into computer programs or data when it is executed within unauthorized programs. The virus may be introduced through a program designed for that purpose (called a pest) or through a Trojan horse. The hidden virus propagates itself into other programs when they are executed, creating new Trojan horses, and may also execute harmful processes under the authority of each unsuspecting computer user whose programs or system have become infected. A worm attack is a variation in

which an entire program replicates itself throughout a computer or computer network.

Although the virus attack method has been recognized for at least 15 years, the first criminal cases were prosecuted only in November 1987. Of the hundreds of cases that occur, most are in academic and research environments. However, disgruntled employees or ex-employees of computer program manufacturers have contaminated products during delivery to customers.

Preventing, Detecting, and Recovering from Virus Attacks

Prevention of computer viruses depends on protection from Trojan horses or unauthorized programs, and recovery after introduction of a virus entails purging all modified or infected programs and hardware from the system. The timely detection of Trojan horse virus attack depends on the alertness and skills of the victim, the visibility of the symptoms, the motivation of the perpetrator, and the sophistication of the perpetrator's techniques. A sufficiently skilled perpetrator with enough time and resources could anticipate most know methods of protection from Trojan horse attacks and subvert them.

Prevention methods consist primarily of investigating the sources of untrusted software and testing foreign software in computers that have been conditioned to minimize possible losses. Prevention and subsequent recovery after an attack are similar to those for any Trojan horse. The system containing the suspected Trojan horse should be shut down and not used until experts have determined the sophistication of the abuse and the extent of damage. The investigator must determine whether hardware and software errors or intentionally produced Trojan horse attacks have occurred.

Investigators should first interview the victims to identify the nature of the suspected attack. They should also use the special tools available (not resident system utilities) to examine the contents and state of the system after a suspected event. The original provider of the software packages suspected of being contaminated should be consulted to determine whether others have had similar experiences. Without a negotiated liability agreement, however, the vendor may decide to withhold important and possibly damaging information.

The following are examples of possible indications of a virus infection:

- The file size may increase when a virus attaches itself to the program or data in the file.
- An unexpected change in the time of last update of a program or file may indicate a recent unauthorized modification.

- If several executable programs have the same date or time in the last update field, they have all been updated together, possibly by a virus.
- A sudden unexpected decrease in free disk space may indicate sabotage by a virus attack.
- Unexpected disk accesses, especially in the execution of programs that do not use overlays or large data files, may indicate virus activity.

All current conditions at the time of discovery should be documented, using documentation facilities separate from the system in use. Next, all physically connected and inserted devices and media that are locally used should be removed if possible. If the electronic domain includes remote facilities under the control of others, an independent means of communication should be used to report the event to the remote facilities manager. Computer operations should be discontinued; accessing system functions could destroy evidence of the event and cause further damage. For example, accessing the contents or directory of a disk could trigger the modification or destruction of its contents.

To protect themselves against viruses or indicate their presence, users can:

- Compare programs or data files that contain checksums or hash totals with backup versions to determine possible integrity loss.
- Write-protect diskettes whenever possible, especially when testing an untrusted computer program. Unexpected write-attempt errors may indicate serious problems.
- Boot diskette-based systems using clearly labeled boot diskettes.
- Avoid booting a hard disk drive system from a diskette.
- Never put untrusted programs in hard disk root directories. Most viruses can affect only the directory from which they are executed; therefore, untrusted computer programs should be stored in isolated directories containing a minimum number of other sensitive programs or data files.
- When transporting files from one computer to another, use diskettes that have no executable files that might be infected.
- When sharing computer programs, share source code rather than object code, because source code can more easily be scanned for unusual contents.

The best protection against viruses, however, is to frequently back up all important data and programs. Multiple backups should be maintained over a period of time, possibly up to a year, to be able to recover from uninfected backups. Trojan horse programs or data may be buried deeply in a computer system — for example, in disk sectors that have been declared by the operating system as unusable. In addition, viruses may contain counters for logic bombs with high values, meaning that the virus may be spread many times before its earlier copies are triggered to cause visible damage.

The perpetrators, detection, and evidence are the same as for Trojan horse attacks (see Exhibit 7).

SALAMI TECHNIQUES

A salami technique is an automated form of abuse involving Trojan horses or secret execution of an unauthorized program that causes the unnoticed or immaterial debiting of small amounts of assets from a large number of sources or accounts. The name of this technique comes from the fact that small slices of assets are taken without noticeably reducing the whole. Other methods must be used to remove the acquired assets from the system.

For example, in a banking system, the demand deposit accounting system of programs for checking accounts could be changed (using the Trojan horse method) to randomly reduce each of a few hundred accounts by 10 cents or 15 cents by transferring the money to a favored account, where it can be withdrawn through authorized methods. No controls are violated because the money is not removed from the system of accounts. Instead, small fractions of the funds are merely rearranged, which the affected customers rarely notice. Many variations are possible. The assets may be an inventory of products or services as well as money. Few cases have been reported.

Detecting Salami Acts

Several technical methods for detection are available. Specialized detection routines can be built into the suspect program, or snapshot storage dump listings could be obtained at crucial times in suspected program production runs. If identifiable amounts are being taken, these can be traced; however, a clever perpetrator can randomly vary the amounts or accounts debited and credited. Using an iterative binary search of balancing halves of all accounts is another costly way to isolate an offending account.

The actions and lifestyles of the few people with the skills, knowledge, and access to perform salami acts can be closely watched for deviations from the norm. For example, the perpetrators or their accomplices usually withdraw the money from the accounts in which it accumulates in legitimate ways; records will show an imbalance between the deposit and withdrawal transaction. However, all accounts and transactions would have to be balanced over a significant period of time to detect discrepancies. This is a monumental and expensive task.

Many financial institutions require employees to use only their financial services and make it attractive for them to do so. Employees' accounts are more completely and carefully audited than others. Such requirements usually force the salami perpetrators to open accounts under assumed

Potential Perpetrators	Methods of Detection	Evidence
• Financial system programmers	• Detailed data analysis using a binary search	• Many small financial losses
• Employee technolgists	• Program comparison	• Unsupported account balance buildups
• Former employees	• Transaction audits	• Trojan horse code
• Contracted programmers	• Observation of financial activities of possible suspects	• Changed or unusual personal financial practices of possible suspects
• Vendor's programmers		

Exhibit 8. Detection of Salami Acts

names or arrange for accomplices to commit the fraud. Therefore, detection of suspected salami frauds might be more successful if investigators concentrate on the actions of possible suspects rather than on technical methods of discovery.

Exhibit 8 lists the methods of detecting the use of salami techniques as well as the potential perpetrators and sources of evidence of the use of the technique.

TRAPDOORS

Computer operating systems are designed to prevent unintended access to them and unauthorized insertion of modification of code. Programmers sometimes insert code that allows them to compromise these requirements during the debugging phases of program development and later during system maintenance and improvement. These facilities are referred to as trapdoors, which can be used for Trojan horse and direct attacks (e.g., false data entry).

Trapdoors are usually eliminated in the final editing, but sometimes they are overlooked or intentionally left in to facilitate future access and modification. In addition, some unscrupulous programmers introduce trapdoors to allow them to later compromise computer programs. Furthermore, designers or maintainers of large complex programs may also introduce trapdoors inadvertently through weaknesses in design logic.

Trapdoors may also be introduced in the electronic circuitry of computers. For example, not all of the combinations of codes may be assigned to instructions found in the computer and documented in the programming manuals. When these unspecified commands are used, the circuitry may cause the execution of unanticipated combinations of functions that allow the computer system to be compromised.

Typical known trapdoor flaws in computer programs include:

- Implicit sharing of privileged data.
- Asynchronous change between time of check and time of use.
- Inadequate identification, verification, authentication, and authorization of tasks.
- Embedded operating system parameters in application memory space.
- Failure to remove debugging aids before production use begins.

During the use and maintenance of computer programs and computer circuitry, ingenious programmers invariably discover some of these weaknesses and take advantage of them for useful and innocuous purposes. However, the trapdoors may be used for unauthorized, malicious purposes as well.

Functions that can be performed by computer programs and computers that are not in the specifications are often referred to as negative specifications. Designers and implementers struggle to make programs and computers function according to specifications and to prove that they do. They cannot practicably prove that a computer system does not perform functions it is not supposed to perform.

Research is continuing on a high priority basis to develop methods of proving the correctness of computer programs and computers according to complete and consistent specifications. However, commercially available computers and computer programs probably will not be proved correct for many years. Trapdoors continue to exist; therefore, computer systems are fundamentally insecure because their actions are not totally predictable.

Detecting Trapdoors

No direct technical method can be used to discover trapdoors. However, tests of varying degrees of complexity can be performed to discover hidden functions used for malicious purposes. The testing requires the expertise of systems programmers and knowledgeable applications programmers. Investigators should always seek out the most highly qualified experts for the particular computer system or computer application under suspicion.

The investigator should always assume that the computer system and computer programs are never sufficiently secure from intentional, technical compromise. However, these intentional acts usually require the expertise of only the technologists who have the skills, knowledge, and access to perpetrate them. Exhibit 9 lists the potential perpetrators, methods of detection, and sources of evidence of the abuse trapdoors.

Potential Perpetrators	Methods of Detection	Evidence
• Expert application programmers	• Exhaustive testing • Comparison of specification to performance • Specific testing based on evidence	• Computer performance or output reports indicating that a computer system performs outside of its specifications

Exhibit 9. Detection of Trapdoors

Potential Perpetrators	Methods of Detection	Evidence
• Programmers with detailed knowledge of a suspected part of a program and its purpose as well as access to it • Employees • Contracted programmers • Vendor's programmers • Computer users	• Program code comparisons • Testing of suspected programs • Tracing of possible gains from the act	• Unexpected results of program execution • Foreign code found in a suspected program

Exhibit 10. Detection of Logic Bombs

LOGIC BOMBS

A logic bomb is a set of instructions in a computer program periodically executed in a computer system that determines conditions or states of the computer, facilitating the perpetration of an unauthorized, malicious act. In one case, for example, a payroll system programmer put a logic bomb in the personnel system so that if his name were ever removed from the personnel file, indicating termination of employment, secret code would cause the entire personnel file to be erased.

A logic bomb can be programmed to trigger an act based on any specified condition or data that may occur or be introduced. Logic bombs are usually placed in the computer system using the Trojan horse method. Methods of discovering logic bombs are the same as for Trojan horses. Exhibit 10 summarizes the potential perpetrators, methods of detection, and kinds of evidence of logic bombs.

ASYNCHRONOUS ATTACKS

Asynchronous attacks take advantage of the asynchronous functioning of a computer operating system. Most computer operating systems function asynchronously on the basis of the services that must be performed for the various computer programs executed in the computer system. For

example, several jobs may simultaneously call for output reports to be produced. The operating system stores these requests and, as resources become available, performs them in the order in which resources are available to fit the request or according to an overriding priority scheme. Therefore, rather than executing requests in the order they are received, the system performs then asynchronously on the basis of the available resources.

Highly sophisticated methods can confuse the operating system to allow it to violate the isolation of one job from another. For example, in a large application program that runs for a long time, checkpoint/restarts are customary. These automatically allow the computer operator to set a switch manually to stop the program at a specified intermediate point and later restart it in an orderly manner without losing data.

To avoid the loss, the operating system must save the copy of the computer programs and data in their current state at the checkpoint. The operating system must also save several system parameters that describe the mode and security level of the program at the time of the stop. Programmers or computer operators might be able to gain access to the checkpoint restart copy of the program, data, and system parameters. They could change the system parameters such that on restart, the program would function at a higher-priority security level or privileged level in the computer and thereby give the program unauthorized access to data, other programs, or the operating system. Checkpoint/restart actions are usually well documented in the computer operations or audit log.

Even more complex methods of attack could be used besides the one described in this simple example, but the technology is too complex to present here. The investigator should be aware of the possibilities of asynchronous attacks and seek adequate technical assistance if suspicious circumstances result from the activities of highly sophisticated and trained technologists. Evidence of such attacks would be discernible only from unexplained deviations from application and system specifications in computer output, or characteristics of system performance. Exhibit 11 lists the potential perpetrators, methods of detecting, and evidence of asynchronous attacks.

DATA LEAKAGE

A wide range of computer crime involves the removal of data or copies of data from a computer system or computer facility. This part of a crime may offer the most dangerous exposure to perpetrators. Their technical act may be well hidden in the computer; however, to convert it to economic gain, they must get the data from the computer system. Output is subject to examination by computer operators and other data processing personnel, who might detect the perpetrators' activity.

Potential Perpetrators	Methods of Detection	Evidence
• Sophisticated advanced system programmers • Sophisticated and advanced computer operators	• System testing of suspected attack methods • Repeat execution of a job under normal and secured circumstances	• Output that deviates from expected output or logs containing records of computer operation

Exhibit 11. Detection of Asynchronous Attacks

Several techniques can be used to secretly leak data from a computer system. The perpetrator may be able to hide the sensitive data in otherwise innocuous-looking output reports — for example, by adding to blocks of data or interspersing the data with otherwise routine data. A more sophisticated method might be to encode data to look like something else. For example, a computer listing may be formatted so that the secret data is in the form of different lengths of printer lines, number of characters per line, or locations of punctuation; is embedded in the least significant digits of engineering data; and uses code words that can be interspersed and converted into meaningful data.

Sophisticated methods of data leakage might be necessary only in high-security, high-risk environments. Otherwise, much simpler manual methods might be used. It has been reported that hidden in the central processors of many computers used in the Vietnam War were miniature radio transmitters capable of broadcasting the contents of the computers to a remote receiver. These were discovered when the computers were returned to the United States.

Detecting Data Leakage

Data leakage would probably best be investigated by interrogating IS personnel who might have observed the movement of sensitive data. In addition, computer operating system usage logs could be examined to determine whether and when data files have been accessed. Because data leakage can occur through the use of Trojan horses, logic bombs, and scavenging, the use of these methods should be investigated when data leakage is suspected.

Evidence will most likely be in the same form as evidence of the scavenging activities described in a preceding section. Exhibit 12 summarizes the detection of crimes resulting from data leakage.

SOFTWARE PIRACY

Piracy is the copying and use of computer programs in violation of copyright and trade secret laws. Commercially purchased computer programs are protected by what is known as a shrink-wrap contract agreement,

Potential Perpetrators	Methods of Detection	Evidence
• Computer programmers • Employees • Former employees • Contracted workers • Vendor's employees	• Discovery of stolen information • Tracing computer storage media back to the computer facility	• Computer storage media • Computer output forms • Type font characteristics • Trojan horse or scavenging evidence

Exhibit 12. Detection of Data Leakage

which states that the program is protected by copyright and its use is restricted.

Since the early 1980s, violations of these agreements have been widespread, primarily because of the high price of commercial programs and the simplicity of copying the programs. The software industry reacted by developing several technical methods of preventing the copying of disks; however, these have not always been successful because of hackers' skills at overcoming this protection and because they are seen as inconvenient to customers.

The software industry has now stabilized and converged on a strategy of imposing no technical constraints to copying, implementing an extensive awareness program to convince honest customers not to engage in piracy, pricing their products more reasonably, and providing additional benefits to purchasers of their products that would not be obtainable to computer program pirates. In addition, computer program manufacturers occasionally find gross violations of their contract agreements and seek highly publicized remedies.

Malicious hackers commonly engage in piracy, sometimes even distributing pirated copies on a massive scale through electronic bulletin boards. Although criminal charges can often be levied against malicious hackers and computer intruders, indictments are most often sought against educational and business institutions, in which gross violations of federal copyright laws and state trade secret laws are endemic.

Detecting Piracy

Investigators can most easily obtain evidence of piracy by confiscating suspects' disks, the contents of their computer hard disks, paper printouts from the execution of the pirated programs, and pictures of screens produced by the pirated programs. Recent court decisions indicate that piracy can also occur when programs are written that closely duplicate the look and feel of protected computer programs, which includes the use of similar command structures and screen displays. Exhibit 13 summarizes the potential perpetrators, detection methods, and evidence of computer program piracy.

Potential Perpetrators	Methods of Detection	Evidence
• Any purchasers and users of commercially available computer programs • Hackers	• Observation of computer users • Search of computer users' facilities and computers • Testimony of legitimate computer program purchasers • Receivers of copied computer programs	• Pictures of computer screens while pirated software is being executed • Copies of computer media on which pirated programs are found • Memory contents of computers containing pirated software • Printouts produced by execution of pirated computer programs

Exhibit 13. Detection of Software Piracy

COMPUTER LARCENY

The theft, burglary, and sale of stolen microcomputers and components are increasing dramatically — a severe problem because the value of the contents of stolen computers often exceeds the value of the hardware taken. The increase in computer larceny is becoming epidemic, in fact, as the market for used computers in which stolen merchandise may be fenced also expands.

It has been suggested that an additional method of protection be used along with standard antitheft devices for securing office equipment. If the user is to be out of the office, microcomputers can be made to run antitheft programs that send frequent signals through modems and telephones to a monitoring station. If the signals stop, an alarm at the monitoring station is set off.

Investigation and prosecution of computer larceny fits well within accepted criminal justice practices, except for proving the size of the loss when a microcomputer worthy only a few hundred dollars is stolen. Evidence of far larger losses (e.g., programs and data) may be needed.

Minicomputers and mainframes have been stolen as well, typically while equipment is being shipped to customers. Existing criminal justice methods can deal with such thefts.

USE OF COMPUTERS FOR CRIMINAL ENTERPRISE

A computer can be used as a tool in a crime for planning, data communications, or control. An existing process can be simulated on a computer, a planned method for carrying out a crime can be modeled, or a crime can be monitored by a computer (i.e., by the abuser) to help guarantee its success.

Potential Perpetrators	Methods of Detection	Evidence
• Computer application programmers • Simulation and modeling experts • Managers in positions to engage in large, complex embezzlement • Criminal organizations	• Investigation of possible computer use by suspects • Identification of equipment	• Computer programs • Computer and communications equipment and their contents • Computer program documentation • Computer input • Computer-produced reports • Computer and data communications usage logs and journals

Exhibit 14. Detection of Simulation and Modeling

In one phase of a 1973 insurance fraud in Los Angeles, a computer was used to model the company and determine the effects of the sale of large numbers of insurance policies. The modeling resulted in the creation of 64,000 fake insurance policies in computer-readable form that were then introduced into the real system and subsequently resold as valid policies to reinsuring companies.

The use of a computer for simulation, modeling, and data communications usually requires extensive amounts of computer time and computer program development. Investigation of possible fraudulent use should include a search for significant amounts of computer services used by the suspects. Their recent business activities, as well as the customer lists of locally available commercial time-sharing and service bureau companies, can be investigated. If inappropriate use of the victim's computer is suspected, logs may show unexplained computer use.

Exhibit 14 lists the potential perpetrators, methods of detection, and kinds of evidence in simulation and modeling techniques.

SUMMARY

Computer crimes will change rapidly along with the technology. As computing becomes more widespread, maximum losses per case are expected to grow. Ultimately, all business crimes will be computer crimes.

Improved computer controls will make business crime more difficult, dangerous, and complex, however. Computers and workstations impose absolute discipline on information workers, forcing them to perform within set bounds and limiting potential criminal activities. Managers receive

improved and more timely information from computers about their businesses and can more readily discern suspicious anomalies indicative of possible wrongdoing.

Although improved response rates from victims, improvements in security, modification of computer use, reactions from the criminal justice community, new laws, and saturation of the news media warning of the problems will cause a reduction of traditional types of crime, newer forms of computer crime will proliferate. Viruses and malicious hacking will eventually be superseded by other forms of computer abuse, including computer larceny, desktop forgery, voice mail and E-mail terrorism and extortion, fax graffiti, phantom computers secretly connected to networks, and repudiation of EDI transactions.

The International Dimensions of Cyber-Crime*

Ed Gabrys, CISSP

It is Monday morning and you begin your prework ritual by going to the World Wide Web and checking the morning electronic newspapers. In the past you might have read the paper edition of *The New York Times* or *The Wall Street Journal;* but with free news services and robust search features available on the Internet, you have decided to spare the expense and now the Internet is your primary news source. Your browser automatically opens to the electronic edition of your favorite news site, where you see the latest headline, "Electronic Terrorist Group Responsible for Hundreds of Fatalities." Now wishing that you had the paper edition, you wonder if this news story is real or simply a teenage hacker's prank. This would not be the first time that a major news service had its Web site hacked. You read further and the story unfolds. A terrorist group, as promised, has successfully struck out at the United States. This time, the group did not use conventional terrorist weapons such as firearms and explosives, but instead has attacked state infrastructure using computers. Electronically breaking into electric power plants, automated pipelines, and air-traffic-control systems, in one evening they have successfully caused havoc and devastation across the United States, including mid-air collisions over major U.S. city airports. To top it off, the U.S. government is unable to locate the culprits. The only thing that authorities know for sure is that the perpetrators are not physically located in the United States.

Is this science fiction or a possible future outcome? As an information security specialist, you have probably heard variations on this theme many times; but now, in the light of both homegrown and foreign terrorism striking the United States, the probability needs to be given serious thought. Considering the growing trends in computer crime, world dependence on computers and communication networks, and the weaknesses in the world's existing laws, it may soon be history. Kenneth A. Minihan, Director of the National Security Agency, has called the Information Superhighway "the economic lifeblood of our nation."[1] When you consider that order, economic prosperity is as important to state security as military power in the New World, an attack on a country's infrastructure may be as devastating as a military attack. This could be the next Pearl Harbor — an *electronic* Pearl Harbor!

To successfully combat the cyber-crime threat, a global solution must be addressed. To date, the only far-reaching and coordinated global response to the cyber-crime problem has been the Convention on Cyber-Crime developed by the Council of Europe (CoE). Unfortunately, the treaty has the potential to achieve its goals at the loss of basic human rights and innovation, and by extending state powers. Those who drafted the treaty have violated an important principle of regime theory — disallowance of the participation of all relevant actors in its decision making by drafting a convention that only represents the voice of the actors in power.

To clarify the arguments outlined above, this chapter first defines the scale and extent of the growing global cyber-crime threat. The second section illustrates how organizations are currently responding and highlights the Council of Europe's solution. In the third section, regime theory is defined and applied to the global cyber-

*A look at the Council of Europe's Cyber-Crime Convention and the need for an international regime to fight cyber-crime

crime problem; then an argument of how the CoE's convention fails to embrace an important element of regime-theory principles is made. Finally, in the last section, an adjusted Council of Europe convention is offered as an alternative and will be compared to a notable and successful international regime.

Part I: Global Cyber-Crime

The Cyber-Crime Threat

> Look at how many clueless admins are out there. Look at what kind of proprietary data they are tasked to guard. Think of how easy it is to get past their pathetic defenses…. 'The best is the enemy of the good.'

A New Age and New Risks

The human race has passed through a number of cultural and economic stages. Most of our progress can be attributed to the ideas and the tools we have created to develop them. Wielding sticks and stones, we began our meager beginnings on a par with the rest of the animal kingdom, as hunters and gatherers. We then graduated to agrarian life using our picks and shovels, through an industrial society with our steam engines and assembly lines, and have arrived in today's Digital Age. Computers and communication networks now dominate our lives. Some may argue that a vast number of people in the world have been overlooked by the digital revolution and have never made a phone call, let alone e-mailed a friend over the Internet. The advent of computers has had far-reaching effects; and although some people may not have had the opportunity to navigate the digital highway, they probably have been touched in other ways. Food production, manufacturing, education, health care, and the spread of ideas have all been beneficiaries of the digital revolution. Even the process of globalization owes its far and rapid reach to digital tools.

For all of the benefits that the computer has brought us, like the tools of prior ages, we have paid little attention to the potential harm they bring until after the damage has been done. On one hand, the Industrial Age brought industrialized states greater production and efficiency and an increase in standards of living. On the other, it also produced mechanized warfare, sweatshops, and a depleting ozone layer, to name a few. Advocates of the Digital Age and its now most famous invention, the Internet, flaunt dramatic commercial growth, thriving economies, and the spread of democracy as only a partial list of benefits. The benefits are indeed great, but so are the costs. One such cost that we now face is a new twist on traditional crime — cyber-crime.

An International Threat

> Because of its technological advancements, today's criminals can be more nimble and more elusive than ever before. If you can sit in a kitchen in St. Petersburg, Russia, and steal from a bank in New York, you understand the dimensions of the problem.[3]
>
> **— Former Attorney General Janet Reno**

Cyber-crime is an extension of traditional crime, but it takes place in cyberspace[4] — the nonphysical environment created by computer systems. In this setting, cyber-crime adopts the nonphysical aspects of cyberspace and becomes borderless, timeless, and relatively anonymous. By utilizing globally connected phone systems and the world's largest computer network, the Internet, cyber-criminals are able to reach out from nearly anywhere in the world to nearly any computer system, as long as they have access to a communications link. Most often, that only needs to be a reliable phone connection. With the spread of wireless and satellite technology, location will eventually become totally irrelevant. In essence, the global reach of computer networks has created a borderless domain for cyber-crimes. Add in automation, numerous time zones, and 24/7 access to computer systems, and now time has lost significance. A famous *New Yorker* cartoon shows a dog sitting at

a computer system speaking to his canine companion, saying, "On the Internet, nobody knows you're a dog."[5] In this borderless and timeless environment, only digital data traverses the immense digital highway, making it difficult to know who or what may be operating a remote computer system. As of today there are very few ways to track that data back to a person, especially if the person is skilled enough to conceal his tracks. Moreover, cyber-criminals are further taking advantage of the international aspect of the digital domain by networking with other cyber-criminals and creating criminal gangs. Being a criminal in cyber space takes technical know-how and sophistication. By dividing up the work, cyber-gangs are better able to combat the sophistication and complexities of cyber space. With computers, telecommunications networks, and coordination, the cyber-criminal has achieved an advantage over his adversaries in law enforcement. Cyber-crime, therefore, has an international aspect that creates many difficulties for nations that may wish to halt it or simply mitigate its effects.

Cyber-Crime Defined

Cyber-crime comes in many guises. Most often, people associate cyber-crime with its most advertised forms — Web hacking and malicious software such as computer worms and viruses, or *malware* as it is now more often called. Who can forget some of these more memorable events? Distributed denial-of-service attacks in early 2000 brought down E-commerce sites in the United States and Europe, including Internet notables Yahoo!, Amazon.com, and eBay. The rash of computer worms that are becoming more sophisticated spread around the world in a matter of hours and cost businesses millions — or by some estimates, billions — in damages related to loss and recovery. Also in 2000, a Russian hacker named "Maxus" stole thousands of credit card numbers from the online merchant CD Universe and held them for ransom at $100,000 (U.S.). When his demands were not met, he posted 25,000 of the numbers to a public Web site. These are just a sample of the more recent and widely publicized events. These types of cyber-crimes are often attributed to hackers — or, as the hacker community prefers them to be called, crackers or criminals.

Most often, the hackers associated with many of the nuisance crimes such as virus writing and Web site defacements are what security experts refer to as script kiddies. They are typically males between the ages of 15 and 25, of whom Jerry Schiller, the head of network security at the Massachusetts Institute of Technology, said, "… are usually socially maladjusted. These are not the geniuses. These are the misfits."[6] Although these so-called misfits are getting much of the public attention, the threat goes deeper. The annual CSI/FBI Computer Crime and Security Survey,[7] as shown in Exhibit 149.1, cited foreign governments and corporations, U.S. competitors, and disgruntled employees as other major players responsible for cyber-attacks.[8]

Because cyber-crime is not bound by physical borders, it stands to reason that cyber-criminals can be found anywhere around the world. They do, however, tend to concentrate in areas where education is focused on mathematics (a skill essential to hacking), computer access is available, and the country is struggling economically, such as Russia, Romania, or Pakistan. Although this does not preclude other countries such as the United

Sofia, Bulgaria	0.56

Source: *Internet World*, February 1, 1999.

Kingdom or United States from having their share of computer criminals, recent trends suggest that the active criminal hackers tend to center in these specific areas around the globe. This is an indication that, if their talented minds cannot be occupied and compensated as they may be in an economically prosperous country, then they will use their skills for other purposes. Sergie Pokrovsky, an editor of the Russian hacker magazine *Khaker*, said hackers in his circle "… have skills that could bring them rich salaries in the West, but they expect to earn only about $300 a month working for Russian companies."[9] An online poll on a hacker-oriented Web site asked respondents to name the world's best hackers and awarded hackers in Russia top honors, with 82 percent of the vote. Compare that to the paltry five percent given to American hackers.[10] Looking at online credit card fraud, a 1999 survey of Yahoo! stores (see Exhibit 149.2) reported that nearly a third of foreign orders placed with stolen credit cards could be traced to ten international cities, which is an indicator of the geographic centers of major international hacker concentrations.[11]

Cyber-crime is quite often simply an extension of traditional crimes; and, similarly, there are opportunities for everyone — foreign spies, disgruntled employees, fraud perpetrators, political activists, conventional criminals, as well as juveniles with little computer knowledge. It is easy to see how crimes such as money laundering, credit card theft, vandalism, intellectual property theft, embezzlement, child pornography, and terrorism can exist both in and outside of the cyber-world. Just think about the opportunities that are available to the traditional criminal when you consider that cyber-crime promises the potential for a greater profit and a remote chance of capture. According to the FBI crime files, the average bank robbery yields $4000; the average computer heist can turn around $400,000.[12] Furthermore, the FBI states that there is less than a 1:20,000 chance of a cyber-criminal being caught. This is more evident when you take into consideration that employees — who, as you know, have access to systems, procedures, and passwords — commit 60 percent of the thefts.[13] Adding insult to injury, in the event that a cyber-criminal is actually caught, there is still only a 1:22,000 chance that he will be sent to prison.[14]

Here are just a few examples of traditional crimes that have made their way to the cyber-world. In 1995, a Russian hacker, Vladimir Levin, embezzled more than $10 million from Citibank by transferring electronic money out of the bank's accounts.[15] Copyright infringement or information theft has reached mass proportions with wildly popular file-sharing programs such as Limewire, Morpheous, and the notorious Napster. Millions of copies of copyrighted songs are freely traded among these systems' users all over the globe, which the record companies are claiming cost them billions of dollars.[16] In August 2000, three Kazakhs were arrested in London for allegedly breaking into Bloomberg L.P.'s computer system in Manhattan in an attempt to extort money from the company.[17] A 15-year-old boy was arrested for making terrorist threats and possessing an instrument of crime after he sent electronic mail death threats to a U.S. judge. He demanded the release of three Arab men imprisoned in connection with the failed 1993 plot to blow up several New York City landmarks. If they were not released, he threatened that a *jihad* would be proclaimed against the judge and the United States. Beginning in 1985 until his capture in 2001, Robert Philip Hanssen, while working for the Federal Bureau of Investigation, used computer systems to share national secrets with Russian counterparts and commit espionage.[18] In 1996, members of an Internet chat room called "KidsSexPics" executed a horrific offense involving child pornography and international computer crime. Perpetrators, who included citizens of the United States, Finland, Australia, and Canada, were arrested for orchestrating a child molestation that was broadcast over the Internet.[19]

Computers Go to War: Cyber-Terrorism

> The modern thief can steal more with a computer than with a gun. Tomorrow's terrorist may be able to do more damage with a keyboard than with a bomb.[20]
>
> **— National Research Council, 1991**

> We are picking up signs that terrorist organizations are looking at the use of technology.[21]
>
> **— Ronald Dick**
> **Head of the FBI's Anti-Cyber-Crime Unit**

One of the most frightening elements of cyber-crime is a threat that has fortunately been relatively absent in the world — cyber-terrorism. Cyber-terrorism is, as one may expect, the marriage of terrorism and cyber space. Dorothy Denning, a professor at Georgetown University and a recognized expert in cyber-terrorism, has described it as "unlawful attacks and threats of attack against computer's networks, and the information stored therein when done to intimidate or coerce a government or its people in furtherance of political or social objectives."[22] Although there have been a number of cyber-attacks over the past few years of a political or social nature, none have been sufficiently harmful or frightening to be classified by most authorities as cyber-terrorism. Most of what has occurred, such as threatening e-mails, e-mail bombs, denial-of-service attacks, and computer viruses, are more analogous to street protests and physical sit-ins.

The threat, however, is still very real. In a controlled study, the Department of Defense attacked its own machines. Of the 38,000 machines attacked, 24,700 (or 65 percent) were penetrated. Only 988 (or four percent) of the penetrated sites realized they were compromised; and only 267 (or 27 percent) of those reported the attack.[23] Keep in mind that the Department of Defense has mandatory reporting requirements and a staff that recognizes the importance of following orders, which makes those numbers even more ominous.

Although government systems may have deficiencies, a greater vulnerability may lie with critical infrastructures. Finance, utilities, and transportation systems are predominately managed by the private sector and are far more prone to an attack because those organizations are simply unprepared. A survey by the U.K.-based research firm Datamonitor shows that businesses have been massively underspending for computer security. Datamonitor estimates that $15 billion is lost each year through E-security breaches, while global spending on defense is only $8.7 billion. Moreover, even if business were to improve security spending habits and correct the weaknesses in computer systems, it is effectively impossible to eliminate all vulnerabilities. Administrators often ignore good security practices or are unaware of weaknesses when they configure systems. Furthermore, there is always the possibility that an insider with knowledge may be the attacker. In March 2000, Japan's Metropolitan Police Department reported that software used by the police department to track 150 police vehicles, including unmarked cars, was developed by the Aum Shinryko cult — the same group that gassed the Tokyo subway in 1995, killing 12 people and injuring 6000 others. At the time of the discovery, the cult had received classified tracking data on 115 vehicles.[24]

Experts believe that terrorists are looking at the cyber-world as an avenue to facilitate terrorism. The first way in which terrorists are using computers is as part of their infrastructure, as might any other business trying to take advantage of technological advancements. They develop Web sites to spread messages and recruit supporters, and they use the Internet to communicate and coordinate action.[25]

Clark State, executive director of the Emergency Response and Research Institute in Chicago, testified before a Senate judiciary subcommittee that "members of some Islamic extremist organizations have been attempting to develop a 'hacker network' to support their computer activities and may engage in offensive information warfare attacks in the future."[26] This defines their second and more threatening use of computer systems — that of a weapon. Militant and terrorist groups such as the Indian separatist group Harkat-ul-Ansar and the Provisional Irish Republican Army have already used computer systems to acquire classified military information and technology. In all of the related terrorist cases, there have been no casualties or fatalities directly related to the attack. For those who doubt that a computer attack may be fatal, consider the following real incident. A juvenile from Worcester, Massachusetts, took control of a local telephone switch. Given the opportunity, he disabled local phone service. That alone is not life-threatening. That switch, however, controlled the activation of landing lights for a nearby airport runway that were subsequently rendered inoperable.[27] Luckily, it was a small airport. If it had been the Newark or Los Angeles airport, the effects could have been devastating.

It is believed that most terrorist groups are not yet prepared to stage a meaningful cyber-attack but that they can be in the near future. Understanding that these groups are preparing, critical systems are and will be

vulnerable to an attack; and a successful attack in the cyber-world will gain them immediate and widespread media attention — it should be expected that a cyber-terrorist attack is imminent.

The Threat is Growing

> Every one of us either has been or will be attacked in cyber space. A threat against one is truly a threat against all.[28]
>
> **— Mary Ann Davidson**
> **Security Product Manager at Oracle**

It is difficult to determine what the real scope of the cyber-crime threat is. Most successful computer crimes go unreported to law enforcement or undetected by the victims. If a business has systems that are compromised by a cyber-criminal, they are hard-pressed to make that information public. The cost of the break-in may have been a few thousand, tens of thousands, or possibly hundreds of thousands of dollars. If that cost is not substantial enough, the cost associated with a loss of customer trust and negative public opinion can bankrupt a company.

The statistics that are available illustrate that cyber-crime is undeniably on the rise. The number of Web sites that are reported vandalized each year is reaching numbers close to 1000 a month.[29] ICSA.net reported that the rate of virus infections doubled annually from 1997 to 1999, starting at 21 incidents per month per 1000 computers up to 88.[30] In the United Kingdom, there was a 56-percent increase in cyber-crime for 2000, with most cyber-criminals seeking financial gain or hacking for political reasons.[31] In the first six months of 2000, cyber-crime accounted for half of all U.K. fraud. The FBI has approximately 1400 active investigations into cyber-crime, and there are at least 50 new computer viruses generated weekly that require attention from federal law enforcement or the private sector.[32] According to a Gartner Group study, smaller companies stand a 50:50 chance of suffering an Internet attack by 2003; and more than 60 percent of the victimized companies will not know that they have been attacked.[33] In the event that an attack is undetected, a cyber-criminal can utilize the pirated system to gather information, utilize system capacity, launch further attacks internally or externally to the organization, or leave behind a logic bomb. A logic bomb is a computer program that will wait until triggered and then release a destructive payload. This can include destruction of data, capturing and broadcasting sensitive information, or anything else that a mischievous programmer may be able to devise.

Beyond the increase in incidents, the costs of dealing with cyber-crime are rising as well. A joint study by the American Society for Industrial Security (ASIS) and consulting firm PricewaterhouseCoopers found that Fortune 1000 companies incurred losses of more than $45 billion in 1999 from the theft of proprietary information. That number is up from roughly $24 billion a year in the middle 1990s.[34] Furthermore, the average Fortune 1000 company reported 2.45 incidents with an estimated loss per incident in excess of $500,000.[35] If these numbers are truly accurate, that is a cost of over $1 trillion.

International Issues

> We cannot hope to prevail against our criminal adversaries unless we begin to use the same interactive mechanisms in the pursuit of justice as they use in the pursuit of crime and wealth.[36]
>
> **— Former Attorney General Janet Reno**

Cyber-criminals and cyber-terrorists are chipping away at the cyber-world, weakening the confidentiality, integrity, and availability of our communications channels, computer systems, and the information that traverses or resides in them. As illustrated, the costs are high in many ways. Moreover, if a nation cannot protect its critical infrastructure, the solvency of its businesses, or the safety of its citizens from this growing threat, then it is possible that the nations most dependent on the cyber-world are jeopardizing their very sovereignty. So what is preventing the world from eliminating or at least reducing the cyber-crime threat? The primary challenges are legal and technical.

Whether a cyber-criminal is the proverbial teenage boy hacker or a terrorist, the borderless, timeless, and anonymous environment that computers and communications networks provide creates an international problem for law enforcement agencies. With most crimes, the physical presence of a perpetrator is necessary. This makes investigation of a crime and identification, arrest, and prosecution of a criminal much simpler.

Imagine for a moment that a group of cyber-criminals located in a variety of countries including Brazil, Israel, Canada, and Chile decide to launch an attack to break into an E-commerce Web site that is physically located in California but maintained for a company in New York City. In an attempt to foil investigators, the cyber-gang first takes control of a computer system in South Africa, which in turn is used to attack a system in France. From the system in France, the attackers penetrate the system in California and steal a listing of credit card numbers that they subsequently post to a Web site in England. If California law enforcement is notified, how are they able to investigate this crime? What laws apply? What technology can be used to investigate such a crime?

Legal Issues

> Currently, at least 60 percent of INTERPOL membership lacks the appropriate legislation to deal with Internet/computer-related crime.[37]
>
> **— Edgar Adamson**
> **Head of the U.S. Customs Service**

Traditional criminal law is ill-prepared for dealing with cyber-crime in many ways. The elements that we have taken for granted, such as jurisdiction and evidence, take on a new dimension in cyber space. Below are some of the more important legal issues concerning cyber-crime. This is not intended to be a comprehensive list but rather a highlight.

Criminalizing and Coordinating Computer-Related Offenses

Probably the most important legal hurdle in fighting cyber-crime is the criminalizing and coordinating of computer-related offenses among all countries. Because computer crime is inherently a borderless crime, fighting cyber-criminals cannot be effective until all nations have established comprehensive cyber-crime laws. A report by Chief Judge Stein Schjolberg of Norway highlights a number of countries that still have "no special penal legislation."[38] According to a study that examined the laws of 52 countries and was released in December 2000, Australia, Canada, Estonia, India, Japan, Mauritius, Peru, Philippines, Turkey, and the United States are the top countries that have "fully or substantially updated their laws to address some of the major forms of cyber-crimes."[39] There are still many countries that have not yet adequately addressed the cyber-crime issue, and others are still just considering the development of cyber-security laws.[40]

An excellent example of this issue involves the developer of the "ILOVEYOU" or Love Bug computer worm that was launched from the Philippines in May 2000 and subsequently caused damages to Internet users and companies worldwide calculated in the billions of dollars. A suspect was quickly apprehended, but the case never made it to court because the Philippines did not have adequate laws to cover computer crimes. Because the Philippines did not have the laws, the United States and other countries that did were unable extradite the virus writer to prosecute him for the damage done outside of the Philippines. Within six weeks after the Love Bug attack, the Philippines outlawed most computer crimes.

Investigations and Computer Evidence

Once an incident has occurred, the crime must be investigated. In most societies, the investigation of any crime deals with the gathering of evidence so that guilt or innocence may be proven in a court of law. In cyber space, this often proves very difficult. Evidence is the "testimony, writings, material objects, or other things presented to the senses that are offered to prove the existence or nonexistence of a fact."[41] Without evidence, there really is no way to prove a case. The problem with electronic evidence, unlike evidence in many traditional crimes, is that it is highly perishable and can be removed or altered relatively easily from a remote location. The collection of useful evidence can be further complicated because it may not be retained for any meaningful duration, or at all, by involved parties. For example, Internet service providers (ISPs) may not maintain audit trails, either because their governments may not allow extended retention for privacy reasons, or the ISP may delete it for efficiency purposes. At this time, most countries do not require ISPs to retain electronic information for evidentiary purposes. These audit trails can be essential for tracing a crime back to a guilty party.

In instances where the investigation involves more than one country, the investigators have further problems because they now need to coordinate and cooperate with foreign entities. This often takes a considerable amount of time and a considerable amount of legal wrangling to get foreign authorities to continue with or cooperate in the investigation.

Assuming that it is possible to locate evidence pertaining to a cyber-crime, it is equally important to have the ability to collect and preserve it in a manner that maintains its integrity and undeniable authenticity. Because the evidence in question is electronic information, and electronic information is easily modified, created, and deleted, it becomes very easy to question its authenticity if strict rules concerning custody and forensics are not followed.

Jurisdiction and Venue

After the evidence has been collected and a case is made, a location for trial must be chosen. Jurisdiction is defined as "the authority given by law to a court to try cases and rule on legal matters within a particular geographic area and/or over certain types of legal cases."[42] Because cyber-crime is geographically complex, jurisdiction becomes equally complex — often involving multiple authorities, which can create a hindrance to an investigation. The venue is the proper location for trial of a case, which is most often the geographic locale where the crime was committed. When cyber-crime is considered, jurisdiction and venue create a complex situation. Under which state or nation's laws is a cyber-criminal prosecuted when the perpetrator was physically located in one place and the target of the crime was in another? If a cyber-criminal in Brazil attacked a system in the United States via a pirated system in France, should the United States or France be the venue for the trial? They were both compromised. Or should Brazil hold the trial because the defendant was physically within its geographic boundaries during the crime?

Extradition

Once jurisdiction is determined and a location for trial is set, if the defendant is physically located in a different state or nation than the venue for trial, that person must be extradited. *Black's Law Dictionary* defines extradition as "the surrender by one state or country to another of an individual accused or convicted of an offense outside its own territory and within the territorial jurisdiction of the other, which being competent to try and punish him, demands the surrender."[43] As seen by the Love Bug case, extradition efforts can become unpredictable if cyber-crime laws are not criminalized and especially if extradition laws are not established or modified to take cyber-crime into consideration. As an example, the United States requires, by constitutional law, that an extradition treaty be signed and that these treaties must either list the specific crimes covered by it or require dual criminality, whereby the same law is recognized in the other country.[44] Because the United States only has approximately 100 extradition treaties, and most countries do not yet have comprehensive computer crime laws, extradition of a suspected cyber-criminal to the United States may not be possible.

Technical Issues

The technical roadblocks that may hinder the ability of nations to mitigate the cyber-crime threat primarily concern the tools and knowledge used in the electronic domain of cyber space. Simply put, law enforcement often lacks the appropriate tools and knowledge to keep up with cyber-criminals.

The Internet is often referenced as the World Wide Web (WWW). However, information security professionals often refer to the WWW acronym as the *Wild Wild Web*. Although some countries do their best to regulate or monitor usage of the Internet, it is a difficult environment for any one country to exercise power over. For every control that is put in place, a workaround is found. One example exists for countries that wish to restrict access to the Internet. Saudi Arabia restricts access to pornography, sites that the government considers defamatory to the country's royal family or to Islam, and usage of Yahoo! chat rooms or Internet telephone services on the World Wide Web.[45] Reporters Without Borders, a media-rights advocacy group based in France, estimates that at least 20 countries significantly restrict Internet access.[46] SafeWeb, a small Oakland, California, company, provides a Web site that allows Internet users to mask the Web site destination. SafeWeb is only one of many such companies; and although the Saudi government has retaliated by blocking the SafeWeb site, other sites appear quickly that either offer the same service as SafeWeb or mirror the SafeWeb site so that it is still accessible. This is one example of a service that has legitimate privacy uses and is perfectly legal in its country of origin. However, it is creating a situation for Saudi Arabia and other countries whereby they are unable to enforce their own laws. Although some may argue that Saudi citizens should have the ability to freely access the Internet, the example given is not intended for arguing ethics but purely to serve as an example of the increasing inability of law enforcement to police what is within its jurisdiction. The same tool in the hands of a criminal can prevent authorities with legal surveillance responsibilities from monitoring criminal activity.

SafeWeb is but one example of a large number of tools and processes used for eluding detection. Similarly, encryption can be used to conceal most types of information. Sophisticated encryption programs were once

solely used by governments but are now readily available for download off of the Internet. If information is encrypted with a strong cryptography program, it will take authorities months or possibly years of dedicated computing time to reveal what the encryption software is hiding. Also available from the Internet is software that not only searches for system vulnerabilities, but also proceeds to run an attack against what it has found; and if successful, it automatically runs subsequent routines to hide traces of the break-in and to ensure future access to the intruder.

These types of tools make investigation and the collection of evidence increasingly more difficult. Until more effective tools are developed and made available to facilitate better detection and deterrence of criminal activities, criminals will continue to become more difficult to identify and capture.

Part 2: International Efforts to Mitigate Cyber-Crime Risk

The cyber-crime threat has received the attention of many different organizations, including national and local governments, international organizations such as the Council of Europe and the United Nations, and nongovernmental organizations dealing with issues such as privacy, human rights, and those opposed to government regulation.

General Government Efforts

> We are sending a strong signal to would-be attackers that we are not going to let you get away with cyber-terrorism.[47]
>
> **— Norman Mineta**
> **Former Secretary of Commerce**

> One thing that we can learn from the Atomic Age is that preparation, a clear desire and a clear willingness to confront the problem, and a clear willingness to show that you are prepared to confront the problem is what keeps it from happening in the first place.[48]
>
> **— Condoleezza Rice**
> **National Security Advisor**

Governments around the world are in an unenviable position. On one hand, they need to mitigate the risk imposed by cyber-crime in an environment that is inherently difficult to control; on the other hand, nongovernmental organizations are demanding limited government interference.

The first order of business for national governments is to take the lead in creating a cyber-crime regime that can coordinate the needs of all the world's citizens and all of the nation's interests in fighting the cyber-crime threat. To date, industry has taken the lead; and in effect, government has in a large part ceded public safety and national security to markets.

Many efforts have been made by various nations to create legislation concerning computer crime. The first was a federal bill introduced in 1977 in the Congress by Senator Ribikoff, although the bill was not adopted.[49] The United States later passed the 1984 Computer Fraud and Abuse Law, the 1986 Computer Fraud and Abuse Act, and the Presidential Decision Directive 63 (PDD-63), all of which resulted in strengthened U.S. cyber-crime laws. Internationally, in 1983 the OECD made recommendations for its member countries to ensure that their penal legislation also applied to certain categories of computer crime. The Thirteenth Congress of the International Academy of Comparative Law in Montreal, the U.N.'s Eighth Criminal Congress in Havana, and a Conference in Wurzburg, Germany, all approached the subject in the early 1990s from an international perspective. The focus of these conferences included modernizing national criminal laws and procedures; improvement of computer security and prevention measures; public awareness; training of law enforcement and judiciary agencies; and collaboration with interested organizations of rules and ethics in the use of computers.[50] In 1997, the High-Tech Subgroup of the G-8's Senior Experts on Transnational Organized Crime developed Ten Principles and a plan of action for combating computer crime. This was followed in 1999 by the adoption of principles of transborder access to stored computer data by the G-8 countries. The Principles and action plan included:[51]

- A review of legal systems to ensure that telecommunication and computer system abuses are criminalized

- Consideration of issues created by high-tech crimes when negotiating mutual assistance agreements and arrangements
- Solutions for preserving evidence prior to investigative actions
- Creation of procedures for obtaining traffic data from all communications carriers in the chain of a communication and ways to expedite the passing of this data internationally
- Coordination with industry to ensure that new technologies facilitate national efforts to combat high-tech crime by preserving and collecting critical evidence

Around the globe, countries are slowly developing laws to address cyber-crime, but the organization that has introduced the most far-reaching recommendations has been the Council of Europe (CoE). The Convention on Cyber-Crime was opened for signature on November 23, 2001, and is being ratified by its 41 member states and the observing states — Canada, United States, and Japan — over a one- to two-year period. The treaty will be open to all countries in the world to sign once it goes into effect. The impact of the treaty has the potential to be significant considering that CoE members and observing countries represent about 80 percent of the world's Internet traffic.[52]

Council of Europe Convention

The objective of the Council of Europe's Convention on Cyber-Crime is aimed at creating a treaty to harmonize laws against hacking, fraud, computer viruses, child pornography, and other Internet crimes and ensure common methods of securing digital evidence to trace and prosecute criminals.[53] It will be the first international treaty to address criminal law and procedural aspects of various types of criminal behavior directed against computer systems, networks or data, and other types of similar misuse.[54] Each member country will be responsible for developing legislation and other measures to ensure that individuals can be held liable for criminal offenses as outlined in the treaty. The Convention has been drafted by the Committee of Experts on Crime in Cyberspace (PC-CY) — a group that is reportedly made up of law enforcement and industry experts. The group worked in relative obscurity for three years, released its first public draft — number 19 — in April 2000, and completed its work in December 2000 with the release of draft number 25. The Convention was finalized by the Steering Committee on European Crime Problems and submitted to the Committee of Ministers for adoption before it was opened to members of the Council of Europe, observer nations, and the world at large.

The Convention addresses most of the important issues outlined in this chapter concerning cyber-crime. As previously described, the major hurdles in fighting cyber-crime are the lack of national laws applicable to cyber-crime and the inability for nations to cooperate when investigating or prosecuting perpetrators.

National Law

At a national level, all signatory countries will be expected to institute comprehensive laws concerning cyber-crime, including the following:

- Criminalize "offenses against the confidentiality, integrity and availability of computer data and systems," "computer-related offenses," and "content-related offenses."
- Criminalize the "attempt and aiding or abetting" of computer-related offenses.
- Adopt laws to expedite the preservation of stored computer data and "preservation and partial disclosure of traffic data."
- Adopt laws that empower law enforcement to order the surrender of computer data, computer systems, and computer data storage media, including subscriber information provided by an ISP.
- Adopt laws that provide law enforcement with surveillance powers over "content data" and require ISPs to cooperate and assist.
- Adopt legislation that establishes jurisdiction for computer-related offenses.

International Cooperation

The section of the Convention dealing with international cooperation concerns the development and modification of arrangements for cooperation and reciprocal legislation. Some of the more interesting elements include the following:

- Acceptance of criminal offenses within the Convention as extraditable offenses even in the absence of any formal extradition treaties. If the extradition is refused based on nationality or jurisdiction over the offense, the "requested Party" should handle the case in the same manner as under the law of the "requesting Party."
- Adoption of legislation to provide for mutual assistance to the "widest extent possible for the purpose of investigations or proceedings concerning criminal offenses related to computer systems and data, or for the collection of evidence in electronic form of a criminal offense."[55]
- In the absence of a mutual assistance treaty, the "requested Party" may refuse if the request is considered to be a political offense or that execution of the request may likely risk its "sovereignty, security or other essential interests."

NGO Responses and Criticisms

> We don't want to pass a text against the people.[56]
>
> **— Peter Csonka**
> **Deputy Head of the Council of**
> **Europe's Economic Crime Division**

> The experts should be proud of themselves. They have managed during the past eight months to resist pernicious influence of hundreds if not thousands of individual computer users, security experts, civil liberties groups, ISPs, computer companies and others outside of their select circle of law enforcement representatives who wrote, faxed and e-mailed their concerns about the treaty.[57]
>
> **— David Banisar**
> **Deputy Director of Privacy International**

> We don't have any comment regarding these protestings. Everyone is entitled to their own opinion, but we have no comment.[58]
>
> **— Debbie Weierman**
> **FBI Spokeswoman**

Within days of the CoE's release of its first public draft of the Convention on Cyber-Crime, as well as the release of its subsequent versions, opposition groups rallied together and flooded the Council with requests urging the group to put a hold on the treaty. The 22nd draft received over 400 e-mails.[59] The Global Internet Liberty Campaign, an organization consisting of 35 lobby groups ranging from Internet users to civil liberties activists and anti-censorship groups, wrote to the European Council stating that they "believe that the draft treaty is contrary to well-established norms for the protection of the individual (and) that it improperly extends the police authority of national governments."[60] Member organizations represent North America, Asia, Africa, Australia, and Europe, and include the American Civil Liberties Union, Privacy International (United Kingdom), and Human Rights Network (Russia). Other groups opposed to the proposed treaty are the International Chamber of Commerce, all the ISP associations, and data security groups that are concerned with some key areas regarding human rights, privacy, and the stifling of innovation.

Lack of NGO Involvement

The primary concern — and the problem from which all the others stem — is the fact that the PC-CY worked in seclusion without the involvement of important interest groups representing human rights, privacy, and industry. According to opposition sources, the PC-CY is comprised of "police agencies and powerful private interests."[61] A request by the author was made to the CoE for a list of PC-CY members; however, the request was declined, stating that they "are not allowed to distribute such a list."[62] Throughout the entire period during which the PC-CY was drafting the treaty, not a single open meeting was held. Marc Rotenberg of the Electronic Privacy Information Center called the draft a "direct assault on legal protections and constitutional protections that have been established by national governments to protect their citizens."[63] If the three years of work done by the PC-CY were more inclusive and transparent, many if not all of the remaining issues could have already

been addressed. Unfortunately, although opposition has been expressed, little has been done to address the issues raised; and the Council of Europe passed the Convention regardless.

Overextending Police Powers and Self-Incrimination

A chief concern of many opposition groups is that the Convention extends the power of law enforcement beyond reasonable means and does not provide adequate requirements to ensure that individual rights are preserved. The Global Internet Liberty Campaign points out that an independent judicial review is not required before a search is undertaken. Under Article 19 of the Convention, law enforcement is empowered to search and seize any computer system within its territory that it believes has data that is lawfully accessible or available to the initial system. With today's operating systems and their advanced networking capabilities, it is difficult to find a computer system without a network connection that would make it accessible to any other system. The only question remaining is whether that access is "lawful." If law enforcement draws the same conclusion, where might they stop their search? Such a broad definition of authority can implicate nearly any personal computer attached to the Internet. Furthermore, Article 19 gives law enforcement the power to order any person who has knowledge about the functioning of the computer system, or measures applied to protect the computer data therein, to provide any information necessary to grant access. This would easily include encryption keys or passwords used to encrypt information. To date, only Singapore and Malaysia are believed to have introduced such a requirement into law. The required disclosure of such information to some people might seem to be contrary to U.S. law and the Fifth Amendment, which does not require people to incriminate themselves.

Privacy

The Convention requires that ISPs retain records regarding the activities of their customers and to make that information available to law enforcement when requested. The Global Internet Liberty Campaign letter to the CoE stated, "these provisions pose a significant risk to the privacy and human rights of Internet users and are at odds with well-established principles of data protection such as the Data Protection Directive of the European Union." They argue that such a pool of information could be used "to identify dissidents and persecute minorities." Furthermore, for ISPs to be able to provide such information, the use of anonymous e-mailers and Web surfing tools such as SafeWeb would need to be outlawed because they mask much of the information that ISPs would be expected to provide.

ISP organizations have also taken exception to the proposed requirements, which would place a heavy responsibility on them to manage burdensome record-keeping tasks as well as capture and maintain the information. In addition, they would be required to perform the tasks necessary to provide the requested information.

Mutual Assistance

Under the Convention's requirements, countries are not obligated to consider dual criminality to provide mutual assistance. That is, if one country believes that a law under the new Convention's guidelines is broken and the perpetrator is in foreign territory, that foreign country, as the "requested nation," is required to assist the "requesting nation," regardless of whether a crime was broken in the requested nation's territory. The "requested nation" is allowed to refuse only if they believe the request is political in nature. What will happen if there is a disagreement in definition? In November of 2001, Yahoo! was brought to trial in France because it was accused of allowing the sale of Nazi memorabilia on its auction site — an act perfectly legal in the United States, Yahoo!'s home country. Barry Steinhardt, associate director for the American Civil Liberties Union, asked, "Is what Yahoo! did political? Or a 'crime against humanity,' as the French call it?" Germany recently announced that anyone, anywhere in the world, who promotes Holocaust denial is liable under German law; and the Malaysian government announced that online insults to Islam will be punished.[64] How will this impact national sovereignty over any country's citizens when that country legally permits freedom of speech?

Stifling of Innovation and Safety

Article 6 of the Convention, titled "Misuse of Devices," specifically outlaws the "production, sale, procurement for use, import, distribution or otherwise making available of, a device, including a computer program,

designed or adapted primarily for the purpose of committing any of the offences established (under Title 1)." The devices outlawed here are many of the same devices that are used by security professionals to test their own systems for vulnerabilities. The law explains that the use of such devices is acceptable for security purposes provided the device will not be used for committing an offense established under Title 1 of the Convention. The problem with the regulation is that it may prohibit some individuals or groups from uncovering serious security threats if they are not recognized as authorities or professionals. The world may find itself in a position whereby it must rely on only established providers of security software. They, however, are not the only ones responsible for discovering system vulnerabilities. Quite often, these companies also rely on hobbyists and lawful hacker organizations for relevant and up-to-date information. Dan Farmer, the creator of the free security program "SATAN," caused a tremendous uproar with his creation. Many people saw his program solely as a hacking device with a purpose of discovering system weaknesses so that hackers could exploit them. Today, many professionals use that tool and others like it in concert with commercially available devices to secure systems. Under the proposed treaty, Dan Farmer could have been labeled a criminal and possession of his program would be a crime.

Council of Europe Response

Despite the attention that the draft Convention on Cyber-Crime has received, CoE representatives appear relatively unconcerned; and the treaty has undergone minimal change. Peter Csonka, the CoE deputy head, told Reuters, "We have learned that we have to explain what we mean in plain language because legal terms are sometimes not clear."[65] It is interesting to note that members of the Global Internet Liberty Campaign — and many other lobby groups that have opposed elements of the Convention — represent and include in their staff and membership attorneys, privacy experts, technical experts, data protection officials, and human rights experts from all over the world. The chance that they all may have misinterpreted or misread the convention is unlikely.

Part 3: Approaches for Internet Rule

The effects of globalization have increasingly challenged national governments. Little by little, countries have had to surrender their sovereignty in order to take advantage of gains available by global economic and political factors. The Council of Europe's Convention on Cyber-Crime is a prime example. The advent of the Internet and global communications networks have been responsible for tearing down national borders and permitting the free flow of ideas, music, news, and possibly a common culture we can call cyber-culture. Saudi Arabia is feeling its sovereignty threatened and is attempting to restrict access to Web sites that it finds offensive. France and Germany are having a difficult time restricting access to sites related to Nazism. And all countries that are taking full advantage of the digital age and its tools are threatened by cyber-criminals, whether they are a neighborhood away or oceans away. Sovereign nations are choosing to control the threat through the CoE's cyber-crime treaty. Is this the only option for governing the Internet? No, not necessarily. The following is a selection of possible alternatives.

Anarchic Space

The Internet has remained relatively unregulated. Despite government attempts, Saudis can still access defamatory information about the Saudi royal family; and U.S. citizens are still able to download copyrighted music regardless of restrictions placed on Napster. It is possible that the Internet could be treated as anarchical space beyond any control of nations. This, however, does not solve the cyber-crime problem and could instead lead to an increase in crime.

Supranational Space

On the opposite end of the spectrum, a theoretical possibility is that of the Internet as supranational space. Under this model, a world governing body would set legislation and controls. Because no world government actually exists, this not a realistic option.

National Space

A more probable approach is the treatment of the Internet as national space, wherein individual nations would be responsible for applying their own territorial laws to the Internet. This, unfortunately, has been an approach that seems to be favored by the more powerful nations such as the United States, but it has little effect without coordination and cooperation from other nations and nongovernmental organizations (NGOs).

Epistemic Communities

Another option for Internet rule could be to establish an epistemic community — a "knowledge-based transnational community of experts with shared understandings of an issue or problem or preferred policy responses."[66] This has been a successful approach leading up to the Outer Space Treaty and the Antarctica Treaty. The Outer Space Treaty claims outer space as the "province of mankind"[67] and the Antarctica Treaty "opens the area to exploration and scientific research, to use the region for peaceful purposes only, and to permit access on an equal, nondiscriminatory basis to all states."[68] Scientists specializing in space and ocean sciences have driven much of the decision making that has taken place. A similar approach was used in the computing environment when decisions were made on how to make the Internet handicap accessible. Experts gathered with an understanding of the issue and implemented systems to manage the problem. However, as has been discussed, national governments have an interest in controlling particular aspects of the Internet; and an epistemic community does not provide them the control they desire. Therefore, the success of an epistemic solution in resolving the cyber-crime threat is unlikely.

International Regimes

The most obvious choice for Internet rule — bearing in mind its borderless nature and the interest of states to implement controls and safeguards — is an international regime. According to the noted regime theory expert Stephen Krasner, a regime is defined as "sets of implicit or explicit principles, norms, rules, and decision-making procedures around which actors' expectations converge in a given area of international relations."[69] In fact, it can be argued that a regime is already in the making concerning Internet rule and cyber-crime, and that the Council of Europe's Convention on Cyber-Crime represents the regime's set of explicit "rules." Regrettably, the rules outlined by the Convention do not represent the principles of all the actors. The actors concerning Internet rule extend beyond national governments and include all of the actors that have been described previously, including individual users, privacy and human rights advocates, corporations, ISPs, and, yes, national governments. The Convention was created solely by government representatives and therefore has ignored these other important actors. If a cyber-crime regime did exist that included all interested parties or actors, the principles, norms, rules, and decision-making procedures would be different than what is currently represented in the CoE cyber-crime treaty.

The principles — "beliefs of fact, causation, and rectitude"[70] — for a government-based regime as witnessed in the Convention are primarily concerned with preservation of sovereignty. The focus of the Convention is based on the needs of government-based law enforcement for pursuing and capturing the agent responsible for limiting state sovereignty — the cyber-criminal. A treaty drafted by a fully represented regime would include recommendations and regulations that consider the need for unhindered innovation and the preservation of privacy and basic human rights. Such a regime would also foster discussions that could take place concerning the detrimental effects of criminalizing hacking tools and maintaining communications records for all Internet users.

The norms — "standards of behavior defined in terms of rights and obligations"[71] — for the government-based regime once again center on the need to pursue and deter cyber-criminals. The articles addressing mutual assistance explicitly define the obligations and rights of states concerning jurisdiction, extradition, and extra-territoriality, while paying little respect to the rights of individuals under their own territorial laws. A fully represented regime could table issues concerning the need for dual criminality.

The rules — "specific prescriptions or proscriptions for action" — that would be included in a government-based regime are now painfully evident. Although most of the convention rules are necessary for addressing the cyber-crime problem, their lack of sensitivity to nongovernmental interests is clear.

Finally, the decision-making procedures — prevailing practices for making and implementing collective choice — are obviously absent of any representation outside of government interests. If it were possible to roll back time by three years — and instead of having closed-door sessions with minimal representation, have open

meetings that practiced transparency in all of its dealings and invited representation of all actors involved in Internet activity — the Convention would most likely be a treaty that truly represented the opinions of the collective Internet community.

Part 4: Formula for Success

It is surprising that the CoE, an organization that proclaims one of its primary aims to be "to protect human rights,"[72] would ignore the basic principles of regime theory and the success factors of thriving international regimes, instead prescribing rules that primarily cater to the needs of law enforcement.

One of the more obvious examples of a successful regime is based on the Montreal Protocol on Substances that Deplete the Ozone Layer signed in 1987. As a result of the Montreal Protocol, industries have developed safer, cleaner methods for handling ozone-depleting chemicals and pollution-prevention strategies.[73] The success of this regime can be directly attributed to the cooperation and coordination among all relevant actors, including government, industry, and environmental sciences.

The Convention on Cyber-Crime is open for signatures, the opposition has spoken, and it appears that the only thing standing in the way of the treaty becoming law is the final ratification and introduction of national laws by individual countries. It is now too late for the cyber-crime treaty to truly represent the opinions of all the primary actors, but it is still possible for individual nations to protect the interests of its citizenry. Pressure on the more powerful nations may be enough to make sure that what is adopted will include appropriate measures and safeguards. Unfortunately, many countries do not have a very good history of keeping the best interests of its citizens in mind when they create their laws. Regardless of the ultimate outcome of the treaty, a broadly represented regime is vital to future success in fighting the cyber-crime threat. Although the Convention may not be an ideal solution, it is possible that the introduction of the Convention on Cyber-Crime and the worldwide attention that it has brought to cyber-crime will be the catalyst for finally establishing an effective cyber-crime regime — one that truly represents all actors.

Honeypot Essentials

Anton Chuvakin, Ph.D., GCIA, GCIH

This chapter discusses honeypot (and honeynet) basics and definitions, and then outlines important implementation and setup guidelines. It also describes some of the security lessons a company can derive from running a research honeypot, based on this author's experience running a research honeypot. This chapter also provides insight into the techniques of attackers and concludes with considerations useful for answering the question, "Should your organization deploy a honeynet?"

Introduction and Background

Although known to security processionals for a long time, honeypots recently became a hot topic in information security. However, the amount of technical information available on their setup, configuration, and maintenance is still sparse, as are qualified people able to run them. In addition, higher-level guidelines (such as need and business-case determination) are similarly absent.

What is a honeypot? Lance Spitzner, a founder of the Honeynet Project (http://project.honeynet.org/) defines a honeypot as "a security resource whose value lies in being probed, attacked, or compromised." The Project differentiates between *research* and *production* honeypots. The former are focused on gaining intelligence information about attackers and their technologies and methods, and the latter are aimed at decreasing the risk to company IT resources and providing advance warning about the incoming attacks on the network infrastructure. Honeypots of any kind are difficult to classify using the "prevention–detection–response" metaphor, but it is hoped that after reading this chapter their value will become clearer to readers.

This chapter focuses on operating a research honeypot or a "honeynet." The term "honeynet," used in this chapter originated in the Honeynet Project and means a network of systems with fairly standard configurations connected to the Internet. The only difference between such a network and a regular production network is that all communication is recorded and analyzed, and no attacks targeted at third parties can escape the network. Sometimes, the system software is slightly modified to help deal with encrypted communication, often used by attackers. The systems are never "weakened" for easier hacking but are often deployed in default configurations with a minimum of security patches. They might or might not have known security holes. The Honeynet Project defines such honeypots as "high-interaction honeypots," meaning that attackers interact with a deception system exactly as they would with a real victim machine. On the other hand, various honeypot and deception daemons are "low-interaction," as they provide only an illusion to an attacker, and one that can hold their attention for a short time only. Such honeypots have value as an early attack indicator but do not yield in-depth information about the attackers.

Research honeypots are set up with no extra effort to lure attackers — blackhats locate and exploit systems on their own. It happens due to the widespread use of automatic hacking tools, such as fast, multiple vulnerability scanners and automatic penetration scripts. For example, an attacker from our honeynet has attempted to scan 200,000 systems for a single FTP vulnerability in one night using such tools. Research honeypots are also unlikely to be used for prosecuting intruders; however, researchers are known to track hacker activities using various covert techniques for a long time after the intruder broke into their honeypot. In addition, prosecution based on honeypot evidence has never been tested in a court of law. It is still wise to involve the company's legal team before setting up such a hacker study project.

Overall, the honeypot is the best tool for looking into malicious hacker activity. The reason is simple: all communication to and from the honeynet is malicious by definition. No data filtering, no false-positives, and no false-negatives (the latter only if the data analysis is adequate) are obscuring the picture. Watching the honeypot provides insight into intruders' personalities and can be used to profile attackers. For example, during the summer of 2002, the majority of penetrated Linux honeypots were hacked by Romanian attackers.

Setting Up a Honeypot

What are some of the common-sense prerequisites for running a honeynet? First, a honeypot is a sophisticated security project, and it makes sense to take care of security basics first. If your firewall crashes or your intrusion detection system (IDS) misses attacks, you are clearly not yet ready for a honeypot deployment. Running a honeypot also requires advanced knowledge in computer security. After running a honeynet for netForensics (http://www.netForensics.com) and as a member of the Honeynet Research Alliance, I can state that operating a honeynet presents the ultimate challenge a security professional can face. The reason is simple: no "lock it down and maintain secure state" model is possible for such a deception network. It requires in-depth expertise in many security technologies and beyond.

Additionally, a honeypot system should not be allowed to attack other systems or, at least, such ability should be minimized. This requirement often conflicts with a desire to create a more realistic environment for malicious hackers to "feel at home" so that they manifest a full spectrum of their behavior. Related to the above is the need for proper separation of a research honey network from company production machines. In addition to protecting innocent third parties, similar measures should be utilized to prevent attacks against your own systems from your honeypot. Honeypot systems should also have reliable out-of-band management. The main reason for having this capability is to be able to quickly cut off the network access to and from the honeypot in cases of emergency (and they do happen!), even if the main network connection is saturated by an attack. That sounds contradictory to the above statement about preventing outgoing attacks but Murphy's law might play a trick or two and "human errors" can never be totally excluded.

The Honeynet Research Alliance (http:// project.honeynet.org/alliance/) has guidelines on data control and data capture for the deployed honeynet. They distill the above ideas and guidelines into a well-written document "Honeynet Definitions, Requirements, and Standards" (http:// project.honeynet.org/alliance/requirements.html). This document establishes some "rules of the game," which have a direct influence on honeynet firewall rule sets and IDS policies.

Data control is a capability required to control the network traffic flow in and out of the honeynet in order to contain the blackhat actions within the defined policy. For example, rules such as "no outgoing connections," "limited number of outgoing connections per time unit," "only specific protocols and/or locations for outgoing connections," "limited bandwidth of outgoing connections," "attack string filtering in outgoing connections" or their combination can be used on a honeynet. Data control functionality should be multi-layered, allow for manual and automatic intervention (such as remote disabling of the honeypot), and make every effort to protect innocent third parties from becoming victims of attacks launched from the honeynet.

Data capture defines the information that should be captured on the honeypot system for future analysis, data retention policies, and standardized data formats that facilitate information sharing between the honeynets and cross-honeynet data processing. Cross-honeypot correlation is an extremely promising area of future research because it allows for the creation of an early warning system about new exploits and attacks. Data capture also covers the proper separation of honeypots from production networks to protect the attack data from being contaminated by the regular network traffic. Another important aspect of data capture is timely documentation of attacks and other incidents occurring in the honeypot. It is crucial for research to have a well-written log of malicious activities and configuration changes performed on the honeypot system.

Running a Honeynet

Consider some of the practical aspects of running a honeynet. Our example setup, a netForensics honeynet, consists of three hosts (see Exhibit 150.1): a victim host, a firewall, and an IDS. This is the simplest configuration to maintain. However, a workable honeynet can even be set up on a single machine if a virtual environment (such as VMWare or UML-Linux) is used. Combining IDS and firewall functionality using a gateway IDS (such as Hogwash) allows one to reduce the requirement to just two machines. A gateway IDS is a host with two

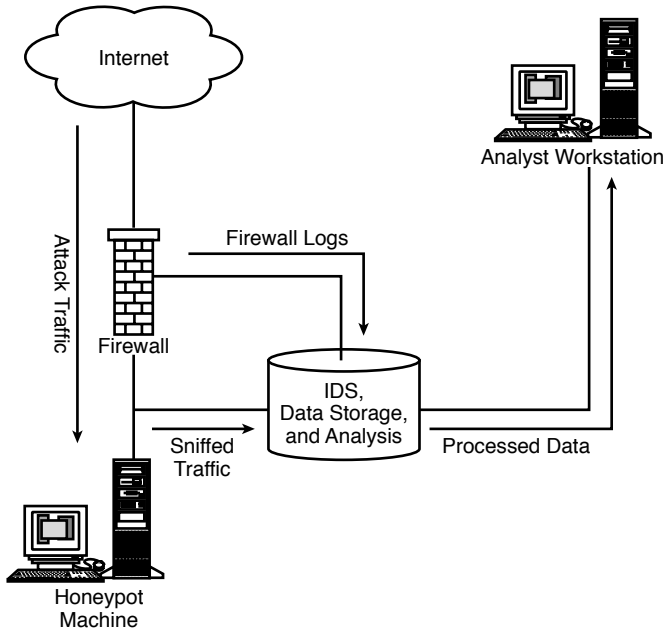

EXHIBIT 150.1 Example setup.

network cards that analyzes the traffic passing through it and can make packet-forwarding decisions (like a firewall) and send alerts based on network packet contents (like an IDS). Currently, the honeynet uses Linux on all systems but various other UNIX flavors will be deployed as "victim" servers by the time this chapter is published. Linux machines in default configurations are hacked often enough to provide a steady stream of data on blackhat activity. "Root"-level system penetration within hours of being deployed is not. UNIX also provides a safe choice for a victim system OS due to its higher transparency and ease of reproducing a given configuration.

The honeypot is run on a separate network connection — always a good idea because the deception systems should not be seen as owned by your organization. The firewall (hardened Linux "iptables" stateful firewall) allows and logs all the inbound connections to the honeypot machines and limits the outgoing traffic, depending on the protocol (with full logging as well). It also blocks all IP spoofing attempts and fragmented packets, which are often used to conceal the source of a connection or launch a denial-of-service attack. The firewall also protects the analysis network from attacks originating from the honeypot. In fact, in the above setup, an attacker has to pierce two firewalls to get to the analysis network. The IDS machine is also firewalled, hardened, and runs no services accessible from the untrusted network. The part of the rule set relevant to protecting the analysis network is very simple: no connections are allowed from the untrusted LAN to an analysis network. The IDS (Snort from www.snort.org) records all network traffic to a database and a binary traffic file via a stealth IP-less interface and also sends alerts on all known attacks detected by its wide signature base (approximately 1650 signatures as of July 2002). In addition, specially designed software is used to monitor the intruder's keystrokes and covertly send them to a monitoring station.

All data capture and data control functionality is duplicated as per Honeynet Project requirements. The 'tcpdump' tool is used as the secondary data capture facility, bandwidth-limiting device serves as the second layer of data control and the stealth kernel-level key logger backs up the keystroke recording. Numerous automated monitoring tools, some custom-designed for the environment, monitor the honeypot network for alerts and suspicious traffic patterns.

Data analysis is crucial for the honeypot environment. The evidence — in the form of system, firewall and IDS log files, IDS alerts, keystroke captures, and full traffic captures — is generated in overwhelming amounts. Events are correlated and suspicious ones are analyzed using the full packet dumps. It is highly recommended to synchronize the time via Network Time Protocol on all the honeypot servers for more reliable data correlation. netForensics software can be used to enable advanced data correlation and analysis. Unlike in the

production environment, having traffic data available in the honeypot is extremely helpful. It also allows for reliable recognition of new attacks. For example, a Solaris attack on the "dtspcd" daemon (TCP port 6112) was first captured in one of the Project's honeypots and then reported to CERT.

The above setup has gone through six system compromises, several massive outbound denial-of-service attacks (all blocked by the firewall!), major system vulnerability scanning, serving as an Internet Relay Chat server for Romanian hackers, and other exciting stuff. It passed with flying colors through all the above "adventures" and can be recommended for deployment.

Lessons Learned

What insight have we gained about the attacking side from running the honeynet? It is true that most of the attackers "caught" in such honeynets are "script kiddies"; that is, the less enlightened part of the hacker community. Although famous early honeypot stories (such as those described in Bill Cheswick's "An Evening with Berferd" and Cliff Stolls' "Cuckoo's Nest") dealt with advanced attackers, most honeypot experiences will probably be related to script kiddies. Opposite to common wisdom, companies do have something to fear from the script kiddies. The number of scans and attacks aimed by the attackers at Internet-facing networks ensures that any minor mistake in network security configuration will be discovered fairly soon. Every unsecured server running a popular operating system (such as Solaris, Linux, or Windows) will be taken over fairly soon. Default configurations and bugs in services (UNIX/Linux ssh, bind, ftpd, and now even Apache Web server and Windows IIS are primary examples) are the reason. We have captured and analyzed multiple attack tools using the above flaws. For example, a fully automated scanner that looks for 25 common UNIX vulnerabilities, runs hundreds of attack threads simultaneously, and deploys a rootkit on the system is one such tool. The software can be set to choose a random A class (16 million hosts) and first scan it for a particular network service (currently, FTP is the favorite, see http://www.dshield. org site for some global scan and attack statistics). Then on the second pass, the program collects FTP banners (such as "ftp. example.com FTP server (Version wu-2.6.1-16) ready") for target selection. On the third pass, the servers that had the misfortune of running a particularly vulnerable version of the FTP daemon are attacked, exploited, and back-doored for convenience. The owner of such a tool can return in the morning to pick up a list of IP addresses that he now "owns" (meaning, has privileged access to).

In addition, malicious attackers are known to compile Internet-wide databases of available network services, complete with their versions so that the hosts can be compromised quickly after the new software flaw is discovered. In fact, there is always a race between various groups to take over more systems. This advantage can come in handy in case of a local denial-of-service (DoS) war. While "our" attackers have not tried to draft the honeypot in their army of "zombie" bots, they did use it to launch old-fashioned, point-to-point DoS attacks (such as UDP, ping floods, and even the ancient modem hang-up ATH DoS).

Attacker behavior seems to indicate that attackers are accustomed to operating with no resistance. One attacker's first action was changing the "root" password on the system — clearly an action that will be noticed the next time the system admin tries to log in. Not a single attacker bothered to check for the presence of the Tripwire integrity checking system, which is included by default in many Linux distributions. On the next Tripwire run, all the "hidden" files are easily discovered. One more attacker had created a directory for himself as "/his-hacker-handle," something that every system admin worth his or her salt will see at once. The rootkits (i.e., hacker toolkits to maintain access to a system that include backdoors, Trojans, and common attack tools) now reach megabyte sizes and feature graphical installation interfaces suitable for novice blackhats. Research indicates that some of the script kiddies "own" networks consisting of hundreds of machines that can be used for DoS or other malicious purposes.

The exposed UNIX system is most often scanned for ports 111 (RPC services) and 21 (FTP). Recent (2000–2002) remote "root" bugs in those services account for this phenomenon. The system with a vulnerable FTP daemon is compromised within two to five days via the WU-FTPD hole described in CERT advisory CA-2001-33.

Another benefit of running a honeypot is a better handle on the Internet noise. Clearly, security professionals who run Internet-exposed networks are well aware of the common Internet noise (such as CodeRed and now SQL worms, warez site FTP scans, etc.). A honeypot allows one to observe the minor oscillations of such noise. Sometimes, such changes are meaningful. In the recent case of the MS SQL worm, we detected a sharp increase

in TCP port 1433 access attempts just before the news of the worm became public. The number of hits was similar to a well-researched CodeRed growth pattern. Thus, we concluded that a new worm was out.

An additional value of the honeypot is in its use as a security training platform. Using the honeypot, a company can bring up the level of incident response skills of its security team. Honeypot incidents can be investigated and then the answers verified by the honeypot's enhanced data collection capabilities. What tool was used to attack? Here it is, on the captured hard drive or extracted from network traffic. What did they want? Look at their shell command history and know. One can quickly and effectively develop network and disk forensics skills, attacker tracking, log analysis, IDS tuning, and many other critical security skills in the controlled but realistic environment of the honeypot.

More advanced research uses of the honeypot include hacker profiling and tracking, statistical and anomaly analysis of incoming probes, the capture of worms, and analysis of malicious code development. By adding some valuable resources (such as E-commerce systems and billing databases) and using the covert intelligence techniques to lure attackers in, more sophisticated attackers can be attracted and studied.

Note that these advanced techniques will increase the operating risks.

Conclusion

Trying to answer the question "Should you do it?" concludes the discussion. The precise answer depends on your organization's mission and available security expertise. Again, the emphasis here is on research honeypots and not on "shield" or protection honeypots. If your organization has taken care of most routine security concerns, has a developed in-house security program (calling an outside consultant to investigate your honeypot incident does not qualify as a wise investment), and requires first-hand knowledge of attacker techniques and last-minute Internet threats, the answer tends toward a tentative "yes." Major security vendors and consultancies or universities with advanced computer security programs might fall into this category. If you are not happy with your existing security infrastructure and want to replace or supplement it with the new, cutting-edge "honeypot technology," the answer is a resounding "no." Research honeypots will not *directly* impact the safety of your organization. Moreover, honeypots have their inherent dangers. They are analyzed in chapters posted on the Honeynet Project site. The dangers include uncertain liability status, possible hacker retaliation, and others.

151

CIRT: Responding to Attack

Chris Hare, CISSP, CISA

This chapter presents a number of topics and issues for today's organization when considering the requirements and impact of establishing a computer incident response team (CIRT). This chapter makes no assumptions as to where a CIRT should be positioned from an organizational perspective within an organization, but focuses on why establishing a CIRT is important and what is involved in setting one up.

The term Computer Emergency Response Team, or CERT, is used to identify the government-funded team located at Carnegie Mellon University. The university has trademarked the name CERT (http://www.cert.org). Consequently, incident response teams are known by one of several other names. These include:

- Computer Incident Response Team (CIRT)
- Computer Security Incident Response Team (CSIRT)
- Systems Security Incident Response Team (SSIRT)

Regardless of the nomenclature, the CIRT is typically responsible for the initial evaluation of a computer security incident and providing corrective action recommendations to management. This chapter explores in detail the prerequisites, roles and responsibilities, and supportive processes necessary for a successful CIRT capability.

History

Prior to the Morris Internet worm of 1988, computer security incidents did not really get a lot of attention, as the problem was not well understood. At that time, there was only a fraction of the total network hosts connected today.

The Morris worm demonstrated to the Internet community, and to the computing world in general, that any determined attacker could cause damage, wreak havoc, and paralyze communication systems by using several commonly known vulnerabilities in UNIX system applications.

The nature of the problem is quite severe. An Internet mailing list known as BUGTRAQ discussed security issues and vulnerabilities in applications and operating systems. This mailing list currently has a volume of more than 1000 messages per quarter, most of which are exploits, bugs, or concerns about commercial applications.

Consider that IBM's mature MVS operating system has 17 million lines of assembly language instructions. Microsoft's Windows NT 5 (Windows 2000) has more than 48 million lines of C and assembly language code. The recognized "bug" factor is one bug for each 1000 lines of code. Windows NT 4 had more than 100,000 validated bugs. This means that there is potential for 48,000 bugs in Windows NT 5.

These bugs provide the perfect opportunity for the attacker to gain access to a system, and either steal, modify, or destroy information or resources from the system owner.

Who Is Attacking Who?

The nature of the attacker is changing dramatically. Considering the movies of a few years ago, *The Net* and *Sneakers*, computer hackers were portrayed as well-educated adults who knew their way around computer systems. They understood what information they needed, how to get it, and what they had to do once they gained access to a system.

Attacker profiles vary considerably:

- *The Naïve*: These attackers have little real knowledge or experience. They are out to do it for fun, with no understanding of the potential consequences.
- *Brutish* (*script kiddies*): These attackers also lack little real knowledge, and make heavy use of the various attack tools that exist. This means that they become obvious and visible on attacked systems due to the heavy probing and scanning used.
- *Clueful*: These are more experienced attackers, who use a variety of techniques to gain access to the system. The attacks are generally more subtle and less obvious.
- *Truly Subtle*: These are the computer criminals of the twenty-first century. They know what they want, who will pay for it, how to get access, and how to move around the system once they enter it. These attackers leave few or no traces on a system that they were in fact there.

The Teenage Attacker

The development of more sophisticated tools has lowered the required sophistication level of the attacker. There are reports of attackers who successfully used the tools to gain access to a system, but then did not know what to do once they got in.

Many teenage attackers also make use of the techniques demonstrated by actor Matthew Broderick in the 1980s movie *War Games*. Broderick used a program known as a "war dialer" to locate the modem tones for computer systems. Today's tools provide the naïve or clueful and brutish attackers with the necessary tools to gain access to almost any system. These tools are meant to be stealthy by nature; and although frequently used by the people outside the organization, they are also used from within. Information on common exploits and attacked sites are available at http://www.rootshell.com, among others.

Although these tools do provide an easier method to compromise a system and gain access, attackers must still know what to do on the system once they have gained access. Recent attempts, as reported in *Systems Administration and Network Security (SANS)* (http://www.sans.org) bulletins and briefings, show that some successful attacks result in little damage or information loss because the attacker did not know how to interact with the system.

The Insider

Insiders may or may not have malicious intent. Their authorized presence on the network allows them virtually unrestricted access to anything, and may allow them to access information that they would normally not have the authority to access. This makes the distinction between the fact that employees are authorized to access the network and specific information and applications available. It does not imply that an employee has any implicit or explicit authorization to access all of the information available on the network.

Malicious insiders are insidious individuals whose goal is to steal or manipulate information so that the company does not have access to complete and accurate data. They may simply destroy it, provide it to the competition, or attempt to embarrass the company by leaking it to the media. These people have authorized access to the network, and therefore are difficult to trace and monitor effectively.

Insiders who are experiencing personal difficulties (e.g., as financial problems), are targets for recruitment by competitive intelligence agencies.

Even more important, insiders can make copies of the information and leave the original intact, thereby making it more difficult to detect that a theft took place. Those insiders that do cause damage lead to detection of the event, but those that undertake some planning make detection much more difficult — if not impossible

The Industrial Spy

Probably the most feared are the industrial spies. These attackers specifically target a particular company as a place from which to obtain information that they have been hired to collect, or that they believe will be considered valuable to others who would buy it. This is known as industrial or economic espionage. The difference between the two is that industrial espionage is conducted by organizations on behalf of companies, and economic espionage is data collection that is authorized and driven by governments.

These criminals are likely well-trained and will use any means at their disposal to discover and steal or destroy information, including social engineering, dumpster diving, coordinated network attacks, even getting a job as a contractor. The FBI (http://www.fbi.org) states that a typical organization can expect that one in every 700 employees is actively working against the company.

Nature of the Attack

The attackers have a variety of tools and an increasing number of vulnerabilities in today's software from which to choose. The nature of the attack and the tools used will vary for each of the attacker types and their intent.

Attack Tools

A very extensive — and for the most part easily obtained — set of attack tools is available to today's attacker. They range from C language files that must be compiled and run against a system, to complex scanning and analysis tools such as nmap. A sample nmap run against several different hosts is illustrated in Exhibit 151.1.

The output of the various attack tools can provide the attacker with a wealth of information regarding the system platform, and as such is used by many attackers and system administrators alike. For example, the output illustrated in Exhibit 151.1 identifies the network services that are configured and additional information regarding how easy it would be to launch a particular types of attack against the system. Take special note that it was able to correctly guess the operating system.

Viruses and Mobile Code

A virus is program code that is intended to replicate from system to system and execute a set of instructions that would not normally be executed by the user. The impact of a virus can range from simple replication, to destruction of the information stored on the system, even to destruction of the computer itself.

EXHIBIT 151.1 Sample Output of nmap of a Linux System.
Log of: ./nmap -O -v -v -o /tmp/log2 192.168.0.4
Interesting ports on linux (192.168.0.4)

Port	State	Protocol	Service
21	open	tcp	ftp
23	open	tcp	telnet
25	open	tcp	smtp
37	open	tcp	time
79	open	tcp	finger
80	open	tcp	http
110	open	tcp	pop-3
111	open	tcp	sunrpc
113	open	tcp	auth
139	open	tcp	netbios-ssn

TCP Sequence Prediction: Class = random positive increments
Difficulty = 4686058 (Good luck!)
Remote operating system guess: Linux 2.2.0-pre6 - 2.2.2-ac5

Viruses are quite common on the Windows platform due to the architecture of the processor and the operating system. It is likely that most computer users today have been "hit" by one virus or another. The attacker no longer has to be able to write the World Wide Web (WWW).

Use of the WWW introduces additional threats through "active code" such as Microsoft's ActiveX and Sun Microsystems' Java languages. These active code sources can be used to collect information from a system, or to introduce code to defeat the security of a system, inject a virus, or modify or destroy information.

The First CERT

The first incident response team was established by the Defense Applied Research Projects Agency (DARPA) (http://www.darpa.mil) in 1988 after the Morris worm disabled approximately 10 percent of the computer systems connected to the Internet. This team is called the Computer Emergency Response Team (CERT) and is located at the Software Engineering Institute at Carnegie Mellon University.

Learning from the Morris Worm

The Morris worm of 1988 was written by Robert Morris, Jr. to demonstrate the vulnerabilities that exist in today's software. Although Morris had contended since his arrest that his intent was not to cause the resulting damage, experts who have analyzed the program have reported that the Morris Worm operated as expected.

There were a large number of reports written in the aftermath of the incident. The General Accounting Office (GAO) issued a thorough report of the Morris worm, its impact and the issues surrounding security on the Internet, and the prosecution of this and similar cases in the future.

The GAO report echoes observations made in other reports on the Morris worm. These observations include:

- The lack of a focal point in addressing Internet-wide security issues contributed to problems in coordination and communication during security emergencies.
- Security weaknesses exist in some sites.
- Not all system managers have the skills and knowledge to properly secure their systems.
- The success of the Morris Worm was through its method of attack, where it made use of known bugs, trusted hosts, and password guessing.
- Problems exist in vendor patch and fix development and distribution.

While these issues were discussed after the Morris worm incident, they are, in fact, issues that exist within many organizations today.

Legal Issues

There are many and inconsistent legal issues to be considered in investigating computer crime. It is worth noting, however, that an incident response team (or corporate investigations unit) typically has considerably more leeway in its operations than law enforcement.

As the property being investigated belongs to the company, the company is free to take any action that it deems appropriate. Once law enforcement is notified of the crime, then the situation becomes a law enforcement issue, and the organization's ability to act is significantly curtailed. This is because once law enforcement is informed, the company's investigators become agents for law enforcement and are then bound by the same constraints.

Among the legal issues that must be addressed are the rules of evidence. These vary from country to country due to differences in legal systems. These rules address how evidence must be collected and handled in order for it to be considered evidence by law enforcement agencies and in a court of law.

The exact actions that the CIRT can perform are governed by the appropriate legislation. The team will be advised by Corporate Counsel, at which point appropriate action will be taken with the intent of not jeopardizing the value of collected evidence or interviews.

Threat Analysis

Threat — and risk analysis in general — is a major proactive role of the CIRT. The CIRT must evaluate every vulnerability report and, based on an analysis of the situation, recommend the appropriate actions to management and who is responsible for completing these actions.

Most often, risk analysis focuses on new exploits or attack methods to determine if there are associated risks within the organizational environment and how such risks can best be mitigated. This is part of the CIRTs ongoing activity, and can include a variety of methods, including research and penetration testing. From this collected information, the CIRT can make recommendations on how to mitigate these risks by making changes to our computing or security infrastructures.

There is, however, the notion of "acceptable" risk. Acceptable risk is that risk which the company is knowingly prepared to accept. For example, if the company can earn $1 million but in the process has an exposure that could cause the loss of $10,000, the company may choose to accept such risk.

These decisions, however, cannot be made by just anyone in the organization. The exact nature of the vulnerability, the threat, and the resulting impact must be clearly evaluated and understood.

- *Threat* is defined as the potential to cause harm to the corporation — intentional or otherwise. Threats include hackers, industrial espionage, and at times, internal employees.
- *Vulnerability* is a weakness or threat to the asset. If there are no vulnerabilities, then a threat cannot put the organization at risk.
- *Impact* reflects degree of harm and is concerned with how significant the problem is, or how much effect it will have on the company.

The threat graph in Exhibit 151.2 illustrates threat, impact, and vulnerability. The risk is lowest when threat and impact are both low. Low impact, low threat, and low vulnerability imply that the *risk* is also low.

If the threat is low, the impact is high, and the vulnerability is low, the company may accept the risk of information loss. The same is true if the impact is low, the vulnerability low, and the threat high. This may still be an acceptable risk to the organization.

Finally, as the impact, vulnerability, and threat all increase, the issue becomes one of high risk. This is typically the area that most companies choose to address and place their emphasis. This is where the greatest risk is and, consequently, where the greatest return on security investment is found.

CIRT: Roles and Responses

Most people think of "Incident Response Teams" as the emergency response unit for computers. The confusing term is "computer." A security incident that involves a computer is only different from a physical security incident in how the event took place. When an unauthorized person gains tactical access to a system or specific information, it should have equivalent importance to unauthorized physical access.

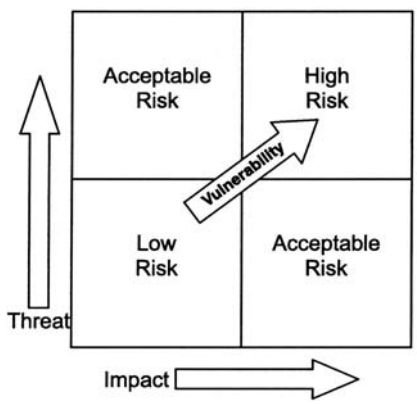

EXHIBIT 151.2 Threat graph: threat, impact, and vulnerability.

The CIRT must be able to handle a crisis and prevent it from becoming worse than it already is. The CIRT, however, has much more to offer, including a proactive role of vulnerability testing, vulnerability analysis, and awareness.

Obviously, the exact nature of responsibilities that one assigns to a CIRT will depend on the size and nature of the organization, the number of incidents recorded, and how many systems and networks exist. Consequently, some of the suggested activities may not be possible for a CIRT to integrate into its day-to-day tasks.

Incident Response

As mentioned, incident response is the prime reason behind establishing a CIRT. This incident response team puts highly trained people at the forefront of any incident, and allows for a consistently applied approach to resolving the incident. The team handles the investigation from start to finish and makes recommendations to management regarding its findings.

Vulnerability Testing

There are two elements to vulnerability testing. The first is to use automated tools with preconfigured tests to determine if there are vulnerabilities that could be exploited by an attacker. The second element test security implementation is to try it out. A penetration or protection test simulates the various types of attacks — internal and external, blind and informed — against the countermeasures of the network. Essentially, a penetration test attempts to gain access through available vulnerabilities by taking on the mindset of the perpetrator.

As the CIRT is responsible for investigating incidents, over time it will develop a set of skills that can be used to offer penetration or protection testing services to the organization's product developers or IS organization. Vulnerability testing is considered the cornerstone of the effort to improve a security program as it attempts to use vulnerabilities as an attacker would. Protection testing is conducted in a similar manner, but the goal is different.

Types of Penetration Tests

There are essentially three major types of penetration testing, each with its own tools and techniques:

> *Level 1. Zero-Knowledge*: This attempts to penetrate the network from an external source without knowledge of its architecture. However, information that is obtained through publicly accessible information is not excluded.
> *Level 2. Full-Knowledge*: This attempts to penetrate the network from an external source with full knowledge of the network architecture and software levels.
> *Level 3. Internal*: This attempts to compromise network security and hosts from inside one's network.

Penetration testing is interval based, meaning that it is done from time to time and against different target points. Penetration testing is not a real-time activity.

The process consists of collecting information about the network and executing the test. In a level 1 test, the only information available is what is published through open source information. This includes network broadcasts, upstream Internet service providers, domain name servers, and public registration records. This helps simulate an attack from an unsophisticated intruder who may try various standard approaches. This approach primarily tests one's ability to detect and respond to an attack.

A Level 2 penetration test assumes full knowledge of the hardware and software used on the network. Such information may be available to meticulous and determined intruders using whatever means, including social engineering, to increase their understanding of one's networks. This stage of the test assumes the worst-possible scenario, and calls to light the maximum number of vulnerabilities.

A Level 3 penetration test (or acid test) is an attack from within the network. This is the best judge of the quality of the implementation of the company's security policy. A real attack from within a network can come from various sources, including disgruntled employees, accidental attacks, and brazen intruders who can socially engineer their way physically into a company.

Penetration testing should be considered very carefully in the implementation of an overall detection program, but it can lead to the negative side effects that one is trying to prevent. Therefore, it should be used

cautiously, but still be used to attempt to locate vulnerabilities and to assess the overall operation of the protection program.

Studying Security Vulnerabilities

When an incident occurs, it is essential to understand what allowed it to happen. Examining the vulnerability used during the incident allows the organization to improve its Security Infrastructure Program to prevent further exploitation.

In addition, security vulnerabilities that are released to the security community need to be assessed for their impact within the organization, and a course of action recommended. The CIRT, with its enhanced skills and knowledge, is capable of reviewing those vulnerabilities and offering the operating system and product groups a method of addressing them.

Publishing Security Alerts

When new issues are found that impact the organization, the CIRT is responsible for the publication of those bulletins and warnings, along with a set of instructions or recommendations regarding how users and systems administrators should react.

Publishing security alerts within the corporation, or new vulnerabilities found, does not include publishing the details of security incidents. The reporting of security incidents is a role for Corporate Security.

Security and Survivability in Wide Area Network-Based Computing

Working from the analysis of incident data, the CIRT is able to make specific recommendations to the systems administrators or applications owners on how to better configure their systems to increase the level of security.

Survivability comes from the application of good administration and consistently applied security techniques to reduce the threat of loss of data from an incident, or the loss of the system. Having to completely rebuild a system is an onerous task that is costly to the business, and one that few people want to repeat frequently.

Defining Incidents

An obvious question is, "What is an incident?" Incidents cannot be easily identified without the team. However, an incident can be defined as any unexpected action that has an immediate or potential effect on the organization.

Example incidents include:

- Viruses
- Unauthorized access, regardless of source
- Information theft or loss of confidentiality
- Attacks against systems
- Denial of service
- Information corruption

However, incidents can be further classified based on the extent to which the incident affects the organization.

The classification of CIRT responses is often based on several factors, including geography, business impact, and the apparent nature of the problem. Business impact includes how many people are affected; how many sites are affected, and will the issue affect stock prices, investor confidence, or damage the organization's reputation.

These classifications are meant to be a guide for discussion purposes — the CIRT may choose to broaden or identify improved characteristics for each.

> *Class 1: Global.* These incidents have the greatest impact on an organization. They have the potential of affecting the entire organization, and they are serious. The uncorrected distribution of a virus can have very significant effects on the organization's ability to function. Other examples include a firewall breach, potential financial loss, customer services, compromise of the corporation's credibility, or the

compromise of the organization's external Web site. In these situations, the CIRT is activated immediately, due to the threat to the company.

Class 2: Regional. Regional incidents affect specific areas of the company. They do, however, have the capability of becoming global. Regional threats include logic bombs, and attacks against specific systems in that region. Although these can become global in nature, the information systems and security organizations in that region may be able to handle the issue without involvement from the CIRT. In this situation, the CIRT is activated at the request of the region IS or Security Directors.

Class 3: Local. Local incidents are isolated to a specific department and are of low impact. Examples include a virus on a single system, and the building cleaning crew playing solitaire on improperly configured desktop systems. In this situation, the CIRT is not activated unless requested by the department manager.

When Does the CIRT Respond?

The CIRT responds in one of several situations:

- At the request of a manager when an event is noticed or reported to them
- When the incident requires it, based on sufficient evidence, probability, or due to a pattern of occurrence
- As the result of issues found during vulnerability testing
- On the advice of the help desk personnel who receive problem reports
- On the advice of an external security agency

CIRT response is based on the severity of an issue, as outlined previously. Managers can request CIRT involvement when they suspect unauthorized activity, regardless of whether there has been an incident reported to the CIRT.

If an incident is believed to have occurred based on evidence (e.g., missing or altered information in a database) or due to alerts from an intrusion detection system, the CIRT is involved to determine the significance, scope, and method of the attack.

It is important to note that help desks can assist in reporting incidents to the CIRT. As employees call their help desks with issues, the help desk may see a pattern emerge that will initiate contacting the CIRT. Consequently, additional training is required for the help-desk staff to inform them of what they should be looking for.

The CIRT then provides a recommendation on how to address the attack and proceed with the investigation of the incident. In some situations, external agencies such as security departments of other organizations may advise of a potential incident and this must be investigated.

Relationship to External Agencies

The CIRT operates within the organizational framework and reviews incidents and provides other services as discussed. It is important, however, that the CIRT establish a relationship with external Computer Emergency Response Teams, such as CERT, CANCERT, etc. These teams provide similar services, but focus on incident reporting and advisory capabilities.

In addition, contact with law enforcement and other external teams that may be required must be established early on, so that if an issue arises, the CIRT is not spending valuable time looking for the correct external resource and then contacting them.

CIRT: The CIRT Process

There is a defined process for creating and establishing the CIRT function. This process is presented in this section. The process consists of six steps. These steps are explained here, but more information on some of the process steps is discussed in other sections.

CIRT is a global process. The team must be available 24 hours a day, 365 days per year. As such, mechanisms to contact the CIRT regardless of where the incident is, must be put into place to allow quick response.

Establishing the Process Owner

The process owner is responsible for supporting the team, and is the individual to whom the team itself reports. The process owner provides the interface to executive management and ensures that the CIRT is fulfilling its responsibilities effectively.

The process owner is assigned by senior management — not by the reputation or position of a single individual. Many organizations choose the Chief Information Officer (CIO) as the process owner, due to the technical nature of the team. Although this is not necessarily incorrect, it is now considered more appropriate to choose either the CFO or the Internal Audit Director to avoid any possibility of conflict of interest. The two alternate positions have legally defined fiduciary responsibilities to protect the corporation's assets and their departments often include staff with fraud investigation backgrounds.

Establishing the Team

The development of a CIRT is a process that requires full acceptance from the corporation's executives, and the groups involved in forming the core team. Specific resources, funding, and authority must be granted for the initiative to be successful and have benefit to the corporation. This section discusses the structure of the CIRT and how it interacts with other internal organizations.

Many organizations consider computer security incidents as an IS problem, although in fact they are a business problem although because any security incident, regardless of how it is caused, has the potential to affect the corporation in many ways, including financial loss, legal or financial liabilities, or customer service.

The very nature of computer involvement means that what is deemed to be an incident may not be when investigated. For example, consider the user who forgets his password and disables it. This may appear like a denial-of-service attack, when in fact it is not. This strains the internal investigative resources, and impacts the company by redirecting resources where they are not needed.

The investigation of an event is a complex process that involves a precise sequence of events and processes to ensure that, should the corporation choose to, it could involve law enforcement and not lose access to the valuable information, or evidence, already collected.

To do this, and for the response to any incident to be effective, people with a wide range of backgrounds and experiences are required. The CIRT ideally would have people from the following areas:

- Technical specialists: An understanding of the production aspects of the technology that are relevant to the investigation
- Information security specialists: Data and systems protection
- Auditors and fraud examiners: Compliance and fraud
- Corporate security: Investigations
- Human resources: Personnel and labor issues
- Business continuity specialists: System and data recovery
- Legal specialists: Protecting the organization's intellectual property
- Corporate public relations: Press and media interaction
- Executive management: The decision makers
- Any other organization- or industry-specific personnel, such as business unit or geographically relevant personnel

The Core Team

For most organizations, it is difficult to rationalize the dedication of such a group of people to the CIRT role and, consequently, it is seen within the industry that the CIRT has two major components: a core team and a support team. The core team is composed of five disciplines, preferably staffed by a single individual from each discipline. These disciplines are:

- Corporate security
- Internal audit
- Information protection
- Legal specialists.
- Technical specialists, as required

The CIRT core team must:

- Determine if the incident is a violation
- Determine the cause and advise management on the action required
- If required, establish the appropriately skilled support team
- Manage the investigation and report
- All in external agencies as necessary

It is essential that the core team be made up of individuals who have the experience required to determine the nature of the incident and involve the appropriate assistance when required.

Many larger organizations have a corporate security group that provides the investigators who are generally prime for the incident. Smaller organizations may have a need to address their investigative needs with a security generalist. This is because the ultimate recommendation for the CIRT may be to turn the incident over to the corporate security organization for further investigation or to contact law enforcement. Obviously, the correct course of action depends on organization structure, and whether or not to contact law enforcement. In that event, specific rules must have been followed. These rules, although important, are not germane to the discussion here.

Internal Audit Services provide the compliance component. Every organization is required to demonstrate compliance with its policies and general business practices. The internal audit organization brings the compliance component to the team; moreover, it will be able to recommend specific actions that are to be taken to prevent further incidents.

The Information Protection or Information Services security specialist is required because the incident involved the use of a computer. The skills that this person holds will enable rapid determination of the path of the attack from one place to another, or gain rapid access to the information contained on a system.

Legal Specialists are essential to make sure that any actions taken by the CIRT are not in violation of any existing corporate procedures, ofany rights of any individuals within the company or country. This is especially important, as there are different laws and regulations governing the corporation and the rights of the individual in many countries.

Although team members have these backgrounds in their respective areas, the core team operates in one of two ways:

- Dedicated full-time to the role of the CIRT and its additional responsibilities identified previously
- Called as needed to examine the incident

In large, geographically dispersed organizations, the CIRT must be capable of deploying quickly and getting the information such as logs, files, buffers, etc., while it is still "fresh," There is no "smoking gun" — only the remnants left behind. Quick action on the part of the CIRT may enable collection of incident-related information that would otherwise be rendered useless as evidence minutes or hours or later.

Selecting the Core Team Members

The selection of the core team members is done based on experience within their knowledge area, their ability to work both individually and as part of a team, and their knowledge of the company as a whole. The process owner, who will select a team leader and then work together to choose the other members of the core team, would conduct the selection process. It is recommended that the team leader be a cooperating member of the team, and that the team leader operate as the point of contact for any requests for assistance.

The Support Team

The support team is used to provide additional resources once the core team has determined what the incident really is, and what other experts need to be called in to assess the situation.

The support team is vital to the operational support of the core team. This is because it is impossible for the core team to have all of the knowledge and expertise to handle every possible scenario and situation. For the core team to be effective, it must identify who the support team members are and maintain contact with and backup information for them over time.

The Support team consists of:

- Human resources (HR)
- Corporate communications
- Platform and technology specialists

- Fraud specialist
- Others as required, such as business unit specialists or those geographically close to the incident

Human resources (HR) is a requirement because any issue that is caused by an employee will require HR's involvement up front to assist in the collection of relevant information, and discussion of the situation with the employee's manager and the employee, and recommendations of appropriate sanctions.

If the incident is a major one that might gain public attention, it is recommended that the corporate public relations function issue a press release earlier, rather than take "knocks" from the public press. Although any bad news can affect a company, by releasing such information on its own, the company can retain control of the incident and report on planned actions. However, it is essential that any press announcements must be cleared through the appropriate departments within the company, including the legal department and senior management. However, there have been sufficient examples with companies (like Microsoft) that would argue this point both ways.

Additionally, the team must designate an individual who is not actively participating to provide information and feedback to management and employees, as deemed appropriate. By choosing a person who does not have an active part in that particular investigation, that person can focus on the communications aspect and let the rest of the team get the job done.

The platform and technology specialists are used to provide support to the team, as no single individual can be aware of and handle all of the technology-related issues in the company. It is also likely that multiple technical specialists will be required, depending on the nature of the incident.

Fraud specialists provide guidance on the direction and investigation of fraud. In some cases, fraud will be hidden behind other issues to cloud the fraud and throw confusion on the issue.

The core team does the selection of the support team members. The core team must evaluate what types of skills it must have access to and then engage the various units within the organization to locate those skills.

It is essential that the core team conduct this activity to allow establishment of a network of contacts should the identified support team member and his or her backup be unavailable. Support team members are selected based on experience within their knowledge area, their ability to work both individually and as part of a team, and their knowledge of the company as a whole.

A major responsibility of the core team is to maintain this database of support team members to allow for quick response by the team when its involvement is required.

Creating the CIRT Operation Process

With the structure of the actual team in mind, it becomes necessary to focus on how the CIRT will operate. This is something that cannot be easily established in advance of core team selection. The process defines the exact steps that are followed each time the team is activated, either by request or due to the nature of the incident.

Aside from some steps that are required to create, establish, and authorize the team, the remaining steps in the process are to be handled by the core team. In addition to training and various other roles, the team must also:

- Document its own practices and procedures
- Establish and maintain databases of contact names and information
- Maintain software and hardware tools required and used during an incident

Several matrices must be developed by the newly formed CIRT. These include an incident matrix and a response matrix. In the incident matrix, the team attempts to discover every possible scenario, and establish the:

- Incident type
- Personnel required
- Financial resources required
- Source of resources

With this, the CIRT can establish the broad budget it will need to investigate incidents. The response matrix identifies the incident type, what the team feels is an appropriate response to the incident, what resources it anticipates will be needed, and how it will escalate the incident should that become necessary. Neither of these matrices can be developed without the core team, and even some initial members of the support teams.

With the matrices completed, it is necessary to establish the training and funding requirements for the team.

Training Requirements

With the CIRT formed, it is necessary that the training requirements be determined. At a minimum, all members of the core team will need to be trained in intrusion management techniques, investigations, interviewing, and some level of computer forensics. (There are organizations that can conduct training specifically in these areas.)

Funding Requirements

The CIRT must now establish its requirements for a budget to purchase the needed equipment that will be used on a frequent or daily basis. A contingency budget is also needed to establish spending limits on equipment that is needed in the middle of an incident.

Given the nature and size of the core team, it is easy to establish that personnel budgets within a large organization will include a minimum of $500K for salaries and other employee costs. Training will approximate $50K per year, with an initial training expense of approximately $100K.

Policy and Procedures

The operation of the CIRT must be supported through policy. The policy establishes the reasons for establishing a CIRT, its authority, and the limits on its actions. Aside from the issues regarding policy in general, policies that support a CIRT must:

- Not violate the law: Doing so results in problems should the need for law enforcement result, or if the employee challenges the actions taken by the company as a result
- Address privacy: Employees must be informed in advance that they have no reasonable expectation of privacy (management has the right to search e-mail, stored files and their on-site workstations during an investigation)
- Have corporate counsel review and approve the policy and procedures as being legal and sustainable in the given local areas

The policy itself leaves out the specifics surrounding the CIRT and how it operates. These are written in standards and procedures and describe how the team will react in specific situations, who the team members are, what the organization structure is, etc.

As mentioned, the employee must not have any expectation of privacy. This can only be accomplished effectively by understanding the privacy laws in the different regions, and stating specifically in policy, that this is the case.

CIRT members should operate within a code of ethics specifically designed for them, as they will be in contact and learn information about employees or situations that they would otherwise not know.

Funding

Funding is essential to the operation of the CIRT. Although it is impossible to know what every investigation will cost, the team will have established a series of matrices identifying possible incidents and the equipment and resources required to handle them. This information is required to establish an operating budget, but contingency funds must be available should an incident cause the team to run over budget, or need a resource that was not planned.

Obviously, not having this information up front affects senior management's decisions to allocate base funding. This means, however, that senior management must believe in the role of the CIRT and the value that it brings to the overall security posture. The CIRT process owner in consultation with the identified CIRT members and external CIRTs, should be able to establish a broad level of required funding and modify it once the matrices are completed.

Authority

The CIRT must be granted the authority to act by senior management. This means that during an investigation of an incident, employees — regardless of level in the company — must be directed to cooperate with the CIRT. They must operate with extreme attention to confidentiality of the information they collect. The CIRT's responsibility is to collect evidence and make recommendations — not to determine guilt.

The role of the CIRT, as previously mentioned, is to investigate incidents and recommend appropriate actions to be taken by management to deal appropriately with the issues. The authority for the creation of the CIRT and its ability to get the job done is conveyed through policy.

Summary

This author has previously discussed intrusion detection.[1] Intrusion detection, regardless of the complexity and accuracy of the system, is not effective without an incident response capability. Consequently, any organization — regardless of size — must bear this in mind when deciding to go ahead with intrusion detection.

But incident response goes well beyond. Incident response is a proactive response to an incident. However, the CIRT can assist in the prevention and detection phases of the security cycle, and thereby create a much stronger, more resilient, and more responsive security infrastructure for today's organization.

Managing the Response to a Computer Security Incident

Michael Vangelos, CISSP

Organizations typically devote substantial information security resources to the prevention of attacks on computer systems. Strong authentication is used, with passphrases that change regularly, tokens, digital certificates, and biometrics. Information owners spend time assessing risk. Network components are kept in access-controlled areas. The least privilege model is used as a basis for access control. There are layers of software protecting against malicious code. Operating systems are hardened, unneeded services are disabled, and privileged accounts are kept to a minimum. Some systems undergo regular audits, vulnerability assessments, and penetration testing. Add it all up, and these activities represent a significant investment of time and money.

Management makes this investment despite full awareness that, in the real world, it is impossible to prevent the success of all attacks on computer systems. At some point in time, nearly every organization must respond to a serious computer security incident. Consequently, a well-written computer incident response plan is an extremely important piece of the information security management toolbox. Much like disaster recovery, an incident response plan is something to be fully developed and practiced — although one hopes that it will never be put into action.

Management might believe that recovering from a security incident is a straightforward exercise that is part of an experienced system administrator's job. From a system administrator's perspective, that may be true in many instances. However, any incident may require expertise in a number of different areas and may require decisions to be made quickly based on factors unique to that incident. This chapter discusses the nature of security incidents, describes how to assemble an incident response team (IRT), and explains the six phases of a comprehensive response to a serious computer security incident.

Getting Started

Why Have an Incident Response Plan?

All computer systems are vulnerable to attack. Attacks by internal users, attacks by outsiders, low-level probes, direct attacks on high-privilege accounts, and virus attacks are only some of the possibilities. Some attacks are merely annoying. Some can be automatically rejected by defenses built into a system. Others are more serious and require immediate attention. In this chapter, incident response refers to handling of the latter group of attacks and is the vehicle for dealing with a situation that is a direct threat to an information system.

Some of the benefits of developing an incident response plan are:

- *Following a predefined plan of action can minimize damage to a network.* Discovery that a system has been compromised can easily result in a state of confusion, where people do not know what to do.

Technical staff may scurry around gathering evidence, unsure of whether they should disable services or disconnect servers from the network. Another potential scenario is that system administrators become aggressive, believing their job is to "get the hacker," regardless of the effect their actions may have on the network's users. Neither of these scenarios is desirable. Better results can be attained through the use of a plan that guides the actions of management as well as technicians during the life of an incident. Without a plan, system administrators may spend precious time figuring out what logs are available, how to identify the device associated with a specific IP address, or perform other basic tasks. With a plan, indecision can be minimized and staff can act confidently as they respond to the incident.

- *Policy decisions can be made in advance.* An organization can make important policy decisions before they are needed, rather than in the heat of the moment during an actual incident. For example, how will decisions be made on whether gateways or servers will be taken down or users disconnected from the network? Will technicians be empowered to act on their own, or must management make those decisions? If management makes those decisions, what level of management? Who decides whether and when law enforcement is notified? If a system administrator finds an intruder with administrative access on a key server, should all user sessions be shut down immediately and log-ins prohibited? If major services are disrupted by an incident, how are they prioritized so that technicians understand the order in which they should be recovered? Invariably, these and other policy issues are best resolved well in advance of when they are needed.
- *Details likely to be overlooked can be documented in the plan.* Often, a seemingly unimportant event turns into a serious incident. A security administrator might notice something unusual and make a note of it. Over the next few days, other events might be observed. At some point, it might become clear that these events were related and constitute a potential intrusion. Unless the organization has an incident response plan, it would be easy for technical staff to treat the situation as simply another investigation into unusual activity. Some things may be overlooked, such as notifying internal audit, starting an official log of events pertaining to the incident, and ensuring that normal cleanup or routine activities do not destroy potential evidence. An incident response plan will provide a blueprint for action during an incident, minimizing the chance that important activities will fall through the cracks.
- *Nontechnical business areas must also prepare for an incident.* Creation of an incident response plan and the act of performing walk-throughs or simulation exercises can prepare business functions for incident response situations. Business functions are typically not accustomed to dealing with computer issues and may be uncomfortable providing input or making decisions if "thrown into the fire" during an actual incident. For example, attorneys can be much better prepared to make legal decisions if they have some familiarity with the incident response process. Human resources and public relations may also be key players in an incident and will be better able to protect the organization after gaining an understanding of how they fit into the overall incident response plan.
- *A plan can communicate the potential consequences of an incident to senior management.* It is no secret that, over time, companies are becoming increasingly dependent on their networks for all aspects of business. The movement toward the ability to access all information from any place at any time is continuing. Senior executives may not have an appreciation for the extent to which automation systems are interconnected and the potential impact of a security breach on information assets. Information security management can use periodic exercises in which potential dollar losses and disruption of services in real-life situations are documented to articulate the gravity of a serious computer security incident.

Requirements for Successful Response to an Incident

There are some key characteristics of effective response to a computer security incident. They follow from effective preparation and the development of a plan that fits into an organization's structure and environment. Key elements of a good incident response plan are:

- *Senior management support.* Without it, every other project and task will drain resources necessary to develop and maintain a good plan.
- *A clear protocol for invoking the plan.* Everyone involved should understand where the authority lies to distinguish between a problem (e.g., a handful of workstations have been infected with a virus because users disabled anti-virus software) and an incident (e.g., a worm is being propagated to hundreds of

workstations and an anti-virus signature does not exist for it). A threshold should be established as a guide for deciding when to mobilize the resources called for by the incident response plan.

- *Participation of all the right players.* Legal, audit, information security, information technology, human resources, protection (physical security), public relations, and internal communications should all be part of the plan. Legal, HR, and protection may play an important role, depending on the type of incident. For some organizations, public relations may be the most important function of all, ensuring that consistent messages are communicated to the outside world.
- *Clear establishment of one person to be the leader.* All activity related to the incident must be coordinated by one individual, typically from IT or information security. This person must have a thorough knowledge of the incident response plan, be technical enough to understand the nature of the incident and its impact, and have the ability to communicate to senior management as well as technical staff.
- *Attention to communication in all phases.* Depending on the nature of the incident, messages to users, customers, shareholders, senior management, law enforcement, and the press may be necessary. Bad incidents can easily become worse because employees are not kept informed and cautioned to refer all outside inquiries concerning the incident to public relations.
- *Periodic testing and updates.* The incident response plan should be revisited regularly. Many organizations test disaster recovery plans annually or more frequently. These tests identify existing weaknesses in the plan and uncover changes in the automation environment that require corresponding adjustments for disaster recovery. They also help participants become familiar with the plan. The same benefits will be derived from simulation exercises or structured walk-throughs of an incident response plan.

Defining an Incident

There is no single, universally accepted definition of incident. The Computer Emergency Response Team Coordination Center (CERT/CC) at Carnegie Mellon University defines incident as "the act of violating an explicit or implied security policy."[1] That may be a great way to describe all events that are bad for computer systems, but it is too broad to use as a basis for the implementation of an incident response plan. The installation of a packet sniffer without management authorization, for instance, may be a violation of policy but probably would not warrant the formality of invoking an incident response plan. However, the use of that sniffer to capture sensitive data such as passwords may be an incident for which the plan should be invoked. The Department of Energy's Computer Incident Advisory Capability (CIAC) uses this definition for *incident*:

> Any adverse event that threatens the security of information resources. Adverse events may include compromises of integrity, denial-of-service attacks, compromise of confidentiality, loss of accountability, or damage to any part of the system. Examples include the insertion of malicious code (e.g., viruses, Trojan horses, or backdoors), unauthorized scans or probes, successful and unsuccessful intrusions, and insider attacks.[2]

This, too, is a good definition and one that is better aligned with the goal of identifying events that should trigger implementation of an incident response plan. To make this definition more useful in the plan, it should be complemented by guidelines for assessing the potential severity of an incident and a threshold describing the level of severity that should trigger invocation of the plan. Responding to an incident, as described in this chapter, involves focused, intense activity by multiple people in order to address a serious condition that may materially affect the health of an organization's information assets. Therefore, as the incident response plan is developed, an organization should establish criteria for deciding whether to invoke the plan.

Developing an Incident Response Team

There is no singularly correct makeup of an incident response team (IRT). However, it is generally agreed that if the following functional units exist in an organization, they should be represented: information security, information technology, audit, legal, public relations, protection (physical security), and human resources. In an ideal situation, specific individuals (preferably a primary and secondary contact) from each of these areas are assigned to the IRT. They will be generally familiar with the incident response plan and have an understanding of what kinds of assistance they may be called upon to provide for any incident. Exhibit 153.1 lists the participants and their respective roles.

EXHIBIT 153.1 Incident Response Team roles

Function	Probable Role
Information security	Often has responsibility for the plan and leads the response; probably leads the effort to put preventive controls in place during preparation phase; staff may also be involved in the technical response (reviewing logs, cleaning virus-infected workstations, reviewing user definitions and access rights, etc.)
Information technology	Performs most eradication and recovery activities; probably involved during detection phase; should be active during preparation phase
Audit	Independent observer who reports to highest level of the organization; can provide valuable input for improving incident response capability
Legal	May be a key participant if the incident was originated by an employee or agency hired by the victim organization; can also advise in situations where downstream liability may exist (e.g., there is evidence that a system was compromised and subsequently used to attack another company's network); may want to be involved any time a decision is made to contact law enforcement agencies; should have input to decisions on whether to prosecute criminal activity; would advise on any privacy issues
Public relations	Should coordinate all communication with the outside world; probably creates the messages that are used
Protection	May be necessary if the incident originated from within the organization and the response may involve confronting a potentially hostile employee or contractor; might also be the best entity to take custody of physical evidence
Human resources	Provides input on how to deal with a situation in which an employee caused the incident or is actively hacking the system

Some organizations successfully manage incidents by effectively splitting an IRT into two distinct units. A technical team is made up of staff with responsibility for checking logs and other evidence, determining what damage if any has been done, taking steps to minimize damage if the incident is ongoing, and restoring systems to an appropriate state. A management team consists of representatives of the functional areas listed above and would act as a steering committee and decision-making body for the life of the incident. An individual leading the response to an incident would appoint leaders of each team or serve as chair of the management team. The two teams, of course, should be in frequent communication with each other, generally with the management team making decisions based on input from the technical team.

Six Phases of Incident Response

It is generally accepted that there are six phases to the discipline of incident response, and the cycle begins well before an incident ever occurs. In any one incident, some of these phases will overlap. In particular, eradication and recovery often occur concurrently. The phases are:

- Preparation
- Detection
- Containment
- Eradication
- Recovery
- Follow-up

Exhibit 153.2 briefly describes the goal of each phase.

Preparation Phase

If any one phase is more important than the others, it is the preparation phase. Before an incident occurs is the best time to secure the commitment of management at all levels to the development of an effective incident

EXHIBIT 153.2 Goal of Each Incident Response Phase

Phase	Goal
Preparation	Adopt policies and procedures that enable effective incident response
Detection	Detect that an incident has occurred and make a preliminary assessment of its magnitude
Containment	Keep the incident from spreading
Eradication	Eliminate all effects of the incident
Recovery	Return the network to a production-ready status
Follow-up	Review the incident and improve incident-handling capabilities

response capability. This is the time when a solid foundation for incident response is built. During this phase, an organization deploys preventive and detective controls and develops an incident response capability.

Management responsible for incident response should do the following:

- Name specific individuals (and alternates) as members of the IRT. Each functional area described in the preceding section of this chapter (audit, legal, human resources, public relations, information security, information technology) should be represented by people with appropriate decision-making and problem-solving skills and authority.
- Ensure that there is an effective mechanism in place for contacting team members. Organizations have a similar need for contacting specific people in a disaster recovery scenario. It may be possible to use the same process for incident response.
- Include guidelines for deciding when the incident response plan is invoked. One of the key areas of policy to be considered prior to an incident is answering the question, "What are the criteria for declaring an incident?"
- Specify the relative priority of goals during an incident. For example,
  - Protect human life and safety (this should always be first).
  - Protect classified systems and data.
  - Ensure the integrity of key operating systems and network components.
  - Protect critical data.
- Commit to conducting sessions to exercise the plan, simulating different types of incidents. Exercises should be as realistic as possible without actually staging an incident. An exercise may, for example, prompt legal, human resources, and protection to walk through their roles in a situation where an employee and contractor have conspired to compromise a network and are actively hacking the system while on company premises. Exercises should challenge IT and information security staff to identify the logs and other forensic data or tools that would be used to investigate specific types of incidents.
- Decide on the philosophy to be used in response to an intrusion. Should an attacker successfully hack in, does the victim organization want to get rid of the intruder as quickly as possible and get back to business (protect and proceed)? Or does the organization want to observe the intruder's movements and potentially gather data for prosecution (pursue and prosecute)?
- Ensure that there is a reasonable expectation that the skills necessary to perform the technical tasks of the incident response plan are present in the organization. Enough staff should understand the applicable network components, forensic tools, and the overall plan so that when an incident occurs, it can be investigated in a full and competent manner.
- Make adjustments to the plan based on test scenario exercises and reviews of the organization's response to actual incidents.
- Review the organization's security practices to ensure that intrusion detection systems are functional, logs are activated, sufficient backups are taken, and a program is in place for regularly identifying system vulnerabilities and addressing those vulnerabilities.

Detection Phase

The goal of the detection phase is to determine whether an incident has occurred. There are many symptoms of a security incident. Some common symptoms are:

- New user accounts not created by authorized administrators
- Unusual activity by an account, such as an unexpected log-in while the user is known to be on vacation or use of the account during odd hours
- Unexpected changes in the lengths of timestamps of operating system files
- Unusually high network or server activity or poor system performance
- Probing activity such as port scans
- For Windows operating systems, unexplained changes in registry settings
- Multiple attempts to log in as root or administrator

Various tools are available to help detect activity that could indicate a security incident. First, there are system logs. Systems should be configured so that logs capture events such as successful and failed log-ins of administrator-level accounts. In addition, failed log-ins of all accounts should be logged. Because log data is relatively worthless unless someone analyzes it, logs should be reviewed on a regular basis. For many systems, the amount of data captured in logs is so great that it is impossible to review it without a utility that searches for and reports those records that might be of interest.

Data integrity checkers exist for UNIX and Windows platforms. These utilities typically keep a database of hash values for specified files, directories, and registry entries. Any time an integrity check is performed, the hash value for each object is computed and compared to its corresponding value in the database. Any discrepancy indicates that the object has changed since the previous integrity check. Integrity checkers can be good indications of an intrusion, but it can take a great deal of effort to configure the software to check only those objects that do not change due to normal system activity.

Intrusion detection systems (IDSs) claim to identify attacks on a network or host in real-time. IDSs basically come in two flavors — network based and host based. A network-based IDS examines traffic as it passes through the IDS sensor, comparing sequences of packets to a database of attack signatures. If it finds a match, the IDS reports an event, usually to a console. The IDS may also be able to send an e-mail or dial a pager as it detects specific events. In contrast, a host-based IDS examines log data from a specific host. As the system runs, the IDS looks at information written to logs in real-time and reports events based on policies set within the IDS.

Organizations become aware of security incidents in many ways. In one scenario, technical staff probably notices or is made aware of an unusual event and begins to investigate. After some initial analysis, it is determined that the event is a threat to the network, so the incident response plan is invoked. If so, the IRT is brought together and formal logging of all activity related to this incident begins. It should be noted that early detection of an incident could mean a huge difference in the amount of damage and cost to the organization. In particular, this is true of malicious code attacks as well as intrusions.

In this phase, the IRT is formally called into action. It is important that certain things occur at this time. Perhaps most importantly, one person should take charge of the process. A log of all applicable events should be initiated at this time and updated throughout the incident. Everyone involved in responding to the incident must be aware of the process. They should all be reminded that the incident will be handled in accordance with guidance provided by the plan, that technical staff should communicate all new developments as quickly as possible to the rest of the team, that everyone must remember to observe evidence chain-of-custody guidelines, and that all communication to employees as well as the outside world should flow through official channels. Some organizations will specify certain individuals who should always be notified when the incident response plan is invoked, even if they are not members of the IRT. For example, the highest internal audit official, COO, the highest information security official, or, in the case where each division of an organization has its own incident response capability, corporate information security may be notified.

Containment Phase

The goal of the containment phase is to keep the incident from spreading. At this time, actions are taken to limit the damage. If it is a malicious code incident, infected servers and workstations may be disconnected from the network. If there is an intruder on the network, the attacker may be limited to one network segment

and most privileged accounts may be temporarily disabled. If the incident is a denial-of-service attack, the sources may be able to be identified and denied access to the target network. If one host has been compromised, communication to other hosts may be disabled.

There is much that can be done prior to an incident to make the job of containment easier. Putting critical servers on a separate subnet, for example, allows an administrator to quickly deny traffic to those servers from any other subnet or network known to be under attack.

It is prudent to consider certain situations in advance and determine how much risk to take if faced with those situations. Consider a situation where information security staff suspects that a rogue NT/2000 administrator with privileges at the top of the tree is logged in to the company's Active Directory (AD). In effect, the intruder is logged in to every Windows server defined to the AD. If staff cannot identify the workstation used by the intruder, it may be best to immediately disconnect all workstations from the network. On the other hand, such drastic action may not be warranted if the intrusion occurs on a less sensitive or less critical network segment. In another example, consider a devastating e-mail-borne worm spreading through an enterprise. At what point is the e-mail service disabled? The incident response plan should contain guidance for making this decision.

The containment phase is also the time when a message to users may be appropriate. Communication experts should craft the message, especially if it goes outside the organization.

Eradication Phase

Conceptually, eradication is simple — this is the phase in which the problem is eliminated. The methods and tools used will depend on the exact nature of the problem. For a virus incident, anti-virus signatures may have to be developed and applied; and hard drives or e-mail systems may need to be scanned before access to infected systems is allowed to resume. For an intrusion, systems into which the intruder was logged must be identified and the intruder's active sessions must be disconnected. It may be possible to identify the device used by the intruder and either logically or physically separate it from the network. If the attack originated from outside the network, connections to the outside world can be disabled.

In addition to the immediate effects of the incident, such as an active intruder or virus, other unauthorized changes may have been made to systems as a result of the incident. Eradication includes the examination of network components that may have been compromised for changes to configuration files or registry settings, the appearance of Trojan horses or backdoors designed to facilitate a subsequent security breach, or new accounts that have been added to a system.

Recovery Phase

During the recovery phase, systems are returned to a normal state. In this phase, system administrators determine (as well as possible) the extent of the damage caused by the incident and use appropriate tools to recover. This is primarily a technical task, with the nature of the incident determining the specific steps taken to recover. For malicious code, anti-virus software is the most common recovery mechanism. For denial-of-service attacks, there may not even be a recovery phase. An incident involving unauthorized use of an administrative-level account calls for a review of (at least) configuration files, registry settings, user definitions, and file permissions on any server or domain into which the intruder was logged. In addition, the integrity of critical user databases and files should be verified.

This is a phase where tough decisions may have to be made. Suppose, for example, the incident is an intrusion and an administrative account was compromised for a period of two days. The account has authority over many servers, such as in a Windows NT domain. Unless one can account for every action taken by the intruder (maybe an impossible task in the real world), one can never be sure whether the intruder altered operating system files, updated data files, planted Trojan horses, defined accounts that do not show up in directory listings, or left time bombs. The only ways to be absolutely certain that a server has been recovered back to its preincident state is to restore from backup using backup tapes known to be taken before the intrusion started, or rebuild the server by installing the operating system from scratch. Such a process could consume a significant amount of time, especially if there are hundreds of servers that could have been compromised. So if a decision is made not to restore from tape or rebuild servers, an organization takes on more risk that the problem will not be fully eradicated and systems fully restored. The conditions under which an organization is willing to live with the added risk is a matter deserving of some attention during the preparation phase.

Follow-Up Phase

It should come as no surprise that after an incident has been detected, contained, eradicated, and all recovery activities have been completed, there is still work to do. In the follow-up phase, closure is brought to the matter with a thorough review of the entire incident.

Specific activities at this time include:

- Consolidate all documentation gathered during the incident.
- Calculate the cost.
- Examine the entire incident, analyzing the effectiveness of preparation, detection, containment, eradication, and recovery activities.
- Make appropriate adjustments to the incident response plan.

Documentation should be consolidated at this time. There may have been dozens of people involved during the incident, particularly in large, geographically dispersed organizations. If legal proceedings begin years later, it is highly unlikely that the documentation kept by each participant will still exist and be accessible when needed. Therefore, all documentation must be collected and archived immediately. There should be no question about the location of all information concerning this incident. Another potential benefit to consolidating all of the documentation is that a similar incident may occur in the future, and individuals handling the new incident should be able to review material from the earlier incident.

The cost of the incident should be calculated, including direct costs due to data loss, loss of income due to the unavailability of any part of the network, legal costs, cost of recreating or restoring operating systems and data files, employee time spent reacting to the incident, and lost time of employees who could not access the network or specific services.

All aspects of the incident should be examined. Each phase of the plan should be reviewed, beginning with preparation. How did the incident occur — was there a preventable breakdown in controls, did the attacker take advantage of an old, unpatched vulnerability, was there a serious virus infection that may have been prevented with more security awareness? Exhibit 153.3 shows questions that could apply at each phase of the incident.

Appropriate adjustments should be made to the incident response plan and to information security practices. No incident response plan is perfect. An organization may be able to avoid future incidents, reduce the damage of future incidents, and get in a position to respond more effectively by applying knowledge gained from a postincident review. The review might indicate that changes should be made in any number of places, including the incident response plan, existing controls, the level of system monitoring, forensic skills of the technical staff, or the level of involvement of non-IT functions.

Other Considerations

Common Obstacles to Establishing an Effective Incident Response Plan

It may seem that any organization committed to establishing an incident response plan would be able to put one in place without much difficulty. However, there are many opportunities for failure as you address the issue of incident response. This section describes some of the obstacles that may arise during the effort.

- There is a tendency to think of serious computer security incidents primarily as IT issues to be handled on a technical level. They are not. Security incidents are primarily business issues that often have a technical component that needs prompt attention. Organizations that consider security incidents to be IT issues are more likely to make the mistake of including only IT and information security staff on the IRT.
- Technical staff with the skills to create and maintain an effective incident response plan may already be overworked simply trying to maintain and improve the existing infrastructure. There can be a tendency to have system administrators put together a plan in their spare time. Typically, these efforts lead to a lot of scurrying to get a plan thrown together in the last few days before a management-imposed deadline for its completion.

EXHIBIT 153.3 Sample Questions for Postincident Review

Preparation

- Were controls applicable to the specific incident working properly?
- What conditions allowed the incident to occur?
- Could more education of users or administrators have prevented the incident?
- Were all of the people necessary to respond to the incident familiar with the incident response plan?
- Were any actions that required management approval clear to participants throughout the incident?

Detection

- How soon after the incident started did the organization detect it?
- Could different or better logging have enabled the organization to detect the incident sooner?
- Does the organization even know exactly when the incident started?
- How smooth was the process of invoking the incident response plan?
- Were appropriate individuals outside of the incident response team notified?
- How well did the organization follow the plan?
- Were the appropriate people available when the response team was called?
- Should there have been communication to inside and outside parties at this time; and if so, was it done?
- Did all communication flow from the appropriate source?

Containment

- How well was the incident contained?
- Did the available staff have sufficient skills to do an effective job of containment?
- If there were decisions on whether to disrupt service to internal or external customers, were they made by the appropriate people?
- Are there changes that could be made to the environment that would have made containment easier or faster?
- Did technical staff document all of their activities?

Eradication and Recovery

- Was the recovery complete — was any data permanently lost?
- If the recovery involved multiple servers, users, networks, etc., how were decisions made on the relative priorities, and did the decision process follow the incident response plan?
- Were the technical processes used during these phases smooth?
- Was staff available with the necessary background and skills?
- Did technical staff document all of their activities?

- It can be difficult to get senior management's attention unless a damaging incident has already occurred. Here is where it may help to draw parallels between business continuity/disaster recovery and incident response. By and large, executives recognize the benefits of investment in a good business continuity strategy. Pointing out the similarities, especially noting that both are vehicles for managing risk, can help overcome this obstacle.
- One can think of a hundred reasons *not* to conduct exercises of the plan. Too many people are involved; it is difficult to stage a realistic incident to test the plan; everybody is too busy; it will only scare people; etc. Lack of testing can very quickly render an incident response plan less than adequate. Good plans evolve over time and are constantly updated as the business and technical environments change. Without periodic testing and review, even a well-constructed incident response plan will become much less valuable over time.

The Importance of Training

It is crucial that an organization conduct training exercises. No matter how good an incident response plan is, periodic simulations or walk-throughs will identify flaws in the plan and reveal where the plan has not kept pace with changes in the automation infrastructure. More importantly, it will keep IRT members aware of the general flow as an incident is reported and the organization responds. It will give technical staff an opportunity to utilize tools that may not be used normally. Each exercise is an opportunity to ensure that all of the tools that might be needed during an incident are still functioning as intended. Finally, it will serve to make key participants more comfortable and more confident during a real incident.

Benefits of a Structured Incident Response Methodology

As this chapter describes, there is nothing trivial about preparing to respond to a serious computer security incident. Development and implementation of an incident response plan require significant resources and specialized skills. It is, however, well worth the effort for the following reasons.

- *An incident response plan provides structure to a response.* In the event of an incident, an organization would be extremely lucky if its technicians, managers, and users all do what they think best and those actions make for an effective response. On the other hand, the organization will almost always be better served if those people acted against the backdrop of a set of guidelines and procedures designed to take them through each step of the way.
- *Development of a plan allows an organization to identify actions and practices that should always be followed during an incident.* Examples are maintaining a log of activities, maintaining an evidentiary chain of custody, notifying specific entities of the incident, and referring all media inquiries to the public relations staff.
- *It is more likely that the organization will communicate effectively to employees if an incident response plan is in place.* If not, messages to management and staff will tend to be haphazard and may make the situation worse.
- *Handling unexpected events is easier if there is a framework that is familiar to all the participants.* Having critical people comfortable with the framework can make it easier to react to the twists and turns that sometimes occur during an incident.

Years ago, security practitioners and IT managers realized that a good business continuity plan was a sound investment. Like business continuity, a computer incident response plan has become an essential part of a good security program.

Cyber-Crime: Response, Investigation, and Prosecution

Thomas Akin, CISSP

> Any sufficiently advanced form of technology is indistinguishable from magic.
>
> **— Arthur C. Clark**

As technology grows more complex, the gap between those who understand technology and those who view it as magic is getting wider. The few who understand the magic of technology can be separated into two sides — those who work to protect technology and those who try to exploit it. The first are information security professionals, the latter hackers. To many, a hacker's ability to invade systems does seem magic. For security professionals — who understand the magic — it is a frustrating battle where the numbers are in the hackers' favor. Security professionals must simultaneously protect every single possible access point, but a hacker only needs a single weakness to successfully attack a system. The lifecycle in this struggle is:

- Protection
- Detection
- Response
- Investigation
- Prosecution

First, organizations work on protecting their technology. Because 100 percent protection is not possible, organizations realized that if they could not completely protect their systems, they needed to be able to detect when an attack occurred. This led to the development of intrusion detection systems (IDSs). As organizations developed and deployed IDSs, the inevitable occurred: "According to our IDS, we've been hacked! Now what?" This quickly led to the formalization of incident response. In the beginning, most organizations' response plans centered on getting operational again as quickly as possible. Finding out the identity of the attacker was often a low priority. But as computers became a primary storage and transfer medium for money and proprietary information, even minor hacks quickly became expensive. In attempts to recoup their losses, organizations are increasingly moving into the investigation and prosecution stages of the life cycle. Today, although protection and detection are invaluable, organizations must be prepared to effectively handle the response, investigation, and prosecution of computer incidents.

Response

Recovering from an incident starts with how an organization responds to that incident. It is rarely enough to have the system administrator simply restore from backup and patch the system. Effective response will greatly affect the ability to move to the investigation phase, and can, if improperly handled, ruin any chances of prosecuting the case. The high-level goals of incident response are to preserve all evidence, remove the

vulnerability that was exploited, quickly get operational again, and effectively handle PR surrounding the incident. The single biggest requirement for meeting all of these goals is preplanning. Organizations must have an incident response plan in place before an incident ever occurs. Incidents invariably cause significant stress. System administrators will have customers and managers yelling at them, insisting on time estimates. Executives will insist that they "just get the damn thing working!" Even the customer support group will have customers yelling at them about how they need everything operational now. First-time decisions about incident response under this type of stress always lead to mistakes. It can also lead to embarrassments such as bringing the system back online only to have it hacked again, deleting or corrupting the evidence so that investigation and prosecution are impossible, or ending up on the evening news as the latest casualty in the war against hackers.

To be effective, incident response requires a team of people to help recover from the incident. Technological recovery is only one part of the response process. In addition to having both IT and information security staff on the response team, there are several nontechnical people who should be involved. Every response should include a senior executive, general counsel, and someone from public relations. Additionally, depending on the incident, expanding the response team to include personnel from HR, the physical security group, the manager of the affected area, and even law enforcement may be appropriate.

Once the team is put together, take the time to plan response priorities for each system. In a Web server defacement, the top priorities are often getting the normal page operational and handling PR and the media. If an online transaction server is compromised and hundreds of thousands of dollars are stolen, the top priority will be tracking the intruder and recovering the money. Finally, realize that these plans provide a baseline only. No incident will ever fall perfectly into them. If a CEO is embezzling money to pay for online sex from his work computer, no matter what the standard response plan calls for, the team should probably discreetly contact the organization's president, board of directors, and general counsel to help with planning the response. Each incident's "big picture" may require changes to some of the preplanned details, but the guidelines provide a framework within which to work.

Finally, it is imperative to make sure the members of the response team have the skills needed to successfully respond to the incident. Are IT and InfoSec staff members trained on how to preserve digital evidence? Can they quickly discover an intruder's point of entry and disable it? How quickly can they get the organization functional again? Can they communicate well enough to clearly testify about technology to a jury with an average education level of sixth grade? Very few system or network administrators have these skills — organizations need to make sure they are developed. Additionally, how prepared is the PR department to handle media inquiries about computer attacks? How will they put a positive spin on a hacker stealing 80,000 credit card numbers from the customer database? Next, general counsel — how up to date are they on the ever-changing computer crime case law? What do they know about the liability an organization faces if a hacker uses its system to attack others?

Without effective response, it is impossible to move forward into the investigation of the incident. Response is more than "just get the damn thing working!" With widespread hacking tools, a volatile economy, and immature legal precedence, it is not enough to know how to handle the hacker. Organizations must also know how to handle customers, investors, vendors, competitors, and the media to effectively respond to computer crime.

Investigation

When responding to an incident, the decision of whether to formally investigate will have to be made. This decision will be based on factors such as the severity of the incident and the effect an investigation will have on the organization. The organization will also have to decide whether to conduct an internal investigation or contact law enforcement. A normal investigation will consist of:

- Interviewing initial personnel
- A review of the log files
- An intrusion analysis
- Forensic duplication and analysis
- Interviewing or interrogating witnesses and suspects

Experienced investigators first determine that there actually was an intrusion by interviewing the administrators who discovered the incident, the managers to whom the incident was reported, and even users to determine if they noticed deviations in normal system usage. Next, they will typically review system and

network log files to verify the organization's findings about the intrusion. Once it is obvious that an intrusion has occurred, the investigator will move to a combination of intrusion analysis and forensics analysis. Although they often overlap, intrusion analysis is most often performed on running systems, and forensic analysis is done offline on a copy of the system's hard drive. Next, investigators will use the information discovered to locate other evidence, systems to analyze, and suspects to interview. If the attacker came from the outside, then locating the intruder will require collecting information from any third parties that the attacker passed through. Almost all outside organizations, especially ISPs, will require either a search warrant or subpoena before they will release logs or subscriber information. When working with law enforcement, they can provide the search warrant. Nonlaw enforcement investigators will have to get the organization to open a "John Doe" civil lawsuit to subpoena the necessary information. Finally, while the search warrant or subpoena is being prepared, investigators should contact the third party and request that they preserve the evidence that investigators need. Many ISPs delete their logs after 30 days, so it is important to contact them quickly.

Due to the volatility of digital evidence, the difficulty in proving who was behind the keyboard, and constantly changing technology, computer investigations are very different from traditional ones. Significant jurisdictional issues can come up that rarely arise in normal investigations. If an intruder resides in Canada, but hacks into the system by going first through a system in France and then a system in China, where and under which country's laws are search warrants issued, subpoenas drafted, or the case prosecuted? Because of these difficulties, international investigations usually require the involvement of law enforcement — typically the FBI. Few organizations have the resources to handle an international investigation. Corporate investigators can often handle national and internal investigations, contacting law enforcement only if criminal charges are desired.

Computer investigations always involve digital evidence. Such evidence is rarely the smoking gun that makes or breaks an investigation; instead, it often provides leads for further investigation or corroborates other evidence. For digital evidence to be successfully used in court, it needs to be backed up by either physical evidence or other independent digital evidence such as ISP logs, phone company records, or an analysis of the intruder's personal computer. Even when the evidence points to a specific computer, it can be difficult to prove who was behind the keyboard at the time the incident took place. The investigator must locate additional proof, often through nontechnical means such as interviewing witnesses, to determine who used the computer for the attack.

Much of technology can be learned through trial and error. Computer investigation is not one of them. Lead investigators must be experienced. No one wants a million-dollar suit thrown out because the investigator did not know how to keep a proper chain of custody. There are numerous opinions about what makes a good investigator. Some consider law enforcement officers trained in technology the best. Others consider IT professionals trained in investigation to be better. In reality, it is the person, not the specific job title, that makes the difference. Investigators must have certain qualities. First, they cannot be afraid of technology. Technology is not magic, and investigators need to have the ability to learn any type of technology. Second, they cannot be in love with technology. Technology is a tool, not an end unto itself. Those who are so in love with technology that they always have be on the bleeding edge lack the practicality needed in an investigation. An investigator's nontechnical talents are equally important. In addition to strong investigative skills, he or she must have excellent communications skills, a professional attitude, and good business skills. Without good oral communications skills, an investigator will not be able to successfully interview people or testify successfully in court if required. Without excellent written communications skills, the investigator's reports will be unclear, incomplete, and potentially torn apart by the opposing attorney. A professional attitude is required to maintain a calm, clear head in stressful and emotional situations. Finally, good business skills help make sure the investigator understands that sometimes getting an organization operational again may take precedent over catching the bad guy.

During each investigation, the organization will have to decide whether to pursue the matter internally or to contact law enforcement. Some organizations choose to contact law enforcement for any incident that happens. Other organizations never call them for any computer intrusion. The ideal is somewhere in between. The decision to call law enforcement should be made by the same people who make up the response team — senior executive management, general counsel, PR, and technology professionals. Many organizations do not contact law enforcement because they do not know what to expect. This often comes from an organization keeping its proverbial head in the sand and not preparing incident response plans ahead of time. Other reasons organizations may choose not to contact law enforcement include:

- They are unsure about law enforcement's computer investigation skills.
- They want to avoid publicity regarding the incident.

- They have the internal resources to resolve the investigation successfully.
- The incident is too small to warrant law enforcement attention.
- They do not want to press criminal charges.

The reasons many organization will contact law enforcement are:

- They do not have the internal capabilities to handle the investigation.
- They want to press criminal charges.
- They want to use a criminal prosecution to help in a civil case.
- They are comfortable with the skills of law enforcement in their area.
- The incident is international in scope.

All of these factors must be taken into account when deciding whether to involve law enforcement. When law enforcement is involved, they will take over and use state and federal resources to continue the investigation. They also have legal resources available to them that corporate investigators do not. However, they will still need the help of company personnel because those people are the ones who have an in-depth understanding of policies and technology involved in the incident. It is also important to note that involving law enforcement does not automatically mean the incident will be on the evening news. Over the past few years, the FBI has successfully handled several large-scale investigations for Fortune 500 companies while keeping the investigation secret. This allowed the organizations to publicize the incident only after it had been successfully handled and avoid damaging publicity. Finally, law enforcement is overwhelmed by the number of computer crime cases they receive. This requires them to prioritize their cases. Officially, according to the Computer Fraud and Abuse Act, the FBI will not open an investigation if there is less than $5000 in damages. The actual number is significantly higher. The reality is that a defaced Web site, unless there are quantifiable losses, will not get as much attention from law enforcement as the theft of 80,000 credit card numbers.

Prosecution

After the investigation, organizations have four options — ignore the incident, use internal disciplinary action, pursue civil action, or pursue criminal charges. Ignoring the incident is usually only acceptable for very minor infractions where there is very little loss and little liability from ignoring the incident. Internal disciplinary action can be appropriate if the intruder is an employee. Civil lawsuits can be used to attempt to recoup losses. Criminal charges can be brought against those violating local, state, or federal laws. Civil cases only require a "preponderance of evidence" to show the party guilty; criminal cases require evidence to prove someone guilty "beyond a reasonable doubt."

When going to trial, not all of the evidence collected will be admissible in court. Computer evidence is very different from physical evidence. Computer logs are considered hearsay and therefore generally inadmissible in court. However, computer logs that are regularly used and reviewed during the normal course of business are considered business records and are therefore admissible. There are two points to be aware of regarding computer logs. If the logs are simply collected but never reviewed or used, then they may not be admissible in court. Second, if additional logging is turned on during the course of an investigation, those logs will not be admissible in court. That does not mean additional logging should not be performed but that such logging needs to lead to other evidence that will be admissible.

Computer cases have significant challenges during trial. First, few lawyers understand technology well enough to put together a strong case. Second, fewer judges understand technology well enough to rule effectively on it. Third, the average jury has extremely little or no computer literacy. With these difficulties, correctly handling the response and investigation phases is crucial because any mistakes will confuse the already muddy waters. Success in court requires a skilled attorney and expert witnesses, all of whom can clearly explain complex technology to those who have never used a computer. These challenges are why many cases are currently plea-bargained before ever going to trial.

Another challenge organizations face is the financial insolvency of attackers. With the easy availability of hacking tools, many investigations lead back to teenagers. Teenagers with automatic hacking tools have been able to cause billions of dollars in damage. How can such huge losses be recovered from a 13-year-old adolescent? Even if the attacker were financially successful, there is no way an organization could recoup billions of dollars in losses from a single person.

It is also important to accurately define the losses. Most organizations have great difficulty in placing a value on their information. How much is a customer database worth? How much would it cost if it were given to a competitor? How much would it cost if it were inaccessible for three days? These are the type of questions organizations must answer after an incident. It is easy to calculate hardware and personnel costs, but calculating intangible damages can be difficult. Undervalue the damages, and the organization loses significant money. Overvaluing the damages can hurt the organization's credibility and allow opposing counsel to portray the organization as a money-hungry goliath more interested in profit than the truth.

Any trial requires careful consideration and preparation — those involving technology even more so. Successful civil and criminal trials are necessary to keep computer crime from becoming even more rampant; however, a successful trial requires that organizations understand the challenges inherent to a case involving computer crime.

Summary

For most people, technology has become magic — they know it works, but have no idea how. Those who control this magic fall into two categories — protectors and exploiters. Society uses technology to store and transfer more and more valuable information every day. It has become the core of our daily communications, and no modern business can run without it. This dependency and technology's inherent complexity have created ample opportunity for the unethical to exploit technology to their advantage. It is each organization's responsibility to ensure that its protectors not only understand protection but also how to successfully respond to, investigate, and help prosecute the exploiters as they appear.

Response Summary

- Preplan a response strategy for all key assets.
- Make sure the plan covers move than only technological recovery — it must address how to handle customers, investors, vendors, competitors, and the media to be effective.
- Create an incident response team consisting of personnel from the technology, security, executive, legal, and public relations areas of the organization.
- Be flexible enough to handle incidents that require modifications to the response plan.
- Ensure that response team members have the appropriate skills required to effectively handle incident response.

Investigation Summary

- Organizations must decide if the incident warrants an investigation.
- Who will handle the investigation — corporate investigators or law enforcement?
- Key decisions should be made by a combination of executive management, general counsel, PR, and technology staff members.
- Investigators must have strong skills in technology, communications, business, and evidence handling — skills many typical IT workers lack.
- Digital evidence is rarely a smoking gun and must be corroborated by other types of evidence or independent digital evidence.
- Knowing what computer an attack came from is not enough; investigators must be able to prove the person behind the keyboard during the attack.
- Corporate investigators can usually successfully investigate national and internal incidents. International incidents usually require the help of law enforcement.
- Law enforcement, especially federal, will typically require significant damages before they will dedicate resources to an investigation.

Prosecution Summary

- Organizations can ignore the incident, use internal disciplinary action, pursue civil action, or pursue criminal charges.
- Civil cases require a "preponderance of evidence" to prove someone guilty; criminal cases require evidence "beyond a reasonable doubt."
- Most cases face the difficulties of financially insolvent defendants; computer-illiterate prosecutors, judges, and juries; and a lack of strong case law.
- Computer logs are inadmissible as evidence unless they are used in the "normal course of business."
- Due to the challenges of testifying about complex technology, many cases result in a plea-bargain before they ever go to trial.
- Placing value on information is difficult, and overvaluing the information can be as detrimental as undervaluing it.
- Most computer attackers are financially insolvent and do not have the assets to allow organizations to recoup their losses.
- Successful cases require attorneys and expert witnesses to be skilled at explaining complex technologies to people who are computer illiterate.

155

Incident Response Exercises

Ken M. Shaurette, CISSP, CISA, CISM, IAM and Thomas J. Schleppenbach

It was a quiet clear morning at about 2:26 a.m. I was sleeping soundly when I felt something on my leg. Whatever it was it was smaller than Holly, our cat, but bigger than a bug or a mouse. I quickly rolled over and, taking a swipe with my hand, knocked it off the bed. Without my glasses I could barely see anything, but I saw something run into the master bathroom. I thought to myself, "That sure looked like a small bunny rabbit."

I got up a bit apprehensive, put on my slippers, and found my glasses so I could focus better. Slowly I walked to the bathroom and, sure enough, there it was; something about the size of a softball, all brown and furry, crouching by the toilet. I had not turned the lights on, so it was still dark and hard to see. I stepped back quickly and closed the bathroom door. Gotcha. I had stopped the animal's activity by confining it to the master bathroom. Now what was I going to do? I walked over to the bed and tapped my wife on the shoulder. "What the heck is going on?" she asked, and I said, "I think there is a dangerous animal in our bathroom, it could be a rabbit." She said, "You're just having a bad dream, go back to sleep." I said, "No I can't, I saw it and felt it on my leg. I knocked it off and now I have it confined to the bathroom. I think it's a rabbit!" She said, "You've been stressed out lately, you're just having a dream, go back to bed." I said, "I don't think so; there is a rabbit in our bathroom." She followed with, "Are you sure? What are we going to do? We should call the Department of Natural Resources!" I said, "No, that won't work; the DNR isn't going to do anything at 2:30 in the morning." Suddenly, as quickly as she had doubted me, she asked, "Can we keep it?" I responded, "No, this is a wild rabbit; we need to get it out of here and figure out how it got in."

What was I to do? That thing could make a terrible mess in the bathroom, I thought, remembering that the kids had butterfly nets downstairs and that I had a pair of old leather gloves down on the counter in the kitchen that I had just used that afternoon. I gathered up my makeshift antirabbit tools and went back upstairs to the bathroom. I went in the bathroom and blocked the escape route by shutting the door behind me. I was now prepared to do battle. I could see it crouching motionless behind the toilet. I quickly determined that if I put the butterfly net on one side of the toilet, I could use the small bathroom garbage can to encourage the little beast to go toward the other side. I swiftly put my counter attack in motion. My hasty plan had worked; the critter ran out from under the toilet right into the net. I pounced on it, quickly grabbing the netting to trap a small rabbit, yes a bunny rabbit, in the net. I picked it up and carried it outside. Shortly, the bunny was released back into the wild.

As I put the battle tools away and walked back to the bedroom, I passed my fearless dog, a yellow lab, sleeping peacefully at the top of the stairs. I patted him and said, "Thanks a lot, where were you? That thing must have hopped right past your nose. Man's best friend indeed!" I walked back into the master bedroom and there was Holly, our fearless cat, rolled up in a cozy little ball in the corner. I thought to myself, "What about you? You didn't do your job either; you are supposed to protect me from undesirable events like what just happened." I got nothing from her but a little meow scolding me for the disturbance.

So now I am at work, a little bit tired from the whole experience and thinking, how did that rabbit get into our house? What measures can I take to better manage the risk of losing another night's sleep in the future? Why did the protection measures — the door, the dog, the cat — not stop the event from occurring? Thank goodness I woke up and was able to put my makeshift response plan into effect.

Information Security: Layered Security

By now you have to be wondering what this story about a little bunny has to do with information security. This entire event brings to mind issues about intrusion detection, incident response procedures, testing, and overall security infrastructure as well as protecting evidence. It is really a great analogy covering several of these aspects. So we will evaluate the incident for comparisons to information security.

Start by asking a few basic questions such as: How secure is your perimeter? Has it been tested for vulnerabilities to undesirable entry? Are you prepared for a security incident? Are you prepared to respond?

We will respond to each question by comparing them to a typical environment.

How Secure Is Your Perimeter?

Is your firewall like the door of the house that let the bunny slip though? Was it just a small hole that allowed undesirable access to the internal environment? It did not take a very large hole to let the bunny into the house. I consciously opened the small porthole so I did not have to keep getting up to let the pets in or out. Does that sound familiar? "We just need one port open in order for this application to work."

Has It Been Tested for Vulnerabilities to Undesirable Entry?

I made sure that both my cat and dog were able to come and go using the small hole that I had opened. I did not consider what other, less-desirable creatures might take advantage of this opportunity. If I had only configured the hole a little differently, it could have kept out many of the other undesirables, including the bunny, and still have been functional for my pets to use.

Are You Prepared for a Security Incident? Are You Prepared to Respond?

I was not prepared. Who would have imagined a little bunny wanting to get into the house? There is nothing inside my house wild animals would want, why should I be concerned? Does your corporation have information someone might see as valuable, or perhaps a network that someone, like the bunny, might just be curious to check out? I was totally unprepared and did not expect the events that occurred. How many times do you hear from users that they do not have access to anything that anyone else would want? I was on my last line of defense and just lucky to have the tools available to quarantine as well as to capture and remove the unwanted visitor.

Are you ready with the necessary tools to stop an intruder? Do you have a policy against normal users running hacker-type tools inside your environment? Does the policy allow for administrators to access similar tools to identify vulnerabilities and track incidents? After you stop an intruder, can you capture the necessary evidence to track any damage that may have been done? Is there an incident response plan in place that would have clearly instructed you on who to call and what to do to protect the evidence of an intrusion? Does your organization plan to prosecute for damages? Does a process exist to ensure that the evidence does not get damaged or tampered with and that a proper chain of custody is in place so the evidence retains its forensic quality and will hold up in court?

This chapter will not attempt to answer all of these questions, but it should leave you with some ideas, points to ponder, and actions to consider.

An incident could be something as simple as an attacker (the bunny) spreading (hopping around the bedroom) the latest virus or worm ("rabbit raisins," poop, all over the room), or a more serious incident like using your e-mail server to send spam to other companies (the bunny biting one of your children) or maybe even penetrating through the external security architecture, the firewall (exterior doors), and getting inside the organization to disrupt services or steal intellectual property and confidential information (eating the dog and cat food or chewing on furniture).

EXHIBIT 155.1 Intrusion Detection: Incident Response Questions

- What actions are to be taken to identify that this is in fact an unwanted attacker who has penetrated the organization?
- Is there a call list for specific incidents?
- Can an automated action be taken to react to the alert, such as closing a port, or shutting down a service?
- Is it possible to identify the type of attack being used from the events logged and the intrusion detection information? (Refer to Figure 155.2 for different types of attacks.)
- Would it be possible to determine where the attack is coming from or where it originated?
- Is this an organized attack against your organization and similar organizations in the same industry?
- What might an attacker want that the organization has, or what might be lost: reputation, public confidence, integrity, credibility?
- Is it possible to identify when the incident occurred along with all previous attempts that may or may not have failed?
- If there is real damage, would it be possible to get sufficient evidence to show damage, or evidence that can stand up to a court's scrutiny and meet forensic-level quality?

Information security is all about defense-in-depth, layering protection so that the valuable assets of the organization are properly protected. In the bunny story I was essentially the last line of defense to protect my family and property from this rogue rabbit that had penetrated my exterior defenses.

What is the first thing you would do if you received a page from your Incident Response System or server system log paging software at 2:26 a.m. alerting you to the potential of a breach of external security?

On the other hand, perhaps the intrusion detection system generates so many alerts that system and network administrators have become numb to them and the messages are just ignored until the next day? Proper configuration of an intrusion detection solution so that it only sends message alerts for events that are considered issues is critical. Numerous alerts, such as every time the network is being "pinged," will cause numbness, resulting in a technician ignoring alerts and potentially missing the real thing.

Just having intrusion detection is inadequate protection. Without an incident response plan to react to the intrusion, just logging the event is not very effective. It is very important to identify the steps to take beyond simply preparing for a long night (or day) by brewing another pot of strong coffee or getting a couple more liters of Code Red.

Most operating environments and network devices already produce volumes of logged activity. The availability of this data causes a need for answers to several more questions (refer to Exhibit 155.1). Finding answers to the questions as outlined will help you select and configure effective intrusion detection as well as plan an organization's incident response system.

Preparing for an incident by planning and building the entire security program is essential. The security program becomes that defense-in-depth or layering of protection. Planning for security as well as selecting and testing intrusion detection and incident response is outlined in the remainder of this chapter.

What Is an Information Security Operations Plan?

Every organization should have an Information Security Operations Plan (ISOP) as the starting point for layers of security. The plan establishes the components in an organization's security program. It ensures that an organization does not place too much emphasis on technology and not enough on people and process. It prioritizes the security activities that will be focused on during each year, helps set budget, and provides a status reports to management on the state of all security activities. The plan should include functional areas defined by industry standards such as ISO17799. Before framing an incident response system, consider the components of an Information Security Operations Plan. The components of an effective security plan include:

- *Baseline:* This establishes where the company is at present. It is a high-level position statement of where security is at this point in time. It becomes an annual review to understand the current status of information security efforts in the organization. Each year it establishes what has been completed in the plan, areas of change, and new areas that have been added during the year.
- *Policies, Standards, and Procedures:* Policies, standards, and procedures are continuously changing. Information Security Policy provides the roadmap by which an organization identifies security philosophy and establishes the importance of security in the organization. Policy is the roadmap that defines

appropriate handling of information in the business environment and sets the ground rules for building the information security architecture and technology. It helps determine the requirements for information security by setting expectations and requires management commitment and sign-off at the highest levels.

- *Architecture and Processes:* Designing security into the creation, selection, approval, and roll out of all technologies is vital. Security must be an integral part of building the data processing environment. Including information security early in the process of application and system development and selection will ensure that security issues can be addressed and that alternatives have sufficient lead time to be implemented within business deadlines. Secure architectures and the processes to support them are crucial to a secure environment.
- *Awareness and Training:* Every computer user in the organization must be made aware of company policy. An effective security program requires that everyone understands their personal responsibilities to protect the corporate information assets to help minimize organization liability.
- *Technologies and Products:* Technology is an important component of the security program. Although people and process make up potentially 70 percent of the security structure, technology alone accounts for probably 30 percent of the requirements to protect an organization. Technologies can range from simple system monitoring tools and access controls such as passwords and multiple factor authentication systems to virtual private networks (VPN) and data encryption or public key infrastructure (PKI) systems. Often, third-party vendor products are required to support and monitor the operating environment.
- *Assessment and Monitoring:* To meet the needs and expectations of customers, auditors, and various levels of management, appropriate information must be collected so that reports can be created and distributed. Perimeter connections to the network and host system logs must also be monitored for unauthorized activities.
- *Compliance:* The mission of information security is to minimize security risks while maintaining the least possible impact on cost and schedules. To meet both company and customer expectations for information security, it is necessary to implement a process of continuous feedback so that business units can provide input to the improvement of information security planning.

The ISOP will frame out the organization's security program. The incident response program and procedures would be included as a component or subset of the overall information security program. In the next few paragraphs we focus on incident response and preparedness.

What Are the Components of an Incident Response Program?

An incident response program should include:

- Forming an incident response team
- Identifying a main contact (this must be a decision maker)
- Defining the monitoring or intrusion detection strategy
- Establishing an incident response flow
- Developing a set of basic required actions based on incident
- Preparing for recovery (business continuance)
- Knowing how and when to report an incident

There are several best-practice guidelines that are worth following, many of which can be found in books such as *Critical Incident Management* by Alan B. Sterneckert (Auerbach Publications, 2004).

As organizations develop their incident response program and associated procedures, they must take into consideration the specifics and details of their own unique networking and operating environment that only a person familiar with the inside workings of the organization would have. An important aspect in establishing intrusion detection and incident response is gaining an understanding of some of the typical attacker intrusion approaches.

Attack Approaches

To better understand intrusion activity and the process of identifying undesirable events, it is important to look at hacking approaches. Attacks can be separated into the following categories:[1]

- *Bomb:* This is a general synonym for crash, normally consisting of software or operating system failures.
- *Buffer Overflow:* This happens when more data is put into a buffer or holding area than the buffer can handle. It can be a result when there is a mismatch between processing rates of the producing and consuming processes. This can result in system crashes or the creation of a backdoor leading to system access.
- *Demon Dialer:* One name for a program that repeatedly calls the same telephone number is a demon dialer. This can be benign and legitimate for access to an authorized network or malicious when used as a denial-of-service attack.
- *Derf:* This is the name given to the act of exploiting a terminal which someone else has absentmindedly left logged on.
- *DNS (Domain Name Service) Spoofing:* The process of assuming the DNS name of another system by either corrupting the name service cache of a victim system or by compromising a domain name server to obtain a valid domain is called "spoofing."
- *Ethernet Sniffing:* This refers to the action of listening for packets or datagrams with software on the network looking at the Ethernet interface for packets that interest the user. Because Ethernet sends data by broadcasting all packets to all machines connected to the local network, it is trivial to receive packets that were intended for other machines. Ethernet interfaces support a feature commonly called "promiscuous mode," in which the interface listens to network traffic "promiscuously." That is, instead of dropping all packets that do not have the machine's Ethernet address in them, the interface processes all of the packets that it receives. When the software sees a packet that fits certain criteria, it logs it to a file. The most common criteria for an interesting packet are ones that contain words like log-in or password.
- *Fork Bomb:* Also known as Logic Bomb. Code that can be written in one line of code on any UNIX system; used to recursively spawn copies of itself; "explodes," eventually eating all the process table entries and effectively locks up the system.
- *IP Splicing/Hijacking:* The action caused when an active, established session is intercepted and co-opted by an unauthorized user. IP splicing attacks can occur after an authentication has been made, permitting the attacker to assume the role of an already authorized user. Primary protections against IP splicing rely on encryption at the session or network layer.
- *IP Spoofing:* This type of attack occurs when the attacker causes one system to impersonate another system by using the system's IP network address without proper authorization. Essentially the attacker impersonates a different address than is normally assigned to him.
- *Keystroke Monitoring:* A specialized form of logging software, or a specially designed hardware device usually placed between the keyboard and the CPU. The device or software can record every keystroke a user makes. Properly used and secured, a legitimate use for this functionality is to capture forensic-quality evidence for prosecuting illegal computer incidents. Improper use can result in an intruder capturing passwords and other personal information.
- *Leapfrog Attack:* The leapfrog attack results in the use of an illicitly obtained user ID and password gained from compromise of information on one host to compromise another host; for example, the act of TELNETing through one or more hosts to confuse attempts to trace the activity. This is a very common attacker activity used to make tracking undesirable activity back to the actual source more difficult.
- *Letter Bomb:* A piece of e-mail containing live data intended to do malicious things to the recipient's machine or terminal. In a UNIX environment, a letter bomb could try to get part of its contents interpreted as a shell command to the mailer. The results of this could range from silly to denial of service or complete system compromise.

- *Logic Bomb:* Also known as a Fork Bomb. A resident computer program which, when executed, checks for a particular condition or particular state of the system that, when satisfied, triggers the perpetration of an unauthorized act. These could be planted in the operating system software or coded into application code by an unscrupulous programmer.
- *Mail Bomb:* The mail sent to urge others to send massive amounts of e-mail to a single system or person, with the intent to crash the target recipient's system. Mail bombing is widely regarded as a serious offense. In more minor amounts or when not targeted to only one system, this is commonly known as spam.
- *Malicious Code:* This hardware, software, or firmware can be intentionally included in a system for an unauthorized purpose; e.g., a Trojan horse, virus, or any other code that might demonstrate nasty, undesirable behavior.
- *Mimicking:* This term is synonymous with impersonation, masquerading, or spoofing.
- *NAK Attack:* NAK stands for negative acknowledgment. It is used as a penetration technique that capitalizes on a potential weakness in an operating system that does not handle asynchronous interrupts properly, and thus leaves the system in an unprotected state during such interrupts.
- *Network Weaving:* Another name for leapfrogging.
- *Phreaking:* This describes the art and science of cracking the telephone networks.
- *Replicator:* A program that copies itself is called a replicator program. Examples include a worm, a fork bomb, or virus. It is even claimed by some that UNIX and C are the symbiotic halves of an extremely successful replicator.
- *Retro-Virus:* A retro-virus is a form of malicious code that waits until all possible backup media are infected, so that it is not possible to restore the system to an uninfected state.
- *Rootkit:* The "root kit" is a hacker security tool that provides that ability to capture passwords and message traffic to and from a computer. It is a collection of tools that allow a hacker to create a backdoor into a system, collect information on other systems on the network, mask the fact that the system is compromised, and much more. Rootkit is a classic example of Trojan horse software and is available for a wide range of operating systems. It gets its name from the name of the system administrative account in UNIX operating environments.
- *Smurfing:* Smurfing is an attack of a network by using spoofing of the source address to exploit Internet Protocol (IP) broadcast addressing and certain other aspects of Internet operation. Smurfing uses a program called Smurf and similar programs to cause the attacked part of a network to become inoperable, such as in a denial-of-service attack. The exploit of smurfing, as it has come to be known, takes advantage of certain known characteristics of the Internet Protocol (IP) and the Internet Control Message Protocol (ICMP). The ICMP is used by network nodes and their administrators to exchange information about the state of the network.
- *Spoofing:* Pretending to be someone else; also see mimicking. This is the deliberate inducement of a user or a resource to take an incorrect action. An attempt to gain access to a system by pretending to be an authorized user.
- *Subversion:* This intrusion act occurs when an intruder modifies the operation of the intrusion detector to force false-negatives to occur. The act can cause an intrusion detection system to send traffic that camouflages an attack.
- *SYN Flood:* The SYN flood attack sends TCP connection requests faster than a machine can process them. When the SYN queue is flooded, no new connection can be opened. The attacker creates a random source address for each packet. A SYN flood attack can be used as part of other attacks, such as disabling one side of a connection in TCP hijacking or by preventing authentication or logging between servers.
- *Terminal Hijacking:* This attack method allows an attacker, on a certain machine, to control any terminal session that is in progress. An attacker can send and receive terminal I/O while a user is on the terminal.
- *Trojan Horse:* The Trojan Horse can appear as an apparently useful and innocent program, but actually contains additional hidden code that allows the unauthorized collection, exploitation, falsification, or destruction of data. The actions can be activated by some other event such as on a specific date or when the deletion occurs of a specific account on a system.

- *Virus:* This is the common name assigned to many malicious programs that can "infect" other programs by modifying them to include a possibly evolved copy of itself.
- *Wardialer:* Made popular by the 1980s movie, *War Games,* this consists of a program that can dial a list or range of numbers and record those that answer with handshake tones, which might be entry points to computer or telecommunications systems. Handshake tones are "answer" tones given by a modem set to answer a request for connection.

Understanding the attack methods can be helpful in understanding why some features are important in selection of an intrusion detection system.

Selecting Intrusion Detection

Picking the proper intrusion detection (IDS) technology is an important step not to be taken lightly, and is not an easy task. An IDS should be easy to install and require minimal training, and should deploy in a "passive" or "parallel" mode, and not inline, which creates a potential bottleneck and failure point. To help with selection of an intrusion detection system, a capabilities matrix has been provided in Exhibit 155.2.

Organizations must establish their internal requirements and priorities as they pertain to intrusion detection, to establish the components identified in Figure 155.3 that are most important in a product.

Once the technology is chosen and deployed, just like a disaster recovery plan, it would be wise to periodically test it along with incident response plans.

Incident Response Exercises

Incident response exercises are one method in helping reduce organizational risk and better prepare a company's staff to respond to intrusive behavior. Like war games, incident response exercises are designed to raise awareness to the security posture of an organization through the continuous testing of incident response procedures and network device and system configuration. The testing is followed by regular review with experienced information security personnel and the organization's IS staff.

The goal is to raise security awareness with an organization's IS and management staff, and to verify and enforce proper and continual setup, configuration, and tuning of security and network systems while ensuring they are kept up to current patch levels.

The IS staff gets continuous exposure to real-world infiltration scenarios in a controlled environment, educating them to identify malicious behavior as well as having the organization's incident response procedures properly tested.

Incident response exercises generally work through continual footprinting of an organization's resources, and surprise infiltrations that are followed up with a meeting to discuss the "whats": what went right, what went wrong, and what could be done better?

If an organization is outsourcing the incident exercise service, the organization must be sure to check references and work with a credible company. Here are a few basic rules for selecting a security outsourcing vendor:

- Demand credentials and expertise, consider background checks
- Seek outside certifications
- Ensure vendor affiliations
- Talk to other customers and references
- Comparison shop
- Take small steps if unsure
- Know your escalation procedures
- Require standard inspections
- Know the rules with the vendor

EXHIBIT 155.2 Modern IDS Capability Comparison

Modern IDS Capability Comparison	Product 1	Product 2	Product 3	Product 4
2.0 Detection				
2.1 Protocol anomaly detection				
2.2 DoS attack detection				
2.3 Network infrastructure attack detection				
2.4 Common application protocol detection				
2.5 Stateful signature detection				
2.6 Custom signature support				
2.7 Full protocol decode				
2.8 Evasion detection and resistance to IDS attack				
2.9 Full fragment reassembly				
2.10 Full multi-interface reassembly				
3.0 Analysis				
3.1 Third-party event integration				
3.2 Real-time event aggregation				
3.3 Real-time analysis				
3.4 Automated correlation and prioritization				
3.5 Cross-node event correlation				
3.6 Full packet capture				
3.7 Secure data store				
3.8 Duplicate suppression				
3.9 User tunable controls				
4.0 Response Capabilities				
4.1 Automated policy-based response				
4.2 Alerting (SNMP, e-mail, console log)				
4.3 Session termination				
4.4 User-defined response actions				
4.5 Traffic recording and playback				
4.6 Remote threat tracing				
4.7 Peer network event notification				
4.8 Session blocking suggestions or integration				
5.0 Performance/Scalability				
5.1 Full 100 Mbps throughput (no packet loss)				
5.2 Full 1 Gbps throughput (no packet loss)				
5.3 Multiple 100 Mbps segment throughput (no packet loss)				
5.4 Handle 500,000 simultaneous TCP sessions				
5.5 Scales to hundreds of sensors				
5.6 Robust under edge conditions				

EXHIBIT 155.2 Modern IDS Capability Comparison (continued)

6.0 High Availability				
6.1 Automatic failover and failback				
6.2 High-speed failover				
6.3 "Five nines" (99.999 percent) reliability				
6.4 Cost-effective high-availability deployment configurations				
7.0 Management				
7.1 Secure remote management				
7.2 Broad platform support for management				
7.3 Scalable information presentation				
7.4 Incident drill-down capability				
7.5 Additional reference data provided (CVE, BUGTRAQ, etc.)				
7.6 Cluster administration support				
7.7 Incident annotation/auditing				
8.0 Deployment				
8.1 Multiple interface support (Gigabit and Fast Ethernet)				
8.2 Sensor roaming in switched networks				
8.3 Easy to deploy and install				
8.4 Nonintrusive deployment (noninline)				
8.5 VLAN-aware detection				
8.6 Minimal training requirements				
9.0 Reporting				
9.1 Integrated deep drill-down console reporting				
9.2 Web-based reporting				
9.3 SQL export				
10.0 Hardware Requirements				
10.1 Multiple sensors per unit				
10.2 Multi-processor scalable				

Moral of the Story

We will go back to the story for a moment. The bunny entered a traditional, two-story house even though the doors were locked. It managed to get past the intrusion prevention system: a dog, which was deployed at the foot of the stairs that lead to the bedrooms. This is a dog that normally enjoys chasing small bunnies all over the backyard because they are invading his territory. The bunny climbed a flight of stairs, and found its way down the hall and into the master bedroom. It even managed to get past another line of defense, a very territorial house cat. The defense-in-depth failed in this case.

Doing a post mortem on the event, it would be necessary to consider the experience of a near-complete breach of security: getting past three layers of defense. Fortunately, the last defense — the owner — was able to react on the internal incident response procedure and take the appropriate actions to minimize damage and manage the risk. That action kept this attack from damaging property or causing terror for the inhabitants.

The moral of the story is that several layers of defense are not always adequate regardless of how technically advanced or how cost effective they may be. A plan or procedure defined in advance with proper testing that can be quickly put into motion might be the last defense to protect the organization's assets. Any organization that does business using the Internet or private wide-area communications networks should have a security incident response program set up before an incident occurs. Having just access control, monitoring, and intrusion detection or prevention are not enough.

Note

1. Definitions come from the NSA's *Glossary of Terms Used in Security and Intrusion Detection.*

156

Software Forensics

Robert M. Slade, CISSP

Introduction and Definitions

Software, and particularly malicious software, has traditionally been viewed in terms of a tool for the attacker. The only value that has been apparent in the study of such software is in regard to protection against malicious code. However, experience in the virus research field, and more recent studies in detecting plagiarism, indicates that we can obtain evidence of intention as well as cultural and individual identity from examination of software itself.

Computer forensics is primarily seen in terms of the recovery of data and its preservation for presentation as evidence from computers that may have been used in the commission of some criminal activity. This restriction of the field to data recovery, and occasionally decryption, has been so complete that a new term has been coined to describe the more generic area of evidence from all forms of computer activity: *digital forensics.*

Aside from the data-recovery activity of computer forensics, network forensics is another major and growing field of digital forensics, and involves analysis of data from network logs and activity. A company can use network forensic analysis to detect intrusions or attacks launched against its network, generally from the Internet. This type of evidence can also be used to trace and track attackers or criminals who are using public systems such as the Internet.

Outside of the virus research community, forensic programming is a little-known field. It involves the analysis of program code, generally object or machine language code, to make a determination of, or provide evidence for, the intent or authorship of a program.

In the case of viruses, object code was usually all that was available. Even so, researchers were often able to determine a lot about a given piece of code. The first conclusion to be pursued was whether or not the program was malicious, and whether or not it was a virus. The next obvious question is to ascertain who wrote the piece of malware. Sometimes virus writers made this an easy task, including names, addresses, and, in one case, ham radio license call-sign letters. However, it was also possible to find out whether one virus was modified from another, which came first, whether the modified version was created by the same author as the original, or whether someone else had used the precursor as a template. Researchers were often able to determine whether the programmer of a piece of software was a member of a specific linguistic, national, ethnic, cultural, or age group, as well as the influence of various schools of programming.

Software forensics, a relatively new addition to digital forensics, is the broader extension of this work. Software forensics involves the analysis of evidence from program code itself. Program code can be reviewed for evidence of activity, function, and intention, as well as evidence of authorship. The technology has a number of possible uses. In analyzing software suspected of being malicious it can be used to determine whether a problem is a result of carelessness, or was deliberately introduced as a payload. Information can be obtained about authorship and the culture behind a given programmer, and the sequence in which related programs were written. This can be used to provide evidence about a suspected author of a program, or to determine intellectual property issues. The techniques behind software forensics can sometimes also be used to recover source code that has been lost.

Two different types of code, source and object, are the commodities for software forensic study. There is source code, which is relatively legible to people. Analysis of source code is often referred to as code analysis, and is closely related to literary analysis. Analysis of object, or machine, code is generally referred to as forensic programming.

Literary analysis has contributed much to code analysis, and is an older and more mature field. It is variously referred to as authorship analysis, stylistics, stylometry, forensic linguistics, or forensic stylistics.

Objectives and Objects of Software Forensics

Historically, the virus research community has used forensic programming for a variety of purposes. First and foremost, of course, was to determine the intent of a program. Was this code actually a virus, a Trojan, or other piece of malware, or had someone merely blamed it for some unrelated event? Various methods are used for this type of assessment, ranging from "black-box" execution of the program to disassembly and decompilation.

Commonly in virus research an attempt is made to determine whether a virus exists in other versions, or belongs to an existing family of viruses. Indications can be found in a direct analysis of the object code, analysis of a disassembly, or a review of text strings and messages that may be found in the code. With slight modifications of code, where only text, specific triggers, or minor functions are changed, the program might be considered a variant, identified with the original name, usually with an additional numeric or letter code. If structural changes have been made or new functions added, a virus may be assigned its own name, but noted to be part of a specific family.

In regard to families, an attempt is generally made to sequence the different variants. Even when a single author is involved, an analysis of the code can determine how the program developed. If we have a sequence of programs from a single author, we can potentially glean even more information that might help us identify the programmer.

Identity

This brings us to another objective for forensic programming and software forensics. From the earliest appearances of Trojan horse programs on bulletin boards there has been an interest in finding the authors of malicious software. In some cases, viruses have contained names, addresses, company names, e-mail addresses, Web sites, and even ham radio license identifiers, either in plaintext or in various forms of encryption. Other information can be obtained from hints in the code that indicate that two programs were written by the same author, or that an author is a member of a group. As well, stylistic or stylometric analysis of messages and text may provide information and evidence that can be used for identification or confirmation of identity.

Individual Identification

I recently spoke at a conference where the section in which I was presenting was titled "Electronic Fingerprints." The term *electronic fingerprint* is particularly well chosen in regard to identification of individuals from this type of analysis. Physical fingerprint evidence frequently does not help us identify a perpetrator in terms of finding the person once we have a fingerprint. However, a fingerprint can confirm an identity, or place a person at the scene of a crime, once we have a suspect. In the same way, the evidence we gather from analyzing the text of a message or a body of messages may help to confirm that a given individual or suspect is the person who created the fraudulent postings. Both the content and the syntactical structure of text can provide evidence that relates to an individual.

Programmers have styles in the same way that writers have styles. Code may be sloppy or optimized, and if optimized, may conserve either processor cycles or memory space. Programmers will have preferences for lookup tables or algorithmic methods and for different types of loop structures. There will be other characteristics that programmers use, either consciously or unconsciously. Taken together, these can be used to compare a sample of program code to a body of such code that a programmer is known to have produced.

Group Identification

Some of the evidence that we discover may not relate to an individual. Some information may relate to a group of people who work together, influence each other, or are influenced from a single outside source. This data

can still be of use to us, in that it provides us with clues in regard to a group with which the author may be associated, and may be helpful in building a profile of the writer.

Groups may also use common tools. One area we need to investigate in regard to program code involves programming environments that may generate or partially generate code for the programmer. Compilers also have specific signatures, sometimes in a header area of the program, and sometimes in terms of the translation of source code into object, or optimization provided by the compiler program itself. Other types of tools, such as text editors or databases, may be commonly used by groups and provide similar evidence.

In software analysis, one can find indications of languages, certain compilers, and other development tools. Compilers leave definite traces in programs, and can be specifically identified. Languages leave evidence in the types of functions and structures supported. Other types of software development tools may contribute to the structural architecture of the program or the regularity and reuse of modules.

It is possible to trace indications of cultures and styles in programming. To those unfamiliar with programming, it may seem very strange to talk about cultures in programming. However, you do not have to be around computers for too long before you realize that there are very definite communities, or trails of influence, involved in the development of programs and systems.

This is not as evident, perhaps, as it used to be. It is ironic to note that the availability of different kinds of programs is less nowadays than it was, for example, in the mid-1980s. During the 1980s, I used approximately 40 different word processors in different situations. During the 1990s, I probably used four. Therefore, computer users formerly had much more of a chance to see different programs in operation, and see different types of approaches to essentially the same problem or issue.

A very broad example is the difference between design of programs in the Microsoft Windows environment and the UNIX environment. Windows programs tend to be large and monolithic, with the most complete set of functions possible built into the main program, large central program files, and calls to related application function libraries. UNIX programs tend to be individually small, with calls to a number of single-function utilities.

One source of indicators of cultural styles is the existence or absence of functions in the program itself. For example, a practically universal function in word processors used to be something called boilerplate. This was the ability to have a standard set of text, possibly a variety of frequently used paragraphs, and to import this text into the appropriate place in the document you were creating. The function was not always called boilerplate, but it was always there. Oddly, this function does not seem to exist in Microsoft's flagship word processor, Word. Of course, it is always possible to open another Word window, open the file that you want to get text from, select the text that you want, cut or copy the text, close the second window or switch to the first, move to the position that you want the text to occupy, and then paste the text, but that does seem to be a rather involved process for such a simple function. (There is also the AutoText function, but it is more generally associated with formatting styles.)

The absence of a boilerplate function, therefore, tells us that the original developers of Word were not thoroughly familiar with a variety of standard word processors, or at least were not familiar with actual word processing operations. In addition, if we then find another word processor that does not have a boilerplate function, we know that there is a very strong probability that the developers are primarily or strongly influenced by Word.

There are, of course, numerous examples of cultural influences in programming that are visible in user interfaces. It was fairly obvious to note the bias toward LISP programming that was evident in the Logo programming language, and the predisposition toward the UCSD P-system editor that clearly drove the developers of Wordstar (among others). This was more evident in the past: the dominance of the Microsoft Windows interface has tended to homogenize interface choices. Yet even this can be seen as a cultural artifact: the inclination towards the Windows (originally the IBM Common User Access) interface has become so commanding that developers go to extraordinary lengths to include File, Edit, View, and Tools menus on programs that have no need for those kinds of functions.

Cultures of programming and design are clearly evident in malware. As a simplistic example, the early distributed denial-of-service (DDoS) tools could simply have opened a characteristic port: the author could then identify likely hosts by scanning for that particular port number. Almost all DDoS agent programs, however, were designed to "announce" availability once a machine had been compromised. The announcement could have been made through a variety of channels, and even anonymous ones, but IRC (Internet Relay Chat) was the one most commonly used. Again, DDoS client or agent programs (commonly called "zombies") could

have been commanded by having them "listen" for commands on IRC or Usenet newsgroups, but the authors all preferred to have the attack controller send attack commands directly to the agents.

In some cases, of course, similarity of code or design does not indicate influence as much as direct copying. Virus variants, for example, tend to be related merely because a virus "author" will simply take an existing virus and make minor variations to the code. (In many cases, the code is not changed at all; the new "programmer" will modify text strings, or will throw "no operation" [NOP] codes into the program — making no functional change.) Yet it is also possible to see where ideas and functions have been taken from one or more sources and added to a program. This is especially clear when the function is coded in a slightly different way.

Evidence of cultural influences exists right down to the machine-code level. Those who work with assembler and machine code know that a given function can be coded in a variety of ways, and that there may be a number of algorithms to accomplish the same end. It is possible, for example, to note whether the programming was intended to accomplish the task in a minimum amount of memory space ("tight" code), a minimum number of machine cycles (high performance code) — or a minimal effort on the part of the programmer (sloppy code).

The Blackhat Community: Hackers, Crackers, Phreaks, and Other Doodz

It is not part of the scope of this chapter to describe the blackhat community in general. (I use the term "blackhat" to avoid arguments about the "true" definition of a "hacker.") However, it is instructive to look at the rough ideas we have been able to obtain about the groups of intruders and writers of malicious software. For this information we are all indebted to researchers such as Sarah Gordon, Dorothy Denning, Ray Kaplan, and more recently, the members of the Honeynet Project.

I must also admit, at the outset, that whenever you deal with people there will always be exceptions. There are those who seem to pursue security breaking from motives which are, if not exactly admirable, at least untainted by thoughts of commerce or attention. There are also those who come up with one or two original ideas and experiment with them. Particularly in doing forensic analysis, we need to beware of falling into mental traps occasioned by our own "profiles" of the adversary. However, as with almost any stereotypes, there are reasons for the characterizations presented here.

First, I should point out that the blackhat community is extremely fragmented. Not only are there different groups, often at odds with each other, but the types of activities also differ. There are those who are trying to break into or intrude upon computer systems or networks. Others specialize in gaining unauthorized use of telephone switches and systems, frequently for the purpose of obtaining or even reselling phone service. Some are primarily interested in damaging or corrupting files, particularly in public ways, such as defacing Web sites. A great many of the blackhats in general, and probably the largest majority, really have very little idea of the technology that they are using, having obtained packaged programs or scripts, and operating them without really understanding the functions or situations appropriate for their use. Those who create programs of any type are actually relatively rare. A number do make slight modifications to the creations of others, usually functionally insignificant changes to viruses, which are widely available because of their reproductive function. There are, of course, those who are primarily interested in making illegal copies of commercial software. And, at every level, there are those who "wannabe" more respected in the blackhat community, but lack even those skills.

It may be important to examine the commonly presented justifications for blackhat activity. There are two reasons for this study. First, this examination does demonstrate something of the mindset and philosophy of the members of the community, and such a philosophy can sometimes be evident in programming style. The second reason is that some of these justifications may be presented, quite seriously, as arguments against the activity of software forensics in general.

One of the most frequently attempted justifications of blackhat activity of all kinds is that it is protected under the concept of freedom of speech. Leaving aside the issue of whether free speech is a universal right, and also ignoring for the moment that most blackhat activity does not involve programming, we still have to ask whether programming is or is not speech. Speech generally does not involve other people, and when it does, such as in the case of yelling "Fire!" in a crowded theatre or producing hate propaganda, it often is not protected. In the case where the blackhat individual is not the author of the software, such as where attack scripts are being utilized or preexisting viruses are being released, the protection of free speech is even more tenuous.

A second bid at vindication of security breaking activities is simply "because we can." Although the shallowness of this argument tends to prompt a sarcastic response from security or law enforcement personnel, we should note that the prevalence of this reasoning does make a very strong point about the anarchic nature and mindset of the blackhat community.

Many individuals who practice system violation activity explain themselves on the basis that they are following in the footsteps of the old-time hackers, who explored and discovered the capabilities of early computing devices; this flies in the face of the reality of the current level of blackhat endeavors. The few instances that are not absolutely repetitive are generally slavishly derivative. Even if we ignore the fact that most "cracking" exercises amount to no more than "knocking on doors," we still have to ask what the objective of these explorations is, which usually cannot be clearly articulated, and look at the eventual result, which, to date, has not been anything significant.

Yet another justification for blackhat activities is stated to be educational. As one who has been involved in education and training as well as reviewing for a great many years, I would be very sympathetic to this argument — if it had any basis. Even considering *2600 Magazine,* which can most charitably be described as the best of a bad lot, one is hard pressed to say anything positive about the writing quality, research, originality, or even such basics as sticking to the topic. When one turns to *phrack, 40Hex,* and the myriad others of the "'zine" ilk, the caliber runs steadily downhill. Even articles dealing with simple penetration testing generally state only that systems are weak (we already knew that, thanks), and say nothing about strengthening them.

General Characteristics

Blackhats, particularly writers of malware and viruses, tend to be young and almost invariably male. Despite occasional speculations on the addictive nature of "hacking," they usually "grow out" of the virus-writing game after a few years.

Virus and malware researchers tend to be dismissive of the technical abilities of virus writers. There exist virus writers who write competent code; there are many more who do not. The general public and the media, of course, continue to be fascinated by the image of the mythical boy genius running rings round the authorities. The blackhats like this cliché, too, and many go to some lengths to encourage the stereotype, whether or not they believe in it.

Most of today's malware programmers gain access to a victim system by tricking the victim into executing malicious code.

Malware writers do not understand or prefer not to think about the consequences for other people, or they simply do not care. Recently one researcher has speculated on the characteristics of the blackhat community in comparison to people who fall somewhere in the range between an admittedly ill-defined "normal" and those suffering from full-blown autism. Austistic individuals tend to perceive and interpret the world in an idiosyncratic manner.

Malware authors draw a false distinction between creating malicious software and distributing it. They eschew any responsibility for the damage caused by their creations. In particular, it is the responsibility of the victim to defend himself from encroaching malware, not the responsibility of the creators to keep their handiwork away from systems other than their own. Targets and victims of attacks are typically dehumanized in blackhat writings, described as losers who do not deserve to own a computer. There is also projection and displacement of guilt, frequently expressed in terms justifying security breaking activities because vendor X makes lousy software or large corporations are doing bad things.

In self-reports from blackhats, a number of aspects are reported to be part of the thrill, including the act of vandalism itself, fighting authority, "matching wits" with the security or law enforcement communities, aggression (often arising out of resentment and reinforced by the feeling of safety and power that is engendered by apparent anonymity), the ability to induce fear and panic in the media and the general public, and the "15 minutes of fame" as well as the recognition of peers. Malware writers tend to feel marginalized and unrecognized in normal society, so they feel a very strong sense of identity with the blackhat tribe.

Blackhat Products

Most of the end result of blackhat activity consists of compromised systems, defaced Web pages, and pointlessly consumed bandwidth. Overall, this might be of interest to people investigating network forensics, but is not of much use for us in software forensics. However, attack tools, DDoS kits, Trojans, viruses, worms, remote access Trojans (RATs), and other forms of malware are.

We will, of course, want to find out as much as possible about what the specific piece of malware does. We also want to find about the author, if we possibly can. Knowing about the broad classes of malicious software can help point out, in general outline, the functions to look for. Knowing the class of malware may also help us to identify the author, because blackhats tend to be just as specialized as any other type of programmer.

Malicious Software

It is sometimes hard to make a hard and fast distinction between malware and bugs. For example, if a programmer left a buffer overflow in a system and it creates a loophole that can be used as a backdoor or a maintenance hook, did he do it deliberately? This question cannot be answered technically, although we might be able to guess at it, given the relative ease of use of a given vulnerability. However, there is general agreement that the following types of software do fall into the malware category.

Trojans

Trojans, or Trojan horse programs, may be the largest and most diverse class of malware. A Trojan is a program that pretends to do one thing while performing another, unwanted action. The extent of the pretense may vary greatly. Many of the early Trojans relied merely on the file name and a description on a bulletin board. "Log-in" Trojans, popular among university student mainframe users, mimicked the screen display and the prompts of the normal log-in program and could, in fact, pass the user name and password along to the valid log-in program at the same time as they stole the user data. Some Trojans may contain actual code that does what it is supposed to be doing while performing additional nasty acts that it does not tell you about.

Given the absence of a specific functional requirement for Trojans, and the variety of types of pretense and social engineering that can be used, Trojan programs can be created or modified, sometimes based on widely available utility software, by relatively unskilled people. In addition, Trojans tend to be reused and passed around within the blackhat community. Therefore, the use of software forensic techniques may be of limited use, until methods are refined further.

Logic Bombs

A logic bomb is generally implanted in or coded as part of an application under development or maintenance. Unlike a RAT or Trojan it is difficult to implant a logic bomb after the fact, unless it is during program maintenance.

A Trojan or a virus may contain a logic bomb as part of its payload.

Because of the inclusion of the logic bomb code with the code of the main program, software forensics may be used to determine whether the bomb was introduced by the author of the application or programmed by someone else. (This does not, of course, preclude the possibility that the programmer introduced code written by someone else into his own program.)

A similar situation applies with respect to a backdoor (sometimes called a trap door), a hidden software or hardware mechanism that can be triggered to permit system protection mechanisms to be circumvented. The function will generally provide unusually high or even full access to the system either without an account or from a normally restricted account. It is activated in some innocent-appearing manner; for example, a key sequence at a terminal. Software developers often introduce backdoors in their code to enable them to reenter the system and perform certain functions; this is known as a "maintenance hook." The backdoor is sometimes left in a fully developed system either by design or accident.

Backdoors can also be introduced into software by poor programming practices, such as the infamous buffer overflow error.

DDoS Agents

DDoS (distributed denial of service) is a modified denial-of-service attack, which does not attempt to destroy or corrupt data, but attempts to use up a computing resource to the point where normal work cannot proceed. The structure of a DDoS attack requires a master computer to control the attack, a target of the attack, and a number of computers in the middle that the master computer uses to generate the attack. These computers

between the master and the target are variously called "agents" or "clients," but are usually referred to as running zombie programs. Although zombie is the most widely used term, it is used somewhat indiscriminately, and it is probably most proper to refer to DDoS agent software.

Unfortunately, DDoS kits are widely available, in ready-to-use form, and in some cases the authors are known. Software forensics has relatively little to contribute in terms of those who actually set up such DDoS networks and attacks, and the developers of DDoS agent software are not reticent about admitting authorship. Network forensics is probably more use in determining who launched an attack.

RATs (Remote Access Trojans)

To convey a sense of legitimacy, the authors of remote access Trojans (RATs) would generally like to see them referred to as remote administration tools.

All networking software can, in a sense, be considered remote access tools: we have file transfer sites and clients, World Wide Web servers and browsers, and terminal emulation software that allows a microcomputer user to log on to a distant computer and use it as if he was on-site. The RATs considered to be in the malware camp tend to fall somewhere in the middle of the spectrum. Once a client, such as Back Orifice, Netbus, Bionet, or SubSeven, is installed on the target computer, the controlling computer is able to obtain information about the target computer. The master computer will be able to download files from, and upload files to, the target. The control computer will also be able to submit commands to the victim, which basically allows the distant operator to do pretty much anything to the prey. One other function is quite important: all of this activity goes on without any alert being given to the owner or operator of the targeted computer.

When a RAT program has been run on a computer, it will install itself in such a way as to be active every time the computer is turned on after that. Information is sent back to the controlling computer (sometimes via an anonymous channel such as IRC) noting that the system is active. The user of the command computer is now able to explore the target, escalate access to other resources, and install other software, such as DDoS zombies, if so desired.

Rootkits, containing software that can subvert or replace normal operating system software, have been around for some time. RATs differ from rootkits in that a working account must be either subverted or created on the target computer to use a rootkit. RATs, once installed by a virus or Trojan, do not require access to an account.

As with DDoS agents, both RATs and rootkits tend to be available and are not commonly rewritten for an attack. However, the authors of this software have not always been identified, so software forensics may be used to identify authors, although these may not be the actual attackers.

Other Objects of Study

In the case of malware, we are primarily concerned with finding out what the program does and who wrote it. Frequently this might be a concern with ordinary application software. Generally speaking, with regular software we will know one, but need to find out the other.

One situation that may arise requiring a forensic determination is in the case of intellectual property. There is the possibility of multiple claims of authorship of a particular piece of software. It should be relatively easy to compare a specific program against two or more known bodies of work, and ascertain which of a number of authors has written the disputed application. In the case of multiple authorship of a single program or module this would be more difficult, but forensic linguistics has, in some cases, been able to distinguish between multiple authors, even down to the level of an individual sentence. In any case, we should be able to conclude whether multiple authors were involved fairly easily. Plagiarism detection is already well established as a technology, and there are a number of automated tools that can help us in this regard.

The technologies used in software forensics have uses in software development itself, and, indeed, some of them originated there. For years, reverse engineering has been a common practice in system development: software forensics performs much the same function, albeit sometimes at different levels of detail. Disassembly and decompilation tools may be able to assist in application development, for example, recovering source code for legacy systems where such has been lost over the years.

As noted, the tools used in software forensics are generally utilities employed in programming. At this point it may be worthwhile to list the instruments that can be helpful in the forensic endeavor.

Software Forensics Tools

Before listing the tools themselves, some brief background on the programming process might be in order. (It is commonly said, and attributed to Edgser W. Djkstra, that if debugging is the process of removing bugs, then programming must be the process of putting them in.)

The Programming Process

In the beginning, of course, programmers created object (or machine, or binary) files directly. The operating instructions (opcodes) for the computer and any necessary arguments or data were presented to the machine in the form that was needed to get it to process properly. Assembly language was produced to help with this process; although there is a fairly direct correspondence between the assembly mnemonics and specific opcodes, at least the assembly files are formatted in a way that is relatively easy to read, rather than being strings of hexadecimal or binary numbers.

With the advent of high- or at least higher-level languages, programming language systems split into two types. High-level languages are those where the source code is somewhat more comprehensible to people. Those who work with C or APL may dispute this assertion, of course. The much-maligned COBOL is possibly the best example: the general structure of a COBOL program should be evident from the source code, even for those not trained in the language.

Compiled languages involve two separate processes before a program is ready for execution. The application must be programmed in the source (the text or human readable) code, and then the source must be compiled into object code that the computer can understand. Those who actually do programming will know that I am radically simplifying a process that generally involves linkers and a number of other utilities, but the point is that the source code for languages like Fortran and Modula cannot be run directly; it must be compiled first. (It is, of course, dangerous to make such statements; undoubtedly some completist computer language historian will be able to identify Fortran and Modula interpreters of which I am totally unaware.)

Interpreted languages shorten the process. Once the program has been written, it can be run, with the help of the interpreter. The interpreter translates the source code into object code "on the fly," rendering it into a form that the computer can use. There is a cost in performance and speed for this convenience: compiled programs are "native" or natural for the CPU to use directly (with some mediation from the operating system), and so run considerably faster. In addition, compilers tend to perform some level of optimization on the programs, choosing the best set of functions for a given situation.

However, interpreted languages have an additional advantage: because the language is translated on the machine where the program is being run, a given interpreted program can be run on a variety of different computers, as long as an interpreter for that language is available. Scripting languages, used on a variety of platforms, are of this type. JavaScript applets, for example, may be embedded in Web pages, and then run in browsers that support the language regardless of the underlying computer architecture or operating system. (JavaScript is probably a bad example to use when talking about cross-platform operation, because a given JavaScript program may not even run on a new version of the same software company's browser, let alone one from another vendor or for another platform. But it is supposed to work across platforms.)

As with most other technologies where two options are present, there are hybrid systems that attempt to provide the best of both worlds. Java, for example, "compiles" source code into a sort of pseudo-object code called bytecode. The bytecode is then processed by the interpreter (called the Java Virtual Machine, or JVM) for the CPU to run. Because the bytecode is already fairly close to object code, the interpretation process is much faster than for other interpreted languages. Because bytecode is still undergoing an interpretation, a given Java program will run on any machine that has a JVM. (Java does have a provision for direct compilation into object code, as do a number of implementations for interpreted languages such as BASIC.

The Products

Of course, what we get for analysis depends on how the program was developed. If it was machine language programming, assembler, or a compiled language, we get an object code file for analysis. In the case of assembler or compilation we may also have a copy of the assembler or high-level language source code. If we have an interpreted language used for development, we have a copy of the source code of the program. (For the purposes of software forensics analysis, partially compiled objects such as Java bytecode can be considered to be subject

to the same type of analysis as object code. Also, source code, where available, can be assessed in the same manner regardless of whether the language used was a compiler or an interpreter.)

However, the development system still has some ways to make our analytical task more difficult.

Complicating Factors

When a program is compiled or assembled, all comments (unless they are handled in special ways) are eliminated. Comments often constitute the programmer's "notes to self" during the development process, and therefore this information is lost.

When a program is assembled or compiled, the assembly or compilation program can introduce strings and signatures into the code. Obviously, these sections of code must be identified and eliminated from consideration when we are trying to determine authorship of the program. (Occasionally in virus research, compiler-introduced strings were mistakenly taken as unique and therefore used as signature strings for scanning programs. The anti-virus scanners that used such strings would generate large numbers of false-positive alarms as the strings were found in any programs that had been compiled from those languages.)

An additional concern is that compilers frequently optimize the code in some way, and this process may eliminate or confuse some parts of the characteristic signature of a given author.

As previously noted, other utilities besides compilers may be part of the program generation process. These utilities may also introduce signatures into the code, and these signatures must be taken into account. In addition, CASE (Computer Aided Software Engineering) tools and even programming environments (such as specialized editors directly associated with compilers) can influence the design and structure of programs. On the other hand, these various characteristics and signatures, if properly identified, can help identify a programmer or group, given a record of the use of specific sets of tools.

The source code that we receive with interpreted language programs generally does contain the comments (if the author made any) and did not eliminate them before releasing the program. We usually are not faced with compiler-introduced signatures, although a number of programming environments for interpreted languages may introduce comments or bias the use of certain types of programming styles or structures. However, the major concern with interpreted source code is that, particularly in regard to viruses and other widely distributed programs, the availability of the source means that a number of people have the opportunity to make minor variations to the program. This is easy to do when you have the source code, and interpreted languages tend to be simple to use, and are therefore within the programming skill level of a much wider group.

Finally, Already, The Tools

The first tool used in forensic research is obvious enough that most ignore it: a computer. I am not merely being sarcastic at this point. A great deal of information can be obtained by noting the behavior and operation of the program under study when it is running. First of all, we can directly observe what the program does, in gross terms, as it runs. Then we can perform more detailed or low-level studies: are attempts made to access specific areas of memory? Are calls being made to specific resources? Are attempts being made to contact other computers via a network, particularly the Internet? Then again, we can attempt to treat the program like a black box, and see what happens when we prod at it in various ways. (Of course, when dealing with malware, it is important to take precautions: if the first thing the program tries to do is to overwrite the hard disk, the information obtained can be limited.)

The next tool is the good old-fashioned hex editor. Used for displaying the content of binary files (in hexadecimal format, and usually also with those bytes that could be displayed in ASCII running parallel down the side), hex editors can help us find a number of interesting items that might be in the code.

The first items to look for are any strings of actual text. There tends to be a lot of text in programs. Some strings may be text that might appear as messages on the screen. Obviously, any program that contains a string stating "ha ha luzer i just blue up yer d!sc" probably warrants further study. When dealing with malware, as strange as it may seem, the authors of malware are often very proud of their creations, and may also include copyright notices, instructions for use, and even personally identifiable information about themselves.

Another set of strings that may appear as text in programs are application programming interface (API) calls. Particularly in Windows-based software, API calls can be very common. Even if you are not familiar with the libraries being used, APIs generally have very explanatory names. If, for example, you view the code for something that is supposed to be a game, APIs that indicate calls to close, open, or monitor network ports would be somewhat suspicious. An additional class of identifiable information might be available here: if calls

are made to contact entities on the Internet, we may find URLs (Uniform Resource Locators) or even e-mail addresses.

As well as API calls, we may be able to recognize some function calls, although this takes a bit more practice. Programs use some printable characters (in fact, for Intel CPUs it is quite possible to write programs using only printable characters), and some functions can be recognized by a particular string of ASCII characters. For example, in the old days of MS-DOS viruses, the string "PSQR" was one to watch for. It was related to a call by the program to "terminate and stay resident." Because few programs in those days needed to "go resident," such a call was an indication to look deeper.

Text strings may not appear in the program. In some cases, there may be no need for any. In other situations, malware authors may use simple forms of encryption to obfuscate messages. Generally the encryption takes the form of a simple byte-by-byte XOR with a given byte value: for some reason 2Fh seems to be quite popular. Cryptanalysis appropriate for simple substitution ciphers should be able to recover these text passages.

As there are assemblers and compilers for turning assembly and high-level languages into object code, so there are disassemblers and decompilers that do the reverse. Disassembly is easier than decompilation. However, note that disassemblers do not deal well with sections of text or data: they try and interpret the material as program code, with rather random results. In addition, malware authors also frequently encrypt sections of the code, specifically to frustrate attempts at disassembly. In this case one must find the decryption routine, which must come prior to the encrypted section in linear programming, and then use that to decrypt the material before disassembly takes place.

Decompilers fare rather worse, and are a less-mature technology in any case. Decompliers generally require assembly rather than object code as input, and usually do better if the language and even version of the original compiler can be determined. Decompilation is seldom fully successful, and most likely will produce some source code interspersed with sections of assembly code.

Another tool to use is a debugger, although the ones used in forensic programming differ from those used in high-level programming. Debuggers used in software forensics need to be able to control the execution of another program. Therefore, they need to act as a kind of software in-circuit emulator, allowing one operation at a time to proceed. The debugger should also have the ability to determine and display changes in memory and the CPU registers. The venerable DEBUG, from MS-DOS systems, is able to perform a number of these functions, albeit in a very limited way with large programs, as well as functioning as a hex and sector editor and a disassembler.

Software Forensic Technologies and Practices

There are a variety of ways of looking at code to obtain information and evidence. The most obvious, of course, is to look for text, functions, and other items in the content of the software. However, there are ways, not initially apparent, of looking for patterns that are independent of the content of the program.

Content Analysis

Recently my wife drew my attention to very similar embroidery charts, one in a book and another in a handout given away by a floss company. The composition, proportions, and detailed parts of the images were identical. The obvious conclusion is that either one copied the other, or that both were copied from a third source. If this situation were to be examined in terms of intellectual property, in the absence of evidence of a third source, we could note that the window framing in the free pattern is more complex, and that the free pattern has additional shading around the window. This would tend to indicate that the free pattern had been copied or modified from the book, because copiers tend to embellish rather than simplify.

This is an example of content analysis. The charts provide a specific representation of an idea, in this case presented in graphical form. In the same way, an idea presented in text or program code will have a certain representation, composition, and structure. The way that authors and programmers present ideas tends to be characteristic, both in terms of overall composition and in terms of details such as vocabulary, phrasing, function, and structure.

In addition, we can use analysis of text and code to find sequences of messages, and trace influences. In material that is copied from an original, the overall structure and composition tends to be unchanged, but details and embellishments tend to be added.

The syntax of text tends to be characteristic. Does the author always use simple sentences? Always use compound sentences? Have a specific preference when a mix of forms is used? Syntactical patterns have been used in programs that detect plagiarism in written papers. The same kind of analysis can be applied to source code for programs, finding identity in the overall structure even when functional units are not considered. A number of such plagiarism detection programs are available, and the methods that they use can assist with this type of forensic study.

Of course, when considering the content of the text, most people consider characteristic use of vocabulary and phrases. This does tend to be effective, but it usually relies on having a large set of samples to analyze. We also generally have to ensure that the texts cover the same or similar subjects to avoid problems with disparate vocabularies in differing fields. Similar analysis can be applied to programs, using functional structures that provide analogues of vocabulary, and assessing modules in the same way we read paragraphs.

It may seem strange to those who do not regularly work with object code to find that there can be characteristic "phrases" in these strings of 1s and 0s. As one example, virus researchers would frequently find strings or patterns that would indicate attempts to perform certain functions. In the days of MS-DOS (or PC-DOS or DR-DOS), a program that was making a call to remain in memory while other programs were running (or "go resident") was unusual, and frequently a sign that the program was viral. When viewed with a text or hex editor, most such programs would contain the string of letters "PQSR." The letters did not mean anything as text, they were simply the common pattern of the operating codes making the "terminate and stay resident" function call. However, this pattern was a characteristic indicator, a kind of vocabulary of a certain type of activity.

Error Analysis

Errors in the material can be extremely helpful in our analysis, and should be identified for further study. In some of my early work published on the history of computer viruses, I made a mistake in the spelling of the name of one person involved in the creation of a specific program. Shortly thereafter, another person also published such a history. The histories were very similar, but that could be expected if two people both had access to the same sources. However, the second history also contained the error that I had made. The author of the second history, had he followed original reference materials, would not have made that error, thus indicating that the later text was a copy of my original.

In another example, two students cheated and copied answers on a test I gave at a college. In my report on the incident, I included a statistical analysis on the results. The likelihood of two students getting exactly the same questions correct was extremely small. But the chance of two students making exactly the same errors was five times smaller, making a much stronger case for the cheating presentation.

The existence of errors in program code is problematic, because certain types of mistakes will ensure that the program either does not compile or does not run. However, we may find that certain types of nonfatal errors; such as a failure to optimize various types of operations, may be characteristic of an individual or group.

Noncontent Analysis

At one point my wife worked as a secretary in a government office, typing reports for a variety of officers. She noted that different writers had different styles. In those days of typewriters and monospaced fonts, one of the factors she discovered was that different people required different line lengths. If the wrong length was used, the report turned out to have a ragged edge down the right side of the page. If the right line length was used, the margin was neater. The line length was characteristic of the writer: Tom needed a 65 space line, Dick used 72, and Harriet required 68 spaces. This characteristic is consistent over time: Harriet will always need 68 spaces. This may seem to be a trivial characteristic, but it does indicate that a number of identifying attributes are available in order to build an electronic fingerprint of text. The same is true of program code.

A specific method of finding such characteristics in text is Cusum, explained in the book, *Analysing for Authorship,* by Jill M. Farringdon. Literary critics are quite used to talking about how an author like Henry James would write enormously long sentences that, in more modern writings, would be split into smaller, more digestible chunks, but which were, in the days when it was considered acceptable for someone like Marcel Proust to write an entire book that was one long sentence, the norm that was to be emulated and adopted. Others wrote differently. Hemingway, for example. Short sentences. Sentence fragments, really. Therefore, critics are quite used to making decisions about authorship based on numeric metrics.

Cusum (or QSUM, the two terms seem to be used interchangeably in the book) is such a technique. Instead of looking at meanings or characteristic turns of phrase, the method looks at combinations of statistical patterns in writing, patterns that the writer is probably unaware of using.

It may seem strange to use meaningless features as evidence. However, Richard Forsyth reported on studies and experiments that found short substrings of letter sequences can be effective in identifying authors of textual material. Even a relative count of the use of single letters can be characteristic of authors. Similar measures can probably be applied to program code, both source and object.

Additional Noncontent Indicators

Certain message formats may provide us with additional information. A number of Microsoft e-mail systems include a data block with every message that is sent. To most readers, this block contains meaningless garbage. However, it may include a variety of information, such as part of the structure of the file system on the sender's machine, the sender's registered identity, programs in use, etc. In the case of material distributed by e-mail, this information may be available.

Other programs may add information that can be used. Microsoft Word, for example, is frequently used to create documents sent by e-mail. Word documents include information about file system structure, the author's name (and possibly company), and a "global user ID." This ID was analyzed as evidence in the case of the Melissa virus. MS Word can provide us with even more data: comments and "deleted" sections of text may be retained in Word files, and simply marked as hidden to prevent them from being displayed. Basic utility tools can recover this information from the file itself. Some compilers create similar tables on data within the executable body of a program.

Legal Considerations

First of all, because this section deals with legal issues, I imagine that I need to make legal disclaimer-type noises. Therefore, be it known to all men by these presents that I am not a lawyer, I have never even played one on TV, this is not to be considered legal advice, for legal advice please see qualified legal counsel, void where prohibited by law, no warranty express or implied is made on the fitness of this information for any purpose including the purpose for which it was intended, no added salt, your mileage may vary, this product contains not less than 70 percent recycled opinions, please do not read while operating heavy machinery, have I missed anything?

There are going to be differences in the permissibility of software forensics evidence depending on the legal system that has jurisdiction over the crime. Admissibility of computer records may vary from system to system: some legal systems will consider it hearsay and require higher standards to accept it. Jurisdiction, as with any situation that deals with possible network involvement, may be a problem as well.

With respect to jurisdiction, of course, what may be considered a crime in one location may not be in another. Canadian law, for example, notes that anyone who, without authorization, modifies data or "causes" it to be modified, is guilty of an offense. Therefore, if we can demonstrate through software forensics that the intent of the program was to create data modification (possibly among other things) and to gain access to systems without active user involvement, then we have a case with regard to computer viruses. In addition, if we can reveal a link to a specific individual as the author of the program, we can make a case against that person. Other jurisdictions may not have the same wording in law, and so we may not be able to prosecute certain types of activity. In regard to the use of software forensics with respect to intellectual property cases, note that a number of countries do not have intellectual property laws.

In dealing with legal issues, we have an immediate problem in that not only do different countries have different laws, but possibly even different legal systems. Those from Britain, the Commonwealth countries, and the United States will be most familiar with the "Common Law" system, based on the presumption of laws that uphold the common good, from an originating charter document and case law precedents laid down over the years. (Common Law is also the system under which a suspected criminal is presumed to be "innocent until proven guilty.") In some of those countries there are specific laws that would make, for example, malicious software illegal. However, most Common Law systems also have provisions against mischief or vandalism, so malicious software could probably be prosecuted even in the absence of a specific law. (Successful prosecution is quite another matter, the requirements for which we will be dealing with at length.)

Some countries, such as France, have Code Law or Civil Law systems. Under these systems, an activity is not illegal unless there is a specific law against the activity. (In access control terms, everything is permitted

unless it is forbidden.) Therefore, under such systems, it may be perfectly legal to write and distribute malicious software (or break into computer systems, or sell pirated copies of copyright protected software) simply because the law against it does not exist: the lawmakers have not caught up with the times.

As this chapter was being written (early 2003), the legal situation with regard to software forensics, particularly in the United States, was very confused. Certain laws intended for the protection of intellectual property could be used to prevent the examination of software. There was the case of a programmer from Russia who came to the United States to speak to a conference about a weakness in a security mechanism in a commercial software product. He was, in fact, arrested and held in custody. It may be possible that authors of malicious software may challenge software forensics evidence on the basis that they hold copyright on their software, and did not grant permission for the software to be examined.

Presentation in Court

Presentation of this kind of technical evidence in court can be problematic. Debates over DNA evidence as identification, and the acceptability of such evidence to nonspecialists, which describes most lawyers, judges, and juries, are directly relevant to this issue. The field of forensic linguistics is still developing, and experts may have to be judged individually. Findings and opinions may be dismissed by the court on the basis that the expert cannot prove sufficient knowledge, skill, experience, training, or education.

There is an additional point to be made about the difference between civil and criminal cases under Common Law systems, and it is directly relevant to forensic studies. The test of evidence and proof is not the same in the two types of cases. A criminal case must be proven "beyond a reasonable doubt." Civil cases require only that a decision be made on the balance of the probabilities. Thus evidence for a criminal trial must be presented much more carefully.

A factor in the admissibility of evidence is the concept of hearsay. As a witness in court, you may be asked to say what you did or directly witnessed. Except in very unusual circumstances, you will not be asked, and will not be allowed to say, what someone else told you that they did or saw. This "second-hand" testimony is called hearsay, and is pretty much automatically suspect. If the court is to accept evidence other than directly from the source, there has to be corroborating testimony.

Business documents are all, in fact, considered to be hearsay in some sense. This is because they are all, in a way, information around a transaction rather than direct evidence of a transaction. This is particularly true in relation to electronic data. When presenting printouts or other representations of digital information, there must be testimony about how the information was stored and handled, whether there are regular procedures, whether there was any kind of departure from regular procedures, what protections are in place to ensure the integrity of the data, who has access and the ability to change the data, etc. This has particular relevance to software forensics, because the evidence gathered may result from very minor differences, and, in addition to proving to the court that the differences are significant, we must be able to prove that the material presented in court is identical, to the bit, with the original data or code.

In choosing evidence for court, content-based analysis may seem to be a more reasonable choice for presentation, but its use may backfire. Content analysis may be "morally" convincing, but still lack specific proof and be dismissed as mere opinion. In the embroidery chart example I gave earlier, it is instantly apparent that the patterns are from the same source, but it takes time to determine specific features and reasons, and the sequence of the patterns. It is, of course, just those specific features and reasons that are important for presentation in court.

Future Work

At this point, it would be premature to draw conclusions or even suggest implications for software forensics work. Certainly there is a potential for promise in the field, but a good deal of work remains to be done. I shall, therefore, suggest only a limited number of additional studies that present themselves as needed research.

A good deal of work needs to be done in regard to building a library of resources and references for software forensics analysis. Virus research has concentrated on signatures for individual pieces of malware as well as signatures for various malware kits, encryption engines, and heuristic signatures for "dangerous" functions. These are helpful. However, we also need to collect signatures of compilers and other software creation tools.

Signatures of good, bad, or mature coding practices should also be ascertained. A fairly quick scan of a piece of code to determine the skill level of a programmer would be a good thing. Unfortunately, it is unlikely that

such can be easily codified or automated. In addition, authors of malicious software, in their quest for "3133t" status, would likely take to embedding such signatures in their code, purely as an attempt to be identified as skilled programmers.

Additional work needs to be done in terms of decompilation software. In particular, it would seem obvious that a combination of the two existing types of decompilers, those that recover function and those that recover structure, should be attempted.

The various projects aimed at detecting plagiarism would seem to be producing very useful tools. For broader application, however, it would be important to attempt to make identification out of larger populations, and to validate, statistically, the assurance we can derive from such identifications.

Reporting Security Breaches

James S. Tiller, CISSP

If you are involved with information systems within an organization — whether at the highest levels of technical management or the end user in a remote office — you will ultimately be faced with a security incident. Managing a security breach life cycle encompasses many managerial, technical, communication, and legal disciplines. To survive an event you need to completely understand the event and the impacts of properly measuring and investigating. When reporting an incident, the information provided will be scrutinized as it rolls up the ranks of the organization. Ultimately, as the report gains more attention and it nears the possibility of publication, the structure of the incident report and supporting information will be critical.

This chapter touches upon the definition of an incident and response concepts, but its focus is on reporting the incident. It is assumed that incident response processes, policy, mitigation, and continuity are all existing characteristics — allowing us to focus on the reporting process and escalation.

SCHROEDINGER'S CAT

A quick discussion on the value of information in the world of incidents is in order.

Quantum mechanics is an interesting code of thought that finds its way into the world of security more often than not. Erwin Schroedinger produced a paper in 1935, "Die gegenwartige Situation in der Quantenmechanik," that introduced the "Cat" and the theory of measurement. In general, a variable *has* no definite value before it is measured; then measuring it does *not* mean ascertaining the value that it *has* but rather the value it has been measured against. Using Schroedinger's example, let us assume there is a cat in a box, a black box. You open the box and the cat is dead. How do you know the cat was dead before you actually made the observation by opening the box? Opening the box could have killed it for all you

know. In the most basic terms, the interaction of variables with measurement requirements will raise the question of how much of the value obtained was associated with the act and process of measurement. Of course, Schroedinger's Cat is a theory that impacts quantum mechanics more so than measuring your waistline, but establishing control sets and clear measurement policy related to the technology is critical in the space between the ordinary and the extraordinary. This simple paradox lends itself to interesting similarities in the world of security incidents — albeit loosely.

Your actions when determining an event, or how you have set the environment for detecting an event, can have ramifications on the interpretation of the event as it is escalated and reported. How does the "cat" apply? It is necessary to measure from multiple points in various ways to properly ascertain the event when reporting as an incident.

For example, if you have an intrusion detection system (IDS) at your perimeter and another on your DMZ with an identical configuration and an anomaly is detected, you have proven an anomaly on both sides of your firewall. With information from the logs of the alleged target server and the firewall, you now have more disparate information sources to state your case and clearly ascertain the scope of the incident. Additionally, this will demonstrate the attention to clarity and comprehensiveness of the detection and documentation process, furthering the credibility of the report.

Another application of the analogy is incident response process and the actual collection of information. Although we are focusing on reporting incidents, it is important for the reader to understand the importance of the information to be shared. Collecting information in support of detailing the incident can be a sensitive process, depending on two fundamental directions decided upon at the initial onset of incident response: *proceed and protect* or *pursue and prosecute*. Care should always be practiced when collecting evidence from impacted systems, but this is most true when the decision to pursue and prosecute has been made. It is here, gathering data for future analysis, reporting, or evidence, that Schroedinger's Cat can become a lesson in forensics. Simply stated, the act of extracting data — no matter the perceived simplicity or interaction — can affect the value as well as the integrity of the information collected. Was that log entry there because you created it? Understandably, an oversimplified example, but the point is clear — every interaction with a system can inherently impact your ability to measure the incident in its purest state. Based on Schroedinger's theory, simply the act of quantifying will inevitably and unavoidably influence the measured outcome.

Understanding the consequences of data collection during and after an incident will help you to clearly detail and report an event, ultimately building efficiencies into the mitigation process.

SECURITY REQUIREMENTS

At the risk of communicating an oversimplification, it is necessary to state that proper configuration and management of security is critical. Through the use of technology and defined processes, you can accurately and confidently identify incidents within the network and quickly determine what happened and the vulnerability that was exploited.

Security Policy

Every discussion on security has a section on security policies and their importance. Security policies define the desired security posture through communicating what is expected of employees and systems as well as the processes used to maintain those systems. Security policies are inarguably the core point of any successful security program within an organization. However, with regard to incident management, the criticality of security policies cannot be understated.

Security policies provide an opportunity to understand the detailed view of security within an organization. In many cases, security policies reflect common activities practiced within the organization regularly and can be used as a training resource as well as a communication tool. However, incident response policies could be considered the most important section of any security policy, based on the criticality and uniqueness of the process combined with the simple fact that incidents are not typical occurrences (usually). In the event of a rare occurrence, no one will know exactly what to do — step by step — and in all cases a referenceable document defining what should be done in accordance with the desired security posture can be your lifeblood.

In the day-to-day activities of a nuclear plant, there is always the underlying threat of a failure or event; but it does not permeate the daily tasks — they are preparing and avoiding those events through regular management of the systems. In the rare times there is a significant occurrence, the proprietors will always reference a process checklist to assist in troubleshooting. Another example is a pilot's checklist — a systematic process that could be memorized; but if one portion is exercised out of order or missed, the result could end in disaster.

Therefore, a security policy that clearly defines the identification and classification of an event should also state the process for handling and reporting the incident. Without this significant portion of a security policy, it is almost assured the unguided response procedures will be painful and intermittent in context.

Security Technology

In the realm of digital information, security is realized and measured through technology. The configuration of that technology and the defined

interaction with other forms of technology will directly impact the ability to recognize an incident and its eventual investigation.

Security-related technology comes in many forms, ranging from firewalls and IDSs to authentication systems. Additionally, security characteristics can emerge from other technologies that are traditionally not directly associated with security and provide services beyond the envelope of information security. However, these become the tools to identify events in addition to becoming collection points for gaining information about the incident.

As briefly mentioned above, more points within a network that have the ability to detect or log events will increase the quantity of information available that can be correlated to amplify the quality and accuracy of the incident description. In addition to the number of points in the network, the type and layer with which it interacts may become the defining factor in isolating the event.

For example, a firewall may log traffic flow by collecting information about source and destination IP addresses and port numbers. Along with time stamps and various other data, the information can be used to identify certain characteristics of the incident. To obtain even more of the picture, the target operating system, located by the destination IP address from the firewall's logs, may have logs detailing certain actions on the system that are suspicious in nature and fall within the time of attack window established by the firewall's logs. The last piece of the puzzle is provided by a system-monitoring package, such as Tripwire — an application that essentially detects changes in files. Based on the information from Tripwire, it may appear that several files were changed during the time of the attack. A short search on the Internet may reveal that a Trojan version of the file is in the wild that can provide temporary administrative access using port 54321, which you have verified from the firewall and system logs. Additionally, the report continues to detail known implantation techniques to install the Trojan — replacing the valid file — by leveraging a weakness in the TCP/IP stack by sending overlapping packets that result in distorted IP headers. It was the "notification" log on the firewall that allowed you to initially determine the time frame of the attack; but without the other information, you would be hard-pressed to come to the same detailed conclusion.

The purpose of the example is to communicate the importance of disparate information points and types within the network. The firewall passed the packet because it was not denied by the rules, and the header structure fell within limits; but the vulnerability exploited in the operating system could not survive those changes. The file implantation would normally go undetected without the added information from Tripwire.

It is clear that ample information is helpful, but the variety of data can be the defining factor. Therefore, how technology is configured in your environment today can dramatically affect the ability to detect and survive an incident in the future.

Additionally, the example further demonstrates the need for incident response policies and procedures. Without a well-documented guide to follow, it is doubtful that anyone would be able to traverse the complicated landscape of technology to quickly ascertain an incident's cause, scope, and remedy.

REPORT REASONING

There are many attributes of incident management that must be considered within the subject of reporting. This section discusses:

- *Philosophy.* Simply stated, why report an incident at all? This question insinuates notifying the public, but it can be applicable for internal as well as partnership communications. What are the benefits and pitfalls of reporting an incident?
- *Audience.* When reporting anything, there must be an audience or scope of the people who will be receiving or wanting the information. It is necessary to know your constituents and the people who may have a vested interest in your technical situation.
- *Content.* As information is collected about an incident, there will certainly exist data that an organization would not want to share with some communities that make up the audience. It is necessary to determine the minimal information required to convey the message.
- *Timing.* The point in time when an incident is reported can have dramatic impacts within and beyond an organization. This is especially true when the incident investigation reveals a vulnerability that affects many people, departments, or companies.

Philosophy

Reporting an incident will undoubtedly have ramifications internally; and based on the type, scope, and impact of the event, there could be residual effects globally. So, given the exposure and responsibility — why bother? What are the benefits of reporting that you have a weakness or that you were successfully attacked because you were simply negligent in providing even the basic security? In this light, it seems ridiculous to breathe a word that you were a victim. To add to the malaise, if you report an incident prior to assuring the vulnerability used for the attack is not rectified, you may be in for many more opportunities to refine your incidence response process. Finally, once attackers know you do not have a strong security program or do not perform sound security practices, they may attempt to attack you in hope of finding another vulnerability or simply slip

under the radar of confusion that runs rampant in most companies after an incident.

The answer, as one may expect, is not simple.

There are several factors that are used to determine if an incident should be reported, and ultimately, to whom, when, and what should be shared. The following are some of the factors that may need to be considered. Ultimately, it is a lesson in marketing.

Impact Crater. Essentially, how bad was the impact and who — or what — was affected by the debris? With certain events that stretch the imagination and had catastrophic results, it is usually best to be a reporter and provide your perspective, position, and mitigation prior to CNN dropping the bomb on you publicly.

It is usually best to report your situation first rather than be put in the position of defending your actions. This is a reality for public reports in addition to internal reporting. For example, if the IS department makes an enormous security oversight and money is lost due to the exploited vulnerability, accepting responsibility prior to having an investigation uncover the real issue may be best.

Who's on First? Somewhat related to the impact crater, many organizations will be attacked and attempt to deal with it internally — or within the group. Unfortunately for these organizations, the attackers are usually trying to prove their capability in the hacking community. After some chest thumping on news groups, your demise will soon be public. Again, when faced with public interpretation of the event, it is typically better to be first.

Customer Facing. If the attack affected customer systems or data, you may have no choice. You may not have to reveal the incident publicly; but in the event a customer or partner was affected, you must report the situation, history, plan for mitigation, recovery options, and future protection. If you do not, you run an extreme liability risk and might never recover from the loss of reputation.

The previous factors can be presented in many ways, but all cast a dark shadow on the concept of exposure and do not present any positive reason for reporting an incident. No one wants to be perceived as weak publicly or internally — to customers or partners. However, there are factors that, when properly characterized within the scope of the incident and business objectives, it is essential that a report evolve from an event. Following are some points of interest regarding reporting.

Well Done. There are many occasions where a vulnerability was exploited but there was little or no loss associated with the attack. Moreover, the vulnerability may have proved to be extreme in terms of industry

exposure; it just so happened that you experienced the attack on a system you practically forgot was still in the wire closet. Or better yet, your security awareness and vigilance allowed you to identify the incident in real-time, mitigate the attack, and determine the structure and target. This, of course, is how it is supposed to work. Detect, identify, eradicate, and learn — all without suffering from the attack. If this is the case, you could substantially benefit from letting people know how good you are at security.

Fix First. In some situations, it may be beneficial to report an incident to convey to your constituents that there is a new threat afoot and demonstrate your agility and accuracy in handling the incident.

Good Samaritan. In some cases, you may simply be ethically drawn to report the details of an incident for the betterment of the security community and vendors who can learn and improve based on the information. Of course, all previous points may apply — mitigate the exposure and clearly identify the incident.

Truly, at the end of the day, if an event is detected — regardless of impact — there should be a report created and forwarded to a mediator to work within the organization's policy and the dynamics of the attack to properly determine the next step. If the vulnerability is like the recent SNMP vulnerability, it is generally accepted that working with the vendors first is the best plan of global mitigation. How you identify and react to an attack will relate to whom, what, and when you report.

Audience

For better or for worse, the decision has been made to report the incident; and now the appropriate audience must be determined. You can report to one group or several, but assume the obvious leakage when dealing with people and sensitive information. For example, if you do not feel the employees need to know, it would be unwise to tell the partners, customers, or the public. Keeping this in mind, it is also necessary to understand the audience (for the purposes of this discussion); this is your primary audience and others may be indirect recipients — purposely. For example, the managers should know that there was an incident that could impact operations temporarily. This should not be kept from the employees, but the managers could be advised to convey the announcement to their respective groups within a certain time frame.

To add to the complexity, the audience type is proportional to the impact of the incident and the philosophy, or mindset, of performing the report. Essentially, a three-dimensional matrix should be constructed, with one axis being the impact or the criticality of the event, another the response structure (speed, ethics-based or self-preservation, etc.), and the

last a timeline of events. The matrix would then help determine who should know the details of the incident and when.

Nevertheless, it is feasible to segment the different audience types with associated descriptions to help you assess the appropriate target based on the incident characteristics.

Customers. Customers are people, groups, or companies to whom you provide a service or product. Depending on the incident type and scope, it may be necessary to notify them of the event. Customers are entities that invest in your organization through their utilization of your product or service. The greater the investment, the greater the expectation for a supportive and long relationship. If a customer's investment in your organization is affected, reporting may be critical.

As stated above in the section "Well Done," properly responding to an attack and formulating a mitigation process to recover from the attack can offset the strain on the relationship between you and the customer and, in some circumstances, enhance the relationship.

Vendors. One of the more interesting aspects of reporting incidents is the involvement of vendors. For example, if you only use Cisco routers and switches and suffer a breach that is directly associated to a vulnerability in their product, you want them to know about your discovery in order to fix it. In the event they already know, you can become more involved in the remedy process. Of course, you must first overcome the "if they knew, why did I have to get attacked" argument.

Another characteristic of vendor notification is the discovery of the vulnerability through a noncatastrophic incident and having to decide how long they have to fix the vulnerability prior to notifying the public. In many cases, this situation evolves from the discovery of a vulnerability through testing and not the exploitation via an active attack. In the event the vulnerability was determined through a recorded incident, the target organization usually is very patient in allowing the vendor to provide a fix. The patience is mostly due to the desire to let the vendor announce the vulnerability and the fix — making the vendor look good — relieving the victim of the responsibility and exposure and alleviating the vulnerability. If the vulnerability is detected through testing, the testers were usually looking for a weakness to discover. Therefore, in many scenarios, the testers want people to know their discovery; and waiting around for a vendor to provide patches runs against that desire.

In all fairness, it is very common for a vulnerability to be discovered and shared with the vendor prior to letting the general public know. There have been occasions when it has taken the vendor a year to get the fix addressed due to its complexity. The person who discovered the vulnerability was

assured they were working on the fix and was ultimately hired to assist in the mitigation. For vendors that want to have a chance to fix something before the vulnerability is exposed and there are no protection options for their customers, it is necessary to communicate on all levels.

Do not ignore the people who provided you the information. For someone who has expended effort in discovering a vulnerability, the feeling that they are not being taken seriously will definitely expedite the public's awareness of your weakness. One example was a large organization that had a firewall product and received an e-mail detailing a vulnerability and a request for an audience to discuss rectifying the proposed serious hole. After many attempts to gain the much-desired attention, the person became frustrated and turned to the public to ensure that someone would know the existence of the vulnerability. The consequence of ignoring the first contact resulted in customers — some of whom had validated the vulnerability — flooding the vendor with demands for assistance, only to realize the vendor had accomplished very little to date. This entire fiasco reflected badly on the vendor by publicizing its incompetence and inability to meet customer demands with its product.

Partners. Partners are usually companies that establish an alliance with your company to reach a similar objective or augment each other's offerings to customers. Partners can be affected by incidents, especially when there are connections between the entities or the sharing of applications that were impacted. If an incident hinders business operations to a point where a partner's success or safe operation is in jeopardy, a notification with details must be communicated.

It is a crucial priority to advise partners of increased exposure to threats because of an incident on your network. Reporting to the partner the incident and the impact it may directly have on them needs to be addressed in the incident response policies.

Employees. Employees (or contractors) are people who perform the necessary functions required by the company to accomplish the defined business objectives. In nearly every situation, where there is an incident that affects multiple users, employees are typically informed immediately with instructions. The reality is that word-of-mouth and rumor will beat you to it, but providing a comprehensive explanation of the incident and procedures they must follow to protect the company's information assets is necessary.

Managers. Managers are typically informed when the incident can lead to more serious business ramifications that may not be technically related. For example, if an attack is detected that results in the exposure of the entire payroll, employees may get very upset — understandably. It is necessary to control the exposure of information of this nature to the general

population to limit unfounded rumors. Additionally, it must be assumed that there is a strong probability the attacker is an employee. Communication of the incident to the general staff could alert the perpetrators and provide time to eliminate any evidence of their involvement. Obviously, it is necessary for the person or department responsible for the investigation to report to managers to allow them the opportunity to make informed decisions. This is especially critical when the data collected in preliminary investigations may provide evidence of internal misconduct.

Public. One of the more interesting aspects of reporting incidents is communicating to the public the exposures to new threats. In most circumstances, reporting security incidents to the public is not required. For example, a privately held company may experience an event that does not directly impact production, the quality of their product, or the customer's access to that product. Therefore, there is little reason to express the issue, generally speaking. However, it depends on the scope of your company. Following are some examples.

- *Product vendor.* Beyond debate, if a product vendor discovers a vulnerability with its implementation, the vendor is inescapably responsible to communicate this to its clientele. Granted, it is best to develop a solution — quickly — to provide something more than a warning when contacting customers. Sometimes, the general public represents the audience. A clear example is Microsoft and its reaction to security vulnerabilities that will virtually impact everyone.
- *Service providers.* Information service providers, such as application service providers (ASPs), Internet service providers (ISPs), etc., are responsible to their customers to make them aware of an exposure that may affect them. Some very large service providers must disseminate information to a global audience. In addition to the possible scope of a provider's clientele, other service providers can greatly benefit from knowing the impact and process associated with the incident in their attempt to avoid a similar incident. A perfect example is the distributed denial-of-service (DDoS) attack. Now that service providers as well as the developmental community understand the DDoS type of attack, it is easier to mitigate the risk, ultimately gaining more credibility for the industry from the customer's perception.
- *Public companies.* After the ENRON and Arthur Andersen debacle, the sensitivity of disclosing information has reached a new peak. In a short time the trend moved from concern over information accuracy to include information breadth. Consequently, if an incident occurs in an organization that is publicly traded, the repercussions of not clearly reporting incidents could cause problems on many levels.

Content and Timing

What you report and when are driven by the type of incident, scope, and the type of information collected. For internal incidents, ones that affect your organization only, it is typical to provide a preliminary report to management outlining the event and the current tasks being performed to mitigate or recover. The timing is usually as soon as possible to alert all those who are directly associated with the well-being of business operations.

As you can see, the content and timing are difficult to detail due to the close relation to other attributes of the incident. Nevertheless, a rule of thumb is to notify management with as much information as practical to allow them to work with the incident team in formulating future communications. As time passes and the audience is more displaced from the effects of the incident, the information is typically more general and is disseminated once recovery is well on its way.

COMMUNICATION

In communications there should always be a single point within an organization that handles information management between entities. A marketing department is an example of a group that is responsible for interpreting information detailed from internal sources to formulate a message that best represents the information conveyed to the audience. With incident management, a triage team must be identified that serves as the single gateway of information coming into the team and controls what is shared and with whom based on the defined policies. The combination of a limited team, armed with a framework to guide them, ensures that information can be collected into a single point to create a message to the selected audience at the appropriate time.

Reporting an incident, and determining the audience and the details to communicate, must be described in a disclosure policy. The disclosure policy should detail the recipients of a report and the classification of the incident. It should also note whether the report would span audiences and whether the primary audience should be another incident response group internally or a national group such as CERT/CC.

The CERT/CC is a major reporting center for Internet security problems. The CERT/CC can provide technical assistance and coordinate responses to security compromises, identify trends in intruder activity, work with other security experts to identify solutions to security problems, and disseminate information to the broad community. The CERT/CC also analyzes product vulnerabilities, publishes technical documents, and presents training courses. Formerly known as the Computer Emergency Response Team of Carnegie Mellon University, it was formed

at the Software Engineering Institute (SEI) by the Defense Advanced Research Projects Agency (DARPA) in 1988.

Incident response groups will often need to interact and communicate with other response groups. For example, a group within a large company may need to report incidents to a national group; and a national incident response team may need to report incidents to international teams in other countries to deal with all sites involved in a large-scale attack.

Additionally, a response team will need to work directly with a vendor to communicate improvements or modifications, to analyze the technical problem, or to test provided solutions. Vendors play a special role in handling an incident if their products' vulnerabilities are involved in the incident.

Communication of information of this nature requires some fundamental security practices. The information and the associated data must be classified and characterized to properly convey the appropriate message.

Classification

Data classification is an important component of any well-established security program. Data classification details the types of information — in its various states — and defines the operational requirements for handling that information.

A data classification policy would state the levels of classification and provide the requirements associated with the state of the data. For example, a sensitive piece of information may only exist on certain identified systems that meet rigorous certification processes. Additionally, it is necessary to provide the distinctive characteristics that allow people to properly classify the information. The data classification policy must be directly correlated with the incident management policy to ensure that information collected during investigation is assigned the appropriate level of security.

Included in the policy is a declassification process for the information for investigative processes. For example, the data classification policy may state that operating system DLL files are sensitive and cannot have their security levels modified. If the DLL becomes a tool or target of an attack, it may be necessary to collect the data that may need to be reported. It is at this point the incident response management policy usually takes precedence. Otherwise, bureaucracy can turn the information collection of the incidence response team into an abyss, leading to communication and collaboration issues that could hinder the response process.

Identification and Authentication

Prior to sharing information, it should be considered a requirement to authenticate the recipient(s) of the information. Any response organization, including your own, should have some form of identification that can be authenticated.

Certificates are an exceptional tool that can be utilized to identify a remote organization, group, individual, or role. Authentication can be provided by leveraging the supporting public key infrastructure (PKI) to authenticate via a trusted third party through digital signatures. Very similar to PKI — and also based on asymmetrical encryption — pretty good privacy (PGP) can authenticate based on the ability to decrypt information or sign data proving the remote entity is in possession of the private key.

Confidentiality

Once you have asymmetrical keys and algorithms established for authentication, it is a short step to use that technology to provide confidentiality. Encryption of sensitive data is considered mandatory, and the type of encryption will more than likely use large keys and advanced algorithms for increased security.

Symmetrical as well as asymmetrical encryption can be used to protect information in transit. However, given the sensitivity, multiple forms of communication, and characteristics of information exchange, asymmetrical encryption is typically the algorithm of choice. (The selection default to asymmetrical also simplifies the communication process, because you can use the same keys for encryption that were used for the authentication.

CONCLUSION

Incident reporting is a small but critical part of a much more comprehensive incident management program. As with anything related to information security, the program cannot survive without detailed policies and procedures to provide guidance before, during, and after an incident occurs. Second only to the policy is the technology. Properly configured network elements that deliver the required information to understand the event and scope are essential.

Collecting the information from various sources and managing that information based on the policies are the preliminary steps to properly reporting the incident. Reporting is the final frontier. Clearly understanding the content and the audience that requires the different levels of information are essentially the core concerns for the individuals responsible for sharing vital and typically sensitive information.

Reporting incidents is not something that many organizations wish to perform outside the company, but this information is critical to the

advancement and awareness of the security industry as a whole. Understanding what attacks people are experiencing will help many others, through increased consciousness of product vendors, developers, and the security community as a whole, to further reduce the seriousness of security incidents to the entire community.

ABOUT THE AUTHOR

James S. Tiller, CISSP, MSCE+I, is the Global Portfolio and Practice Manager for International Network Services in Tampa, Florida.

Incident Response Management

Alan B. Sterneckert, CISA, CISSP, CFE, CCCI

Incident response management is the most critical part of the enterprise risk management program. Frequently, organizations form asset protection strategies focused primarily on perceived rather than actual weaknesses, while failing to compare incident impact with continuing profitable operations. In the successful implementation of risk management programs, all possible contingencies must be considered, along with their impact on the enterprise and their chances of occurring.

By way of illustration, in the 1920s and 1930s, France spent millions of francs on the construction of the Maginot Line defenses, anticipating an invasion similar to the World War I German invasion. At that time, these fortifications were considered impregnable. During the 1940 German army invasion, they merely bypassed the Maginot Line, rendering these expensive fortifications ineffective. The Maginot planners failed to consider that invaders would take a route different than previous invasions, resulting in their defeat.

RISK MANAGEMENT PROJECT

Risk management is not a three-month project; it is not a project that, when completed, becomes shelved and never reviewed again. Rather, it is a continuous process requiring frequent review, testing, and revision. In the most basic terms, risk has two components: the probability of a harmful incident happening and the impact the incident will have on the enterprise.

TOP-DOWN RISK MANAGEMENT PROJECT PLANNING

Beginning at the end is a description of top-down planning. Information technology (IT) professionals must envision project results at the highest level by asking, what are my deliverables? Information risk management deliverables are simply defined: confidentiality, integrity, and availability (CIA). CIA, and the whole risk management process, must be first considered

in the framework of the organization's strategic business plans. A formula for success is to move the risk management program forward with a clear vision of the business deliverables and their effect on the organization's business plans.

The concept of risk management is relatively simple. Imagine that the organization's e-mail service is not functioning or that critical data has been destroyed, pilfered, or altered. How long would the organization survive? If network restoration is achieved, what was the business loss during the restoration period? It is a situation in which one hopes for the best but expects the worst. Even the best risk management plan deals with numerous *what-if* scenarios. What if a denial-of-service (DoS) attacks our network? Or what if an employee steals our customer list? What if a critical incident happens — who is responsible and authorized to activate the incident response team?

In the world of risk management, the most desirable condition is one in which risks are avoided. And if risks cannot be avoided, can their frequency be increased and can their harmful effects be mitigated?

RISK MANAGEMENT KEY POINTS

These are general key points in developing a comprehensive risk management plan:

- Document the impact of an extended outage on profitable business operations in the form of a business impact analysis. Business impact analysis measures the effects of threats, vulnerabilities, and the frequency of their occurrence, against the organization's assets.
- Remember that risk management only considers risks at a given moment. These risks change as the business environment changes, necessitating the constantly evolving role of risk management.
- Complete a gap analysis, resulting in the measured difference between perceived and actual weaknesses and their effects on key assets.

OVERALL PROJECT PLANNING

Incident response planning is no different than other planning structures. There are four basic key phases:

1. Assess needs for asset protection within the organization's business plan
2. Plan
3. Implement
4. Revise

In assessing needs, representatives of the affected departments should participate in the initial stage and should form the core of the project team.

Additional experts can be added to the project team on an ad hoc basis. This is also a good time to install the steering committee that has overall responsibility for the direction and guidance of the project team. The steering committee acts as a buffer between the project team and the various departmental executives. The early stage is the time for hard and direct questions to be asked by the project team members in detailing the business environment, corporate culture, and the minimum organizational infrastructure required for continuing profitable operations.

It becomes important to decide the project's owners at the outset. Project ownership and accountability are based on two levels: one is the line manager who oversees the project team, and the other is the executive who handles project oversight. This executive–owner is a member of the steering committee and has departmental liaison responsibilities. Project scope, success metrics, work schedules, and other issues should be decided by the project team. Project team managers, acting in cooperation with the steering committee, should keep the project focused, staffed, and progressing.

Planning is best conducted in an atmosphere of change control. The project team's direction will become lost if formal change control procedures are not instituted and followed. Change controls decide what changes may be made to the plan, who may approve changes, why these changes are being made, and the effect of these changes. It is critical that change controls require approvals from more than one authority, and that these changes are made part of any future auditing procedure. Once changes are proposed, approved, and adopted, they must be documented and incorporated as part of the plan.

With planning completed, implementation begins. Implementations do not usually fail because of poor planning; rather, they fail due to lack of accountability and ownership. Initial testing is conducted as part of the implementation phase. During the implementation step, any necessary modifications must be based on test results. Specific testing activities should include defining the test approach, structuring the test, conducting the test, analyzing the test results, and defining success metrics with modifications as required. In an organizational setting, the testing process should be executed in a quarantined environment, where the test is not connected to the work platforms and the data used for the test is not actual data. During testing, criteria should be documented so performance can be measured and a determination made as to where the test succeeded or failed.

With the implementation and testing completed, the project moves toward final adjustments that are often tuned to the changing business environment. Remember to maintain change controls in this phase also. More than one engineer has been surprised to find two identical hosts offering the same services with different configurations.

ENTERPRISE RISK

Risk is the possibility of harm or loss. Risk analysis often describes the two greatest sources of risk as human causes and natural causes. Before a risk can be managed, consideration must be given to the symptom as well as the result. Any risk statement must include what is causing the risk and the expected harmful results of that risk.

KEY ASSETS

Key assets are those enterprise assets required to ensure that profitable operations continue after a critical incident. Define, prioritize, and classify the organization's key assets into four general areas: personnel, data, equipment, and physical facilities. Schedule, in the form of a table, the priority of the organization's key assets and their associated threats and vulnerabilities. This table will serve the purpose of identifying security requirements associated with different priority levels of assets.

In developing asset values, the asset cost is multiplied by the asset exposure factor, with the resulting product being the single loss expectancy. The asset value is the replacement value of a particular asset, while the exposure factor is the measure of asset loss resulting from a specific harmful event. Multiplying this single loss expectancy by the annualized rate of occurrence will result in the annualized loss expectancy. An example of this equation is as follows: assume the replacement value of a server facility, complete with building, equipment, data, and software, is $10 million. This facility is located in a geographic area prone to hurricanes that have struck three times in the past ten years and resulted in total facility losses. Annualized expectancy is the loss of the facility, data, and equipment once every three years, or 33 percent annually.

Step two of our four-step process is a threat assessment. Threats are simply defined as things that can possibly bring harm upon assets. Threats should be ranked by type, the impact they have on the specific asset, and their probability of occurrence. Even the most effective risk management plan cannot eliminate every threat; but with careful deliberation, most threats can be avoided or their effects minimized.

Identify vulnerabilities (weaknesses) in the security of the enterprise's key assets. Vulnerable areas include physical access, network access, application access, data control, policy, accountability, regulatory and legal requirements, operations, audit controls, and training. Risk levels should be expressed as a comparison of assets to threats and vulnerabilities. Create a column in the table (Exhibit 48-1) providing a relative metric for threat frequency. Once completed, this table provides a measurement of the level of exposure for a particular key asset.

Exhibit 48-1. Measurement of the level of exposure.

Asset	Threat	Frequency	Vulnerability	Impact
Name and Replacement Value	Type	Annualized	Type and Ranking: High, Medium, Low	Ranking: High, Medium, Low

Avoidance and mitigation steps are processes by which analyses are put into action. Having identified the organization's key assets, threats to these assets, and potential vulnerabilities, there should be a final analytical step detailing how the specific risk can be avoided. If risk avoidance is not possible, then can the chance of its occurrence be extended?

From the outset it is recommended to include auditors. Audits must be scheduled and auditors' workpapers amended, assuring compliance with laws, regulations, policies, procedures, and operational standards.

RISK MANAGEMENT BEST PRACTICES DEVELOPMENT

As part of risk management best practices, there are three principle objectives: avoiding risk, reducing the probability of risk, and reducing the impact of the risk.

Initiate and foster an organizational culture that names every employee as a risk manager. Employee acceptance of responsibility and accountability pays short- and long-term dividends. In some circumstances, the creation of this risk manager culture is more important than developing and issuing extensive policies and procedures.

In a general sense, there are four key best practice areas that should be addressed: organizational needs, risk acceptance, risk management, and risk avoidance.

Organizational needs determine the requirement for more risk study and more information in ascertaining the characteristics of risk before taking preventive or remedial action.

Risk acceptance is defined in these terms: if these risks occur, can the organization profitably survive without further action?

Risk management is defined as efforts to mitigate the impact of the risk should it occur.

Risk avoidance includes the steps taken to avoid the risk from happening.

RISK CONTROLS

Avoidance controls are proactive in nature and attempt to remove, or at least minimize, the risk of accidental and intentional intrusions. Examples of these controls include encryption, authentication, network security architecture, policies, procedures, standards, and network services interruption prevention.

Assurance controls are actions, such as compliance auditing, employed to ensure the continuous effectiveness of existing controls. Examples of these controls include application security testing, standards testing, and network penetration testing.

Detection controls are tools, procedures, and techniques employed to ensure early detection, interception, containment, and response to unauthorized intrusions. Examples of these controls include intrusion detection systems (IDSs) and remotely managed security systems.

Recovery controls involve response-related steps in rapidly restoring secure services and investigating the circumstances surrounding information security breaches. Included are legal steps taken in the criminal, civil, and administrative arenas to recover damages and punish offenders. Examples of these recovery controls include business continuity planning, crisis management, recovery planning, formation of a critical incident response team, and forensic investigative plans.

CRITICAL INCIDENT RESPONSE TEAM (CIRT)

A CIRT is a group of professionals assembled to address network risks. A CIRT forms the critical core component of the enterprise's information risk management plan. Successful teams include management personnel having the authority to act; technical personnel having the knowledge to prevent and repair network damage; and communications experts having the skills to handle internal and external inquiries. They act as a resource and participate in all risk management phases. CIRT membership should be composed of particular job titles rather than specifically named individuals. The time for forming a CIRT, creating an incident response plan, notification criteria, collecting tools, training, and executive-level support is not the morning after a critical incident. Rather, the CIRT must be ready for deployment before an incident happens. Rapidly activating the CIRT can

mean the difference between an outage costing an organization its livelihood or being a mere annoyance.

Organizational procedures must be in place before an incident so the CIRT can be effective when deployed. This point is essential, because organizations fail to address critical incidents even when solid backup and recovery plans are in place. The problem is usually found to be that no one was responsible to activate the CIRT.

The CIRT plan must have clearly defined goals and objectives integrated in the organization's risk management plan. CIRT's mission objectives are planning and preparation, detection, containment, recovery, and critique. As part of its pre-incident planning, the CIRT will need: information flowcharts, hardware inventory, software inventory, personnel directories, emergency response checklists, hardware and software tools, configuration control documentation, systems documentation, outside resource contacts, organization chart, and CIRT activation and response plans. For example, when arriving on the scene, the CIRT should be able to review its documentation ascertaining information flow and relevant critical personnel of the organization's employee healthcare benefits processing unit.

Considering the nature, culture, and size of the organization, an informed decision must be made about when to activate the CIRT. What is the extent of the critical incident before the CIRT is activated? Who is authorized to make this declaration? Is it necessary for the whole CIRT to respond? Included in the CIRT activation plan should be the selection of team members needed for different types or levels of incidents.

If circumstances are sensitive or if they involve classified materials, then the CIRT activation plan must include out-of-band (OOB) communications. OOB communications take place outside the regular communications channels. Instead, these OOB communication methods include encrypted telephone calls, encrypted e-mail not transmitted through the organization's network, digital signatures, etc. The purpose of OOB communications is to ensure nothing is communicated through routine business channels that would alert someone having normal access to any unusual activity.

INCIDENT RESPONSE STEPS

The goals of incident response must serve a variety of interests, balancing the organization's business concerns with those of individual rights, corporate security, and law enforcement officials. An incident response plan will address the following baseline items:

- Determine if an incident has occurred and the extent of the incident.
- Select which CIRT members should respond.
- Assume control of the incident and involve appropriate personnel, as conditions require.
- Report to management for the decision on how to proceed.
- Begin interviews.
- Contain the incident before it spreads.
- Collect as much accurate and timely information as possible.
- Preserve evidence.
- Protect the rights of clients, employees, and others, as established by law, regulations, and policies.
- Establish controls for the proper collection and handling of evidence.
- Initiate a chain of custody of evidence.
- Minimize business interruptions within the organization.
- Document all actions and results.
- Restore the system.
- Conduct a post-incident critique.
- Revise response as required.

Pre-incident preparation is vital in approaching critical incidents. Contingency plans that are tested and revised will be invaluable in handling incidents where a few minutes can make the difference between disaster and a complete restoration of key services. Network administrators should be trained to detect critical incidents and contact appropriate managers so a decision can be made relative to CIRT deployment. Some of the critical details that administrators should note are the current date and time, nature of the incident, who first noticed the incident, the hardware and software involved, symptoms, and results.

Suspected incidents will usually be detected through several processes, including intrusion detection systems (IDSs), system monitors, and firewalls. Managers should decide whether the administrators should attempt to isolate the affected systems from the rest of the network. Trained, experienced administrators can usually perform these preliminary steps, thereby preventing damage from spreading (see Exhibit 48-2).

At the time of the initial response by the CIRT, no time should be lost looking for laptops, software, or tools. They should arrive at the scene with their plan, tools, and equipment in hand. CIRT members will begin interviews immediately in an effort to determine the nature and extent of any damage. It is important that they document these interviews for later action or as evidence. The CIRT will obtain and preserve the most volatile evidence immediately. After an initial investigation, the CIRT will formulate the best response and obtain management approval to proceed with further investigation and restoration steps.

Exhibit 48-2. Immediate actions to be taken by administrators to contain an incident.

1. Extinguish power to the affected systems. This is a drastic but effective decision in preventing any further loss or damage.
2. Disconnect the affected equipment from the network. There should be redundant systems so users will have access to their critical services.
3. Disable specific services being exploited.
4. Take all appropriate steps to preserve activity and event logs.
5. Document all symptoms and actions by administrators.
6. Notify system managers. If authorized, notify the CIRT for response.

CRITICAL INCIDENT INVESTIGATION

The goals of law enforcement officers and private investigators are basically the same. Both types of investigators want to collect evidence and preserve it for analysis and presentation at a later date. Evidence is simply defined as something physical and testimonial, material to an act. It is incumbent upon the CIRT to establish liaison with the appropriate levels of law enforcement to determine the best means of evidence collection, preservation, and delivery. If there are circumstances where law enforcement officers are not going to be involved, then the CIRT members should consider the wisdom of either developing forensic analysis skills or contracting others to perform these functions. Evidence collection and analysis are critical because incorrect crime scene processing and analysis can render evidence useless. Skilled technicians with specialized knowledge, tools, and equipment should accomplish collecting, processing, and analyzing evidence. Frequently, investigators want to be present during evidence collection and interviews; consequently, CIRT members should establish liaison with law enforcement and private investigators to establish protocols well in advance of a critical incident.

Evidence may be voluntarily surrendered, obtained through the execution of a search warrant, through a court order or summons, or through subpoenas. It is a common practice for investigators to provide a receipt for evidence that has been delivered to them. This receipt documents the transfer of items from one party to another and supports the chain of custody. It is important to note that only law enforcement investigators use search warrants and subpoenas to obtain evidence. Once received, the investigator will usually physically mark the evidence for later identification. Marking evidence typically consists of the receiving investigators placing the date and their initials on the item. In the case of electronic media, the item will be subjected to special software applications, causing a unique one-way identifier to be created and written to the media, thereby identifying any subsequent changes in the media's contents.

Does the investigator have the right to seize the computer and examine its contents? In corporate environments this right may be granted by policy. The enterprise should have a policy stating the ownership of equipment, data, and systems. It is a usual practice that organizations have policies requiring employees to waive any right to privacy as a condition of their employment. If the organization has such policies, it is important that its legal and human resources officers are consulted before any seizure takes place.

Under current United States law and the Fourth Amendment to the U.S. Constitution, the government must provide a judge or magistrate with an affidavit detailing the facts and circumstances surrounding the alleged crime. Search warrants are two-part documents. The first part is the search warrant, which bears a statutory description of the alleged crime, a description of the place to be searched, and the items or persons to be seized. At the conclusion of the search warrant execution, a copy of this search warrant document must be deposited at the premises, regardless of whether it was occupied. Affidavits are the second part of the search warrant and are statements where the officer or agent, known as the *affiant*, swears to the truth of the matter. The law does not require the affiant to have first-hand knowledge of the statement's details, merely that the affiant has reliable knowledge. Search warrants are granted based upon the establishment of probable cause. It is important to note that the affidavit must stand on its own; all relevant information must be contained within its borders.

Questions surrounding search warrants are these: is it probable that a crime has been committed, and is it probable that fruits, instrumentalities, or persons connected to that crime are located at a given location now? Unless there are unusual circumstances, search warrants may only be executed in daylight hours from 6 a.m. to 10 p.m. If unusual circumstances exist, then these must be submitted to the court. Such circumstances include the possibility of extreme danger to the officers or the likelihood of evidence destruction. Search warrants must be announced, and authorities must declare their purpose. At the completion of the search warrant, the officers are required to deposit a copy of the search warrant and an inventory of the items seized at the searched premises. Under special circumstances, the search warrant will be *sealed* by the issuing court. This means the sworn statement is not public record until unsealed by the issuing court. If the affidavit is not sealed, then it is a public document and retrievable from the court's office. At the conclusion of the search warrant, a return is completed and accompanied by an inventory of the seized items. This search warrant return is part of the original search warrant document and reflects the date, by whom, and where it was executed. Along with the search warrant return, an inventory of seized items is filed with the court, where it is available for public review. Law enforcement and non-law enforcement personnel, depending upon the nature of the investigation, may obtain court orders and summons. These documents are

based upon applications made to the court of jurisdiction and may result in orders demanding evidence production by the judge or magistrate. Similar to search warrants, court orders are usually two-part documents with an application stating the reason the judge should issue an order to a party to produce items or testimony. The second part is the actual court order document. Court orders state the name of the case, the items to be brought before the court, the date the items are to be brought before the court, the location of the court, the name of the presiding judge, and the seal of the court. Summonses are similar to court orders and vary from jurisdiction to jurisdiction. Subpoenas are generally categorized as one of two types: one resulting from a grand jury investigation, and the second resulting from a trial or other judicial proceeding. Both documents carry the weight of the court — meaning these documents are demands that, if ignored, can result in contempt charges filed against persons or other entities. Grand juries are tasked with hearing testimony and reviewing evidence, hence their subpoenas are based upon investigative need. Their members are selected from the local community, and they are impaneled for periods of several months. Items or persons may be subpoenaed before a grand jury for examination. It is possible for a motion to quash the subpoena to be filed, causing the court to schedule a hearing where the subpoena's merits are heard. Different than grand jury subpoenas, judicial subpoenas are issued for witnesses and evidence to be presented at trial or other hearings. Testimony is obtained through interviews, depositions, and judicial examinations. Interviewing someone is a conversation directed toward specific events. Interviews may be recorded in audio or video form, or the investigator may take carefully written notes. In the latter case, the interviewer's notes are reduced to a report of the interview. This report serves as the best recollection of the investigator and is not generally considered a verbatim transcript of the interview.

Depositions are more formal examinations and are attended by attorneys, witnesses, and persons who create a formal record of the proceedings. Usually, depositions are part of civil and administrative proceedings; however, in unusual circumstances they may be part of a criminal proceeding. Attorneys ask questions of the witnesses, with the plaintiff and defense attempting to ask questions that will cause the witness to provide an explanation favorable to their side. Judicial examinations are made before a judge or magistrate judge, and the witnesses are sworn to tell the whole truth while the proceedings are recorded.

It is important to note that providing mischaracterizations, lies, or withholding information during interviews may be considered grounds for criminal prosecution. In a similar vein, the CIRT and others must be very careful interviewing potential subjects and collecting evidence. If interviews are conducted or evidence is collected through coercion, these actions could be considered as intimidating and may be considered for charges.

FORENSIC EXAMINATION

There are several schools of thought in completing the forensic examination of evidence. Regardless, one rule remains steadfast — no examination should be conducted on original media; and the media, constituting evidence, must remain unchanged. There are several ways to obtain copies of media. There are forensic examination suites designed to perform exact bit-by-bit duplication; and there are specific software utilities used in duplicating media and hardware-copying devices that are convenient, but these are generally limited to the size and characteristics of the disks they can clone. There are also utilities that are part of some operating platforms that can produce bit-by-bit media duplications. It is important to remember that all forensic examination processes must be documented in the form of an activity log and, in the case of some very sensitive matters, witnessed by more than one examiner.

Forensic examiners must ensure that their media is not contaminated with unwanted data; so many have a policy that, before any evidence is copied, media will be cleansed with software utilities or a degaussing device designed for such purposes. In this fashion, the examiner can testify that appropriate precautions were taken to prevent cross-contamination from other sources.

As in the case of all evidence-handling practices, a chain of custody is prepared. Chain of custody is merely a schedule of the evidence, names, titles, reason for possession, places, times, and dates. From the time of the evidence seizure, the chain of custody is recorded and a copy attached to the evidence. The chain of custody documentation is maintained regardless of how the evidence was seized or whether the evidence is going to be introduced in criminal, civil, or administrative proceedings.

A covert search is one targeting a specific console or system involving real-time monitoring, and it is usually conducted discreetly. In a practical example, an organization may suspect one of its employees of downloading inappropriate materials in violation of its use policy. After examining logs, an exact workstation cannot be identified. There are two ways to conduct a covert search after authorization is obtained. One method copies the suspected hard drive and replaces it with the copy, with the original considered as evidence. The second method duplicates the suspect's hard drive while it remains in the computer. The duplicate is considered evidence and is duplicated again for examination. In either method it is important to ascertain that the organization has the right to access the equipment and that the suspect does not have any reasonable expectation of privacy. This topic must be fully addressed by the legal and human resources departments.

After having seized the evidence, the examiner decides to either conduct an analysis on the premises or take the media to another location. The advantage of having the examination take place where the evidence is seized is obvious. If there is something discovered requiring action, it can be addressed immediately. However, if the examination takes place in the calm of a laboratory, with all the tools available, then the quality of the examination is at its highest.

The CIRT and other investigators must consider the situation of sensitive or classified information that is resident on media destined for a courtroom. Sometimes, this consideration dissuades some entities from reporting criminal acts to the authorities. However, there are steps that can be legally pursued to mitigate the exposure of proprietary or sensitive information to the public.

CRIMINAL, FORFEITURE, AND CIVIL PROCESSES

Criminal acts are considered contrary to publicly acceptable behavior and are punished by confinement, financial fines, supervised probation, and restitution. Felonies are considered major crimes and are usually punished by periods of confinement for more than one year and fines of more than $1000. In some jurisdictions, those convicted of felonies suffer permanent loss of personal rights. Misdemeanors are minor crimes punishable by fines of less than $1000 and confinement of less than one year.

Sentencing may include confinement, fines, or a period of probation. The length of sentence, fines, and victim restitution depends upon the value of the crime. If proprietary information is stolen and valued at millions of dollars, then the sentence will be longer with greater fines than for an act of Web page defacement. There are other factors that can lengthen sentencing. Was the defendant directing the criminal actions of others? Was the defendant committing a crime when he committed this crime? Has the defendant been previously convicted of other crimes? Was the defendant influencing or intimidating potential witnesses? There are also factors that can reduce a sentence. Has the defendant expressed remorse? Has the defendant made financial restitution to the victim? Has the defendant cooperated against other possible defendants? Under the laws of the United States, the length of sentence, the type of sentence, and fines are determined in a series of weighted numerical calculations and are codified in the Federal Sentencing Guidelines. At the time of sentencing, a report is usually prepared and delivered to the sentencing judge detailing the nature of the crime and the extent of the damage. It is at the judge's discretion whether to order financial restitution to the victim; however, in recent times, more and more judges are inclined to order financial restitution as part of sentencing (see Exhibit 48-3).

Exhibit 48-3. Partial list of applicable federal criminal statutes.

- 18 United States Code Section 1030 Fraud Activities with Computers
- 18 United States Code Section 2511 Unlawful Interception of Communications
- 18 United States Code Section 2701 Unlawful Access to Stored Electronic Communications
- 18 United States Code Section 2319 Criminal Copyright Infringement
- 18 United States Code Section 2320 Trafficking in Counterfeit Goods or Services
- 18 United States Code Section 1831 Economic Espionage
- 18 United States Code Section 1832 Theft of Trade Secrets
- 18 United States Code Section 1834 Criminal Asset Forfeiture
- 18 United States Code Section 1341 Mail Fraud
- 18 United States Code Section 1343 Wire Fraud
- 18 United States Code Sections 2251–2253 Sexual Exploitation of Children Act
- 18 United States Code Section 371 Criminal Conspiracy

Frequently, organizations ask if there are statutory requirements for reports of criminal activities. Under the criminal codes of the United States, Title 18, Section 4, it states: "Whoever having knowledge of the actual commission of a felony cognizable by a court of the United States, conceals and does not as soon as possible make known the same to some judge or other person in civil or military authority under the United States, shall be fined under this title or imprisoned not more than three years or both." Many jurisdictions have similar statutes requiring the reporting of criminal activities.

Civil matters are disputes between parties that are resolved by the exchange of money or property. Civil suits may have actual, punitive, and statutory damages. In the case of actual damages, the plaintiff must prove to a preponderance of evidence (51 percent) that they suffered specific losses. Punitive damages are amounts that punish the defendant for harming the plaintiff. Statutory damages are those prescribed by law.

Many jurisdictions have laws allowing the simultaneous criminal prosecution of a defendant, a civil suit naming the same defendant, and allowing forfeiture proceedings to take place. This type of multifaceted prosecution is known as parallel-track prosecution.

Pursuant to criminal activities, many jurisdictions and the U.S. federal government, file concurrent forfeiture actions against offending entities. These proceedings also impact the relationship between CIRT members and the court system. Depending upon the specific jurisdiction, these actions may take the form of the criminal's assets being indicted, or civil suits filed against those assets, or those assets being administratively forfeited. An example of this type of parallel-track prosecution is illustrated with the person who unlawfully enters an organization's network and steals sensitive protected information that is subsequently sold to a competitor.

Investigators conduct a thorough investigation, and the perpetrator is indicted. In this same case, a seizure warrant is obtained; and the defendant's computer equipment, software, and the crime's proceeds are seized. Depending upon the laws, the perpetrator may suffer confinement, loss of money resulting from the information sale, the forfeiture of his equipment or other items of value, restitution to the victim, and fines. It is also a reasonable and acceptable process that the subject is civilly sued for damages while he is criminally prosecuted and his assets forfeited.

USE OF MONITORING DEVICES

The enterprise must have policies governing the use of its system resources and the conduct of its employees. Pursuant to those policies, the CIRT may monitor network use by suspected employee offenders. The use of monitoring techniques is governed by the employees' reasonable expectation of privacy and is defined by both policy and law. Techniques used to monitor employee activities should be made part of audit and executive-level review processes to make certain these monitoring practices are not abused. Before implementing computer monitoring, it is wise to consult the organization's human resources and legal departments because, if these policies are not implemented correctly, computer monitoring can run afoul of legal, policy, and ethical standards. Under federal statutes, network administrators are granted the ability to manage their systems. They may access and control all areas of their network and interact with other administrators in the performance of their duties. Because unauthorized system intruders do not have an expectation of privacy, their activities are not subject to such considerations. If administrators discover irregularities, fraud, or unauthorized software such as hacking tools on their systems, they are allowed to take corrective actions and report the offenders.

However, this is not the case for government agencies wanting access to network systems and electronic communications. Depending upon the state of the electronic communications, they may be required to obtain a court order, search warrant, or subpoena.

It is important to note that most jurisdictions do not allow retributive actions. For example, if a denial-of-service attack causes the organization to suffer losses, it may be considered unlawful for the organization to return a virus to the offender.

NATURE OF CRIMINAL INCIDENTS

Viruses and worms have been in existence for many years. Since the introduction of the Morris Worm in 1988, managers and administrators have paid attention to their potential for harm. In years past, viruses and worms were ignored by law enforcement, and treated as merely a nuisance. However, in more recent times, following the outbreaks of Melissa and the

Love Bug, persons responsible for their creation and proliferation are being investigated and prosecuted.

Insider attacks usually consist of employees or former employees gaining access to sensitive information. Because they are already located inside the network, it is possible they have already bypassed many access barriers; and, by elevating their privileges, they may gain access to the organization's most valuable information assets. Among the insiders are those who utilize the organization's information assets for their own purposes. Downloading files in violation of use policies wastes valuable resources and, depending upon their content, may be a violation of law.

Outsider attacks are more than an annoyance. A determined outsider may hammer at the target's systems until an entry is discovered. Attackers may be malicious or curious. Regardless, their efforts have the same results in that unauthorized entry is made. Often, their attacks cause serious damage to information systems and compromise sensitive data. Attackers do not need thorough systems knowledge because there are many Web sites that provide the necessary tools for intrusions and DoS attacks.

Unauthorized interception of communications may take place when an unauthorized intrusion takes place and software is installed allowing the intruder to monitor keystrokes and communications traffic. Because this activity is performed without the permission of the system owners, it may have the same net effect as an illegal wiretap.

DoS attacks gained significant negative publicity recently as unscrupulous persons targeted high-profile Web sites, forcing them offline. In some cases, perpetrators were unwitting participants, wherein their broadband assets were compromised by persons installing software executing distributed DoS attacks. These attacks flood their target systems with useless data launched from single or multiple sources, causing the target's network to crash.

CONCLUSION

Risk management consists of careful planning, implementation, testing, and revision. The most critical part of risk management is critical incident response. The principal purpose of risk management is avoidance and mitigation of harm. Incident response, with the development of a solid response strategy, outside liaison, and a well-trained CIRT, can make the difference between a manageable incident and a disaster costing the organization its future.

ABOUT THE AUTHOR

Alan B. Sterneckert, CISA, CISSP, CFE, CCCI, is the owner and general manager of Risk Management Associates located in Salt Lake City, Utah. A retired Special Agent, Federal Bureau of Investigation, Mr. Sterneckert is a

professional specializing in risk management, IT system security, and systems auditing. In 2003, Mr. Sterneckert will complete a book about critical incident management, to be published by Auerbach.

Ethics and the Internet

Micki Krause, CISSP

The research for this chapter was done entirely on the Internet. The Net is a powerful tool. This author dearly hopes that the value of its offerings is not obviated by those who would treat the medium in an inappropriate and unethical manner.

Ethics: Social values; a code of right and wrong

Introduction

The ethical nature of the Internet has been likened to "a restroom in a downtown bus station," where the lowest of the low congregate and nothing good ever happens. This manifestation of antisocial behavior can be attributed to one or more of the following:

- The relative anonymity of those who use the Net
- The lack of regulation in cyberspace
- The fact that one can masquerade as another on the Internet
- The fact that one can fulfill a fantasy or assume a different persona on the net, thereby eliminating the social obligation to be accountable for one's own actions

Whatever the reason, the Internet, also known as the "Wild West" or the "untamed frontier," is absent of law and therefore is a natural playground for illicit, illegal, and unethical behavior.

In the ensuing pages, we will explore the types of behavior demonstrated in cyberspace, discuss how regulation is being introduced and by whom, and illustrate the practices that businesses have adopted in order to minimize their liability and encourage their employees to use the Net in an appropriate manner.

The Growth of the Internet

When the Internet was born approximately 30 years ago it was a medium used by the government and assorted academicians, primarily to perform and share research. The user community was small and mostly self-regulated. Thus, although a useful tool, the Internet was not considered "mission-critical," as it is today. Moreover, the requirements for availability and reliability were not as much a consideration then as they are now, because Internet usage has grown exponentially since the late 1980s.

The increasing opportunities for productivity, efficiency and world-wide communications brought additional users in droves. Thus, it was headline news when a computer worm, introduced into the Internet by Robert Morris, Jr., in 1988, infected thousands of Net-connected computers and brought the Internet to its knees.

In the early 1990s, with the advent of commercial applications and the World Wide Web (WWW), a graphical user interface for Internet information, the number of Internet users soared. Sources such as the *Industry Standard*, "The Newsmagazine of the Internet Economy," published the latest Nielsen Media Research Com-

merce Net study in late 1998, which reported the United States Internet population at 70.5 million (out of a total population of 196.5 million).

Today, the Internet is a utility, analogous to the electric company, and "dotcom" is a household expression. The spectrum of Internet users extends from the kindergarten classroom to senior citizenry, although the Gen-X generation, users in their 20s, are the fastest adopters of Net technology (see Exhibit 157.1).

Because of its popularity, the reliability and availability of the Internet are critical operational considerations, and activities that threaten these attributes, e.g., spamming, spoofing, hacking and the like, have grave impacts on its user community.

Unethical Activity Defined

Spamming, in electronic terminology, means electronic garbage. Sending unsolicited junk electronic mail, for example, such as an advertisement, to one user or many users via a distribution list, is considered spamming.

One of the most publicized spamming incidents occurred in 1994, when two attorneys (Laurence Carter and Martha Siegel) from Arizona, flooded the cyber waves, especially the Usenet newsgroups,* with solicitations to the immigrant communities of the United States to assist them in the green card lottery process to gain citizenship. Carter and Siegel saw the spamming as "an ideal, low-cost and perfectly legitimate way to target people likely to be potential clients" (*Washington Post*, 1994). Many Usenet newsgroup users, however, saw things differently. The lawyers' actions resulted in quite an uproar among the Internet communities primarily because the Internet has had a long tradition of noncommercialism since its founding. The attorneys had already been ousted from the American Immigration Lawyers' Association for past sins, and eventually they lost their licenses to practice law.

There have been several other spams since the green card lottery, some claiming "MAKE MONEY FAST," others claiming "THE END OF THE WORLD IS NEAR." There have also been hundreds, if not thousands, of electronic chain letters making the Internet rounds. The power of the Internet is the ease with which users can forward data, including chain letters. More information about spamming occurrences can be found on the Net in the Usenet newsgroup (alt.folklore.urban).

Unsolicited Internet e-mail has become so widespread that lawmakers have begun to propose sending it a misdemeanor. Texas is one of 18 states considering legislation that would make spamming illegal. In February 1999, Virginia became the fourth state to pass an antispamming law. The Virginia law makes it a misdemeanor for a spammer to use a false online identity to send mass mailings, as many do. The maximum penalty would be a $500 fine. However, if the spam is deemed malicious and results in damages to the victim in excess of $2500 (e.g., if the spam causes unavailability of computer service), the crime would be a felony, punishable by up to five years in prison. As with the Virginia law, California law allows for the jailing of spammers. Laws in Washington and Nevada impose civil fines.

*Usenet newsgroups are limited communities of Net users who congregate online to discuss specific topics.

This legislation has not been popular with everyone, however, and has led organizations such as the American Civil Liberties Union (ACLU), to complain about its unconstitutionality and threat to free speech and the First Amendment.

Like spamming, threatening electronic mail messages have become pervasive in the Internet space. Many of these messages are not taken as seriously as the one that was sent by a high school student from New Jersey, who made a death threat against President Clinton in an electronic mail message in early 1999. Using a school computer that provided an option to communicate with a contingent of the U.S. government, the student rapidly became the subject of a Secret Service investigation.

Similarly, in late 1998, a former investment banker was convicted on eight counts of aggravated harassment when he masqueraded as another employee and sent allegedly false and misleading Internet e-mail messages to top executives of his former firm.

Increasingly, businesses are establishing policy to inhibit employees from using company resources to perform unethical behavior on the Internet. In an early 1999 case, a California firm agreed to pay a former employee over $100,000 after she received harassing messages on the firm's electronic bulletin board, even though the company reported the incident to authorities and launched an internal investigation. The case is a not-so-subtle reminder that businesses are accountable for the actions of their employees, even actions performed on electronic networks.

Businesses have taken a stern position on employees surfing the Web, sending inappropriate messages, and downloading pornographic materials from the Internet. This is due to a negative impact on productivity, as well as the legal view that companies are liable for the actions of their employees. Many companies have established policies for appropriate use and monitoring of computers and computing resources, as well as etiquette on the Internet, or "Netiquette."

These policies are enhancements to the Internet Advisory Board's (Request for Comment) RFC 1087, "Internet Ethics," January 1989, which proposed that access to and use of the Internet is a privilege and should be treated as such by all users of the system. The IAB strongly endorsed the view of the Division Advisory Panel of the National Science Foundation Division of Network Communications Research and Infrastructure. That view is paraphrased below.

Any activity is characterized as unethical and unacceptable that purposely:

- Seeks to gain unauthorized access to the resources of the Internet
- Disrupts the intended use of the Internet
- Wastes resources (people, capacity, computers) through such actions
- Destroys the integrity of computer-based information
- Compromises the privacy of users
- Involves negligence in the conduct of Internet-wide experiments*

A sample "Appropriate Use of the Internet" policy is attached as Appendix A. Appendix B contains the partial contents of RFC 1855, "Netiquette Guidelines," a product of the Responsible Use of the Network (RUN) Working Group of the Internet Engineering Task Force (IETF).

In another twist on Internet electronic mail activity, in April 1999 Intel Corporation sued a former employee for doing a mass e-mailing to its 30,000 employees, criticizing the company over workers' compensation benefits. Intel claims the e-mail was an assault and form of trespass, as well as an improper use of its internal computer resources. The former employee contends that his e-mail messages are protected by the First Amendment. "Neither Intel nor I can claim any part of the Internet as our own private system as long as we are hooked up to this international network of computers," said Ken Hamidi in an e-mail to *Los Angeles Times* reporters. The case was not settled as of this writing ("Ruling is Due on Mass E-mail Campaign Against Intel," Greg Miller, *Los Angeles Times*, April 19, 1999).

Using electronic media to stalk another person is known as "cyber stalking." This activity is becoming more prevalent, and the law has seen fit to intercede by adding computers and electronic devices to existing stalking legislation. In the first case of cyber stalking in California, a Los Angeles resident, accused of using his computer to harass a woman who rejected his romantic advances, is the first to be charged under a new cyber stalking law that went into effect in 1998. The man was accused of forging postings on the Internet, on America Online (AOL), and other Internet services, so that the messages appeared to come from the victim. The message provided the woman's address and other identifying information, which resulted in at least six men visiting

EXHIBIT 157.2

Information Collected when You Send Us an E-Mail Message

When inquiries are e-mailed to us, we again store the text of your message and e-mail address information, so that we can answer the question that was sent in, and send the answer back to the e-mail address provided. If enough questions or comments come in that are the same, the question may be added to our Question and Answer section, or the suggestions are used to guide the design of our Web site.

We do not retain the messages with identifiable information or the e-mail addresses for more than 10 days after responding unless your communication requires further inquiry. If you send us an e-mail message in which you ask us to do something that requires further inquiry on our part, there are a few things you should know.

The material you submit may be seen by various people in our Department, who may use it to look into the matter you have inquired about. If we do retain it, it is protected by the Privacy Act of 1974, which restricts our use of it, but permits certain disclosures.

Also, e-mail is not necessarily secure against interception. If your communication is very sensitive, or includes personal information, you might want to send it by postal mail instead.

her home uninvited. The man was charged with one count of stalking, three counts of solicitation to commit sexual assault, and one count of unauthorized access to computers.

In another instance where electronic activity has been added to existing law, the legislation for gambling has been updated to include Internet gambling. According to recent estimates, Internet-based gambling and gaming has grown from about a $500 million-a-year industry in the late 1990s, to what some estimate could become a $10 billion-a-year enterprise by 2000. Currently, all 50 states regulate in-person gambling in some manner. Many conjecture that the impetus for the regulation of electronic gambling is financial, not ethical or legal.

Privacy on the Internet

For many years, American citizens have expressed fears of invasion of privacy, ever since they realized that their personal information is being stored on computer databases by government agencies and commercial entities. However, it is just of late that Americans are realizing that logging on to the Internet and using the World Wide Web threatens their privacy as well. Last year, the Center for Democracy and Technology (CDT), a Washington, D.C. advocacy group, reported that only one third of federal agencies tell visitors to their Web sites what information is being collected about them.

AT&T Labs conducted a study early last year, in which they discovered that Americans are willing to surrender their e-mail address online, but not much more than that. The study said that users are reluctant to provide other personal information, such as a phone number or credit card number.

The utilization of technology offers the opportunity for companies to collect specific items of information. For example, Microsoft Corporation inserts tracking numbers into its Word program documents. Microsoft's Internet Explorer informs Web sites when a user bookmarks them by choosing the "Favorites" option in the browser. In 1998, the Social Security Administration came very close to putting a site on line that would let anyone find out another person's earnings and other personal information. This flies in the face of the 1974 Privacy Act, which states that every agency must record "only such information about an individual as is relevant and necessary to accomplish a purpose of the agency required to be accomplished by statute or by executive order of the President."

There is a battle raging between privacy advocates and private industry aligned with the U.S. government. Privacy advocates relate the serious concern for the hands-off approach and lack of privacy legislation, claiming that citizens are being violated. Conversely, the federal government and private businesses, such as American Online, defend current attempts to rely on self-regulation and other less government-intrusive means of regulating privacy, for example, the adoption of privacy policies. These policies, which state intent for the protection of consumer privacy, are deployed to raise consumer confidence and increase digital trust. The CDT has urged the federal government to post privacy policies on each site's home page, such as is shown in Exhibit 157.2 from the Health and Human Services Web site from the National Institute of Health (www.nih.gov).

HHS Web Privacy Notice

(as of April 13, 1999)

Thank you for visiting the Department of Health and Human Services Web site and reviewing our Privacy Policy. Our Privacy Policy for visits to www.hhs.gov is clear:
We will collect no personal information about you when you visit our Web site unless you choose to provide that information to us.
Here is how we handle information about your visit to our Web site:

Information Collected and Stored Automatically

If you do nothing during your visit but browse through the website, read pages, or download information, we will gather and store certain information about your visit automatically. This information does not identify you personally. We automatically collect and store only the following information about your visit:

- The Internet domain (for example, "xcompany.com" if you use a private Internet access account, or "yourschool.edu" if you connect from a university's domain), and IP address (an IP address is a number that is automatically assigned to your computer whenever you are surfing the Web) from which you access our Web site
- The type of browser and operating system used to access our site
- The date and time you access our site
- The pages you visit
- If you linked to our Web site from another Web site, the address of that Web site

We use this information to help us make our site more useful to visitors — to learn about the number of visitors to our site and the types of technology our visitors use. We do not track or record information about individuals and their visits.

Links to Other Sites

Our Web site has links to other federal agencies and to private organizations. Once you link to another site, it is that site's privacy policy that controls what it collects about you.

Anonymity on the Internet

Besides a lack of privacy, the Internet promulgates a lack of identity. Users of the Internet are virtual, meaning that they are not speaking with, interacting with, or responding to others, at least not face to face. They sit behind their computer terminals in the comfort of their own home, office, or school. This anonymity makes it easy to masquerade as another, since there is no way of proving or disproving who you are or who you say you are.

Moreover, this anonymity lends itself to the venue of Internet chat rooms. Chat rooms are places on the Net where people congregate and discuss topics common to the group, such as sports, recreation, or sexuality. Many chat rooms provide support to persons looking for answers to questions on health, bereavement, or disease and, in this manner, can be very beneficial to society.

Conversely, chat rooms can be likened to sleazy bars, where malcontents go seeking prey. There have been too many occurrences of too-good-to-be-true investments that have turned out to be fraudulent. Too many representatives of the dregs of society lurk on the net, targeting the elderly or the innocent, or those who, for some unknown reason, make easy marks.

A recent *New Yorker* magazine ran a cartoon showing a dog sitting at a computer desk, the caption reading "On the Internet, no one knows if you're a dog." Although the cartoon is humorous, the instances where child molesters have accosted their victims by way of the Internet are very serious. Too many times, miscreants have struck up electronic conversations with innocent victims, masquerading as innocents themselves, only to lead them to meet in person with dire results. Unfortunately, electronic behavior mimics conduct that has always

occurred over phone lines, through the postal service, and in person. The Internet only provides an additional locale for intentionally malicious and antisocial behavior. We can only hope that advanced technology, as with telephonic caller ID, will assist law enforcement in tracking anonymous Internet "bad guys."

Attempts at self-regulation have not been as successful as advertised, and many question whether the industry can police itself. Meanwhile, there are those within the legal and judicial systems that feel more laws are the only true answer to limiting unethical and illegal activities on the Internet. How it will all play out is far from known at this point in time. The right to freedom of speech and expression has often been at odds with censorship. It is ironic, for example, that debates abound on the massive amounts of pornography available on the Internet, and yet, in early 1999, the entire transcript of the President Clinton impeachment hearings was published on the Net, complete with sordid details of the Monica Lewinsky affair.

Internet and the Law

The Communications Decency Act of 1996 was signed into law by President Clinton in early 1996 and has been challenged by civil libertarian organizations ever since. In 1997, the United States Supreme Court declared the law's ban on indecent Internet speech unconstitutional.

The Childrens' Internet Protect Act (S.97, January 1999), introduced before a recent Congress, requires "the installation and use by schools and libraries of a technology for filtering or blocking material on the Internet on computers with Internet access to be eligible to receive or retain universal service assistance."

Monitoring the Web

Additionally, many commercial businesses have seen the opportunity to manufacture software products that will provide parents the ability to control their home computers. Products such as Crayon Crawler, Family-Connect, and KidsGate are available to provide parents with control over what Internet sites their children can access, although products like WebSense, SurfControl and Webroot are being implemented by companies that choose to limit the sites their employees can access.

Summary

Technology is a double-edged sword, consistently presenting us with benefits and disadvantages. The Internet is no different. The Net is a powerful tool, providing the ability for global communications in a heartbeat; sharing information without boundaries; a platform for illicit and unethical shenanigans.

This chapter has explored the types of behavior demonstrated in cyberspace, antisocial behavior, which has led to many discussions about whether or not this activity can be inhibited by self-regulation or the introduction of tougher laws. Although we do not know how the controversy will end, we know it will be an interesting future in cyberspace.

Appendix A "Appropriate Use and Monitoring of Computing Resources"

Policy

The Company telecommunications systems, computer networks, and electronic mail systems are to be used only for business purposes and only by authorized personnel. All data generated with or on the Company's business resources are the property of the Company; and may be used by the Company without limitation; and may not be copyrighted, patented, leased, or sold by individuals or otherwise used for personal gain.
Electronic mail and voice mail, including pagers and cellular telephones, are not to be used to create any offensive or disruptive messages. The Company does not tolerate discrimination, harassment, or other offensive messages and images relating to, among other things, gender, race, color, religion, national origin, age, sexual orientation, or disability.

The Company reserves the right and will exercise the right to review, monitor, intercept, access, and disclose any business or personal messages sent or received on Company systems. This may happen at any time, with or without notice.
It is the Company's goal to respect individual privacy, while at the same time maintaining a safe and secure workplace. However, employees should have no expectation of privacy with respect to any Company computer or communication resources. Materials that appear on computer, electronic mail, voice mail, facsimile and the like, belong to the Company. Periodically, your use of the Company's systems may be monitored.
The use of passwords is intended to safeguard Company information, and does not guarantee personal confidentiality.
Violations of company policies detected through such monitoring can lead to corrective action, up to and including discharge.

Appendix B
Netiquette

RFC 1855
Netiquette Guidelines

Status of this Memo

This memo provides information for the Internet community. This memo does not specify an Internet standard of any kind. Distribution of this memo is unlimited.

Abstract

This document provides a minimum set of guidelines for Network Etiquette (Netiquette) which organizations may take and adapt for their own use. As such, it is deliberately written in a bulleted format to make adaptation easier and to make any particular item easy (or easier) to find. It also functions as a minimum set of guidelines for individuals, both users and administrators. This memo is the product of the Responsible Use of the Network (RUN) Working Group of the IETF.

1.0 Introduction

In the past, the population of people using the Internet had "grown up" with the Internet, were technically minded, and understood the nature of the transport and the protocols. Today, the community of Internet users includes people who are new to the environment. These "newbies" are unfamiliar with the culture and do not need to know about transport and protocols. To bring these new users into the Internet culture quickly, this Guide offers a minimum set of behaviors which organizations and individuals may take and adapt for their own use. Individuals should be aware that no matter who supplies their Internet access, be it an Internet Service Provider through a private account, or a student account at a University, or an account through a corporation, that those organizations have regulations about ownership of mail and files, about what is proper to post or send, and how to present yourself. Be sure to check with the local authority for specific guidelines.
We have organized this material into three sections: One-to-one communication, which includes mail and talk; One-to-many communications, which includes mailing lists and NetNews; and Information Services, which includes ftp, WWW, Wais, Gopher, MUDs and MOOs. Finally, we have a Selected Bibliography, which may be used for reference.

2.0 One-to-One Communication (Electronic Mail, Talk)

We define one-to-one communications as those in which a person is communicating with another person as if face-to-face: a dialog. In general, rules of common courtesy for interaction with people should be in force for any situation and on the Internet it is doubly important where, for example, body language and tone of voice must be inferred. For more information on Netiquette for communicating via electronic mail and talk, check references [1,23,25,27] in the Selected Bibliography.

2.1 User Guidelines

2.1.1 For Mail:

- Unless you have your own Internet access through an Internet provider, be sure to check with your employer about ownership of electronic mail. Laws about the ownership of electronic mail vary from place to place.
- Unless you are using an encryption device (hardware or software), you should assume that mail on the Internet is not secure. Never put in a mail message anything you would not put on a postcard.
- Respect the copyright on material that you reproduce. Almost every country has copyright laws.
- If you are forwarding or reposting a message you have received, do not change the wording. If the message was a personal message to you and you are reposting to a group, you should ask permission first. You may shorten the message and quote only relevant parts, but be sure you give proper attribution.
- Never send chain letters via electronic mail. Chain letters are forbidden on the Internet. Your network privileges will be revoked. Notify your local system administrator if your ever receive one.
- A good rule of thumb: Be conservative in what you send and liberal in what you receive. You should not send heated messages (we call these "flames") even if you are provoked. On the other hand, you should not be surprised if you get flamed and it is prudent not to respond to flames.
- In general, it is a good idea to at least check all your mail subjects before responding to a message. Sometimes a person who asks you for help (or clarification) will send another message which effectively says "Never Mind." Also make sure that any message you respond to was directed to you. You might be cc:ed rather than the primary recipient.
- Make things easy for the recipient. Many mailers strip header information which includes your return address. To ensure that people know who you are, be sure to include a line or two at the end of your message with contact information. You can create this file ahead of time and add it to the end of your messages. (Some mailers do this automatically.) In Internet parlance, this is known as a ".sig" or "signature" file. Your .sig file takes the place of your business card. (And you can have more than one to apply in different circumstances.)
- Be careful when addressing mail. There are addresses which may go to a group but the address looks like it is just one person. Know to whom you are sending.
- Watch "CCs" when replying. Do not continue to include people if the messages have become a two-way conversation.
- In general, most people who use the Internet do not have time to answer general questions about the Internet and its workings. Do not send unsolicited mail asking for information to people whose names you might have seen in RFCs or on mailing lists.
- Remember that people with whom you communicate are located across the globe. If you send a message to which you want an immediate response, the person receiving it might be at home asleep when it arrives. Give them a chance to wake up, come to work, and log in before assuming the mail didn't arrive or that they do not care.
- Verify all addresses before initiating long or personal discourse. It is also a good practice to include the word "long" in the subject header so the recipient knows the message will take time to read and respond to. Over 100 lines is considered "long".
- Know whom to contact for help. Usually you will have resources close at hand. Check locally for people who can help you with software and system problems. Also, know whom to go to if you receive anything questionable or illegal. Most sites also have "Postmaster" aliased to a knowledgeable user, so you can send mail to this address to get help with mail.
- Remember that the recipient is a human being whose culture, language, and humor have different points of reference from your own. Remember that date formats, measurements, and idioms may not travel well. Be especially careful with sarcasm.
- Use mixed case. UPPER CASE LOOKS AS IF YOU ARE SHOUTING.
- Use symbols for emphasis. That *is* what I meant. Use underscores for underlining. _War and Peace_ is my favorite book.

- Use smileys to indicate tone of voice, but use them sparingly. :-) is an example of a smiley (Look sideways). Do not assume that the inclusion of a smiley will make the recipient happy with what you say or wipe out an otherwise insulting comment.
- Wait overnight to send emotional responses to messages. If you have really strong feelings about a subject, indicate it via FLAME ON/OFF enclosures. For example:
  FLAME ON
  This type of argument is not worth the bandwidth it takes to send it. It is illogical and poorly reasoned. The rest of the world agrees with me.
- FLAME OFF
- Do not include control characters or non-ASCII attachments in messages unless they are MIME attachments or unless your mailer encodes these. If you send encoded messages make sure the recipient can decode them.
- Be brief without being overly terse. When replying to a message, include enough original material to be understood but no more. It is extremely bad form to simply reply to a message by including all the previous message: edit out all the irrelevant material.
- Limit line length to fewer than 65 characters and end a line with a carriage return.
- Mail should have a subject heading which reflects the content of the message.
- If you include a signature keep it short. Rule of thumb is no longer than four lines. Remember that many people pay for connectivity by the minute, and the longer your message is, the more they pay.
- Just as mail (today) may not be private, mail (and news) are (today) subject to forgery and spoofing of various degrees of detectability. Apply common sense "reality checks" before assuming a message is valid.
- If you think the importance of a message justifies it, immediately reply briefly to an e-mail message to let the sender know you got it, even if you will send a longer reply later.
- "Reasonable" expectations for conduct via e-mail depend on your relationship to a person and the context of the communication. Norms learned in a particular e-mail environment may not apply in general to your e-mail communication with people across the Internet. Be careful with slang or local acronyms.
- The cost of delivering an e-mail message is, on the average, paid about equally by the sender and the recipient (or their organizations). This is unlike other media such as physical mail, telephone, TV, or radio. Sending someone mail may also cost them in other specific ways like network bandwidth, disk space or CPU usage. This is a fundamental economic reason why unsolicited e-mail advertising is unwelcome (and is forbidden in many contexts).
- Know how large a message you are sending. Including large files such as Postscript files or programs may make your message so large that it cannot be delivered or at least consumes excessive resources. A good rule of thumb would be not to send a file larger than 50 kb. Consider file transfer as an alternative, or cutting the file into smaller chunks and sending each as a separate message.
- Do not send large amounts of unsolicited information to people.
- If your mail system allows you to forward mail, beware the dreaded forwarding loop. Be sure you have not set up forwarding on several hosts so that a message sent to you gets into an endless loop from one computer to the next to the next.

Selected Bibliography

This bibliography was used to gather most of the information in the sections above as well as for general reference. Items not specifically found in these works were gathered from the IETF-RUN Working Group's experience.

Computer Ethics

Peter S. Tippett

The computer security professional needs both to understand and to influence the behavior of everyday computer users. Traditionally, security managers have concentrated on building security into the system hardware and software, on developing procedures, and on educating end users about procedures and acceptable behavior. Now, the computer professional must also help develop the meaning of ethical computing and help influence computer end users to adopt notions of ethical computing into their everyday behavior.

Fundamental Changes to Society

Computer technology has changed the practical meaning of many important, even fundamental, human and societal concepts. Although most computer professionals would agree that computers change nothing about human ethics, computer and information technologies have caused and will pose many new problems. Indeed, computers have changed the nature and scope of accessing and manipulating information and communications. As a result, computers and computer communications will significantly change the nature and scope of many of the concepts most basic to society. The changes will be as pervasive and all encompassing as the changes accompanying earlier shifts from a society dependent on hunters and gatherers to one that was more agrarian to an industrial society.

Charlie Chaplin once observed, "The progress of science is far ahead of man's ethical behavior." The rapid changes that computing technology and the digital revolution have brought and will bring are at least as profound as the changes prompted by the industrial revolution. This time, however, the transformation will be compressed into a much shorter time frame.

It will not be known for several generations whether the societal changes that follow from the digital revolution will be as fundamental as those caused by the combination of easy transportation, pervasive and near-instantaneous news, and inexpensive worldwide communication brought on by the industrial and radio revolutions. However, there is little doubt that the digital age is already causing significant changes in ways that are not yet fully appreciated.

Some of those changes are bad. For example, combining the known costs of the apparent unethical and illegal uses of computer and information technology — factors such as telephone and PBX fraud, computer viruses, and digital piracy — amounts to several billion dollars annually. When these obvious problems are combined with the kinds of computing behavior that society does not yet fully comprehend as unethical and that society has not yet labeled illegal or antisocial, it is clear that a great computer ethics void exists.

No Sandbox Training

By the time children are six years old, they learn that eating grasshoppers and worms is socially unacceptable. Of course, six-year-olds would not say it quite that way. To express society's wishes, children say something more like: "Eeewwww!, Yich! Johnny, you are not going to eat that worm are you?"

As it turns out, medical science shows that there is nothing physically dangerous or wrong with eating worms or grasshoppers. Eating them would not normally make people sick or otherwise cause physical harm. But children quickly learn at the gut level to abhor this kind of behavior — along with a whole raft of other behavior. What is more, no obvious rule exists that leads to this gut-feeling behavior. No laws, church doctrine, school curriculum, or parental guides specifically address the issue of eating worms and grasshoppers. Yet, even without structured rules or codes, society clearly gives a consistent message about this. Adults take the concept as being so fundamental that it is called common sense.

By the time children reach the age of ten, they have a pretty clear idea of what is right and wrong, and what is acceptable and unacceptable. These distinctions are learned from parents, siblings, extended families, neighbors, acquaintances, and schools, as well as from rituals like holiday celebrations and from radio, television, music, magazines, and many other influences.

Unfortunately, the same cannot be said for being taught what kind of computing behavior is repugnant. Parents, teachers, neighbors, acquaintances, rituals, and other parts of society simply have not been able to provide influence or insight based on generations of experience. Information technology is so new that these people and institutions simply have no experience to draw on. The would-be teachers are as much in the dark as those who need to be taught.

A whole generation of computer and information system users exists. This generation is more than one hundred million strong and growing. Soon information system users will include nearly every literate individual on earth. Members of this new generation have not yet had their sandbox

training. Computer and information users, computer security professionals included, are simply winging it.

Computer users are less likely to know the full consequences of many of their actions than they would be if they could lean on the collective family, group, and societal experiences for guidance. Since society has not yet established much of what will become common sense for computing, individuals must actively think about what makes sense and what does not. To decide whether a given action makes sense, users must take into account whether the action would be right not only for themselves personally but also for their peers, businesses, families, extended families, communities, and society as a whole. Computer users must also consider short-term, mid-term, and long-term ramifications of each of the potential actions as they apply to each of these groups. Since no individual can conceivably take all of this into consideration before performing a given action, human beings need to rely on guides such as habit, rules, ritual, and peer pressure. People need to understand without thinking about it, and for that, someone needs to develop and disseminate ethics for the computer generation.

Computer security professionals must lead the way in educating the digital society about policies and procedures and behavior that clearly can be discerned as right or wrong. The education process involves defining those issues that will become gut feelings, common sense, and acceptable etiquette of the whole society of end users. Computer professionals need to help develop and disseminate the rituals, celebrations, habits, and beliefs for users.

In other words, they are the pivotal people responsible for both defining computer ethics and disseminating their understanding to the computer-using public.

COMMON FALLACIES OF THE COMPUTER GENERATION

The lack of early, computer-oriented, childhood rearing and conditioning has led to several pervasive fallacies that generally (and loosely) apply to nearly all computer and digital information users. The generation of computer users includes those from 7 to 70 years old who use computing and other information technologies. Like all fallacies, some people are heavily influenced by them, and some are less so. There are clearly more fallacies than those described here, but these are probably the most important. Most ethical problems that surface in discussions show roots in one or more of these fallacies.

The Computer Game Fallacy

Computer games like solitaire and game computers like those made by Nintendo and Sega do not generally let the user cheat. So it is hardly

surprising for computer users to think, at least subliminally, that computers in general will prevent them from cheating and, by extension, from otherwise doing wrong.

This fallacy also probably has roots in the very binary nature of computers. Programmers in particular are used to the precise nature that all instructions must have before a program will work. An error in syntax, a misplaced comma, improper capitalization, and transposed characters in a program will almost certainly prevent it from compiling or running correctly once compiled. Even non-programming computer users are introduced to the powerful message that everything about computers is exact and that the computer will not allow even the tiniest transgression. DOS commands, batch file commands, configuration parameters, macro commands, spreadsheet formulas, and even file names used for word processing must have precisely the right format and syntax, or they will not work.

To most users, computers seem entirely black and white — sometimes frustratingly so. By extension, what people do with computers seems to take on a black-and-white quality. But what users often misunderstand while using computers is that although the computer operates with a very strict set of inviolable rules, most of what people do with computers is just as gray as all other human interactions.

It is a common defense for malicious hackers to say something like "If they didn't want people to break into their computer at the [defense contractor], they should have used better security." Eric Corley, the publisher of the hacker's *2600 Magazine*, testified at hearings for the House Telecommunications and Finance Subcommittee (June 1993) that he and others like him were providing a service to computer and telecommunication system operators when they explored computer systems, found faults and weaknesses in the security systems, and then published how to break these systems in his magazine. He even had the audacity while testifying before Congress to use his handle, Emanuel Goldstein (a character from the book *1984*), never mentioning that his real name was Eric Corley.

He, and others like him, were effectively saying "If you don't want me to break in, make it impossible to do so. If there is a way to get around your security, then I should get around it in order to expose the problem."

These malicious hackers would never consider jumping over the four-foot fence into their neighbor's backyard, entering the kitchen through an open kitchen window, sitting in the living room, reading the mail, making a few phone calls, watching television, and leaving. They would not brag or publish that their neighbor's home was not secure enough, that they found a problem or loophole, or that it was permissible to go in because it was possible to do so. However, using a computer to perform analogous activities makes perfect sense to them.

The computer game fallacy also affects the rest of the members of the computer-user generation in ways that are a good deal more subtle. The computer provides a powerful one-way mirror behind which people can hide. Computer uses can be voyeurs without being caught. And if what is being done is not permissible, the thinking is that the system would somehow prevent them from doing it.

The Law-Abiding Citizen Fallacy

Recognizing that computers can't prevent everything that would be wrong, many users understand that laws will provide some guidance. But many (perhaps most) users sometimes confuse what is legal, which defines the minimum standard about which all can be justly judged, with what is reasonable behavior, which clearly calls for individual judgment. Sarah Gordon, one of the leaders of the worldwide hobbyist network FidoNet said, "In most places, it is legal to pluck the feathers off of a live bird, but that doesn't make it right to do it."

Similarly, people confuse things that they have a right to do with things that are right to do. Computer virus writers do this all the time. They say: "The First Amendment gives me the constitutional right to write anything I want, including computer viruses. Since computer viruses are an expression, and a form of writing, the constitution also protects the distribution of them, the talking about them, and the promotion of them as free speech."

Some people clearly take their First Amendment rights too far. Mark Ludwig has written two how-to books on creating computer viruses. He also writes a quarterly newsletter on the finer details of computer virus authors and runs a computer virus exchange bulletin board with thousands of computer viruses for the user's downloading pleasure. The bulletin board includes source code, source analysis, and tool kits to create nasty features like stealthing, encryption, and polymorphism. He even distributes a computer virus CD with thousands of computer viruses, a source code, and some commentary.

Nearly anyone living in the United States would agree that in most of the western world, people have the right to write almost anything they want. However, they also have the responsibility to consider the ramifications of their actions and to behave accordingly. Some speech, of course, is not protected by the constitution — like yelling "fire" in a crowded theater or telling someone with a gun to shoot a person. One would hope that writing viruses will become nonprotected speech in the future. But for now, society has not decided whether virus writing, distribution, and promotion should be violently abhorred or tolerated as one of the costs of other freedoms.

The Shatterproof Fallacy

How many times have computer novices been told "Don't worry, the worst you can do with your computer is accidentally erase or mess up a file — and even if you do that, you can probably get it back. You can't really hurt anything."

Although computers are tools, they are tools that can harm. Yet most users are totally oblivious to the fact that they have actually hurt someone else through actions on their computer. Using electronic-mail on the Internet to denigrate someone constitutes malicious chastisement of someone in public. In the nondigital world, people can be sued for libel for these kinds of actions; but on the Internet, users find it convenient to not be held responsible for their words.

Forwarding E-mail without at least the implied permission of all of its authors often leads to harm or embarrassment of participants who thought they were conferring privately. Using E-mail to stalk someone, to send unwanted mail or junk mail, and to send sexual innuendoes or other material that is not appreciated by the recipient all constitute harmful use of computers.

Software piracy is another way in which computer users can hurt people. Those people are not only programmers and struggling software companies but also end users who must pay artificially high prices for the software and systems they buy and the stockholders and owners of successful companies who deserve a fair return on their investment.

It is astonishing that a computer user would defend the writing of computer viruses. Typically, the user says, "My virus is not a malicious one. It does not cause any harm. It is a benign virus. The only reason I wrote it was to satisfy my intellectual curiosity and to see how it would spread." Such users truly miss out on the ramifications of their actions. Viruses, by definition, travel from computer to computer without the knowledge or permission of the computer's owner or operator.

Viruses are just like other kinds of contaminants (e.g., contaminants in a lake) except that they grow (replicate) much like a cancer. Computer users cannot know they have a virus unless they specifically test their computers or diskettes for it. If the neighbor of a user discovers a virus, then the user is obliged to test his or her system and diskettes for it and so are the thousand or so other neighbors that the user and the user's neighbors have collectively.

The hidden costs of computer viruses are enormous. Even if an experienced person with the right tools needs only 10 minutes to get rid of a virus — and even if the virus infects only 4 or 5 computers and only 10 or 20 floppy disks in a site (these are about the right numbers for a computer

virus incident in a site of 1000 computers), then the people at the site are obliged to check all 1,000 computers and an average of 35,000 diskettes (35 active diskettes per computer) to find out just which five computers are infected.

As of early 1995, there were demonstrably more than a thousand people actively writing, creating, or intentionally modifying the more than 6000 computer viruses that currently exist — and at least as many people knowingly participated in spreading them. Most of these people were ignorant of the precise consequences of their actions.

In 1993, there was a minor scandal in the IRS when clerical IRS employees were discovered pulling computerized tax returns of movie stars, politicians, and their neighbors — just for the fun of it. What is the harm? The harm is to the privacy of taxpayers and to the trust in the system, which is immeasurably damaged in the minds of U.S. citizens. More than 350 IRS employees were directly implicated in this scandal. When such large numbers of people do not understand the ethical problem, then the problem is not an isolated one. It is emblematic of a broad ethical problem that is rooted in widely held fallacies.

The shatterproof fallacy is the pervasive feeling that what a person does with a computer could hurt at most a few files on the machine. It stems from the computer generation's frequent inability to consider the ramifications of the things we do with computers before we do them.

The Candy-from-a-Baby Fallacy

Guns and poison make killing easy (i.e., it can be done from a distance with no strength or fight) but not necessarily right. Poisoning the water supply is quite easy, but it is beyond the gut-level acceptability of even the most bizarre schizophrenic.

Software piracy and plagiarism are incredibly easy using a computer. Computers excel at copying things, and nearly every computer user is guilty of software piracy. But just because it is easy does not mean that it is right.

Studies by the Software Publisher's Association (SPA) and Business Software Alliance (BSA) show that software piracy is a multibillion dollar problem in the world today — clearly a huge problem.

By law and by any semblance of intellectual property held both in Western societies and most of the rest of the world, copying a program for use without paying for it is theft. It is no different than shoplifting or being a stowaway on an airliner, and an average user would never consider stealing a box of software from a computer store's display case or stowing away on a flight because the plane had empty seats.

The Hacker's Fallacy

The single most widely held piece of The Hacker's Ethic is "As long as the motivation for doing something is to learn and not to otherwise gain or make a profit, then doing it is acceptable." This is actually quite a strong, respected, and widely held ethos among people who call themselves non-malicious hackers.

To be a hacker, a person's primary goal must be to learn for the sake of learning — just to find out what happens if one does a certain thing at a particular time under a specific condition (Emmanuel Goldstein, *2600 Magazine,* Spring 1994). Consider the hack on Tonya Harding (the Olympic ice skater who allegedly arranged to have her archrival, Nancy Kerrigan, beaten with a bat). During the Lillehammer Olympics, three U.S. newspaper reporters, with the *Detroit Free Press, San Jose Mercury News,* and *The New York Times,* discovered that the athletes' E-mail user IDs were, in fact, the same as the ID numbers on the backs of their backstage passes. The reporters also discovered that the default passwords for the Olympic Internet mail system were simple derivatives of the athlete's birthdays. Reporters used this information to gain access to Tonya Harding's E-mail account and discovered that she had 68 messages. They claim not to have read any of them. They claim that no harm was done, nothing was published, no privacy was exploited. As it happens, these journalists were widely criticized for their actions. But the fact is, a group of savvy, intelligent people thought that information technology changed the ground rules.

The Free Information Fallacy

There is a common notion that information wants to be free, as though it had a mind of its own. The fallacy probably stems from the fact that once created in digital form, information is very easy to copy and tends to get distributed widely. The fallacy totally misses the point that the wide distribution is at the whim of people who copy and disseminate data and people who allow this to happen.

ACTION PLAN

The following procedures can help security managers encourage ethical use of the computer within their organizations:

- Developing a corporate guide to computer ethics for the organization.
- Developing a computer ethics policy to supplement the computer security policy.
- Adding information about computer ethics to the employee handbook.
- Finding out whether the organization has a business ethics policy, and expanding it to include computer ethics.
- Learning more about computer ethics and spreading what is learned.

- Helping to foster awareness of computer ethics by participating in the computer ethics campaign.
- Making sure the organization has an E-mail privacy policy.
- Making sure employees know what the E-mail policy is.

Exhibits 1 through 6 contain sample codes of ethics for end users that can help security managers develop ethics policies and procedures.

RESOURCES

The following resources are useful for developing computer-related ethics codes and policies.

Computer Ethics Institute

The Computer Ethics Institute is a non-profit organization concerned with advancing the development of computers and information technologies within ethical frameworks. Its constituency includes people in business, the religious communities, education, public policy, and computer professions. Its purpose includes the following:

- The dissemination of computer ethics information.
- Policy analysis and critique.
- The recognition and critical examination of ethics in the use of computer technology.
- The promotion of identifying and applying ethical principles for the development and use of computer technologies.

In 1991 the Computer Ethics Institute held its first National Computer Ethics Conference in Washington, D.C. The conference theme was "In Pursuit of a 'Ten Commandments' of Computer Ethics." These commandments were drafted by Dr. Ramon C. Barquin, founder and president of the Institute, as a working document for that conference. Since then, they have been among the most visible guidelines for computer ethics. The following are the ten commandments:

1. Thou shalt not use a computer to harm other people.
2. Thou shalt not interfere with other people's computer work.
3. Thou shalt not snoop around in other people's computer files.
4. Thou shalt not use a computer to steal.
5. Thou shalt not use a computer to bear false witness.
6. Thou shalt not copy or use proprietary software for which you have not paid.
7. Thou shalt not use other people's computer resources without authorization or proper compensation.
8. Thou shalt not appropriate other people's intellectual output.
9. Thou shalt think about the social consequences of the program you are writing or the system you are designing.
10. Thou shalt use a computer in ways that ensure consideration and respect for your fellow humans.

Exhibit 1. The Ten Commandments of Computer Ethics

In an effort to define responsible computing behavior in terms that are easy to grasp, the Working Group on Computer Ethics created the End User's Basic Tenets of Responsible Computing. These tenets are not intended as a panacea for the myriad of complex information ethics dilemmas; rather, they are intended to address many of the day-to-day problems faced by individual end users.

Responsible and ethical computing is not a black and white issue. However, many problems can be avoided by abiding by the following basic tenets:

1. I understand that just because something is legal, it isn't necessarily moral or right.
2. I understand that people are always the ones ultimately harmed when computers are used unethically. The fact that computers, software, or a communications medium exists between me and those harmed does not in any way change my moral responsibility toward my fellow humans.
3. I will respect the rights of authors, including authors and publishers of software as well as authors and owners of information. I understand that just because copying programs and data is easy, it is not necessarily right.
4. I will not break into or use other people's computers or read or use their information without their consent.
5. I will not write or knowingly acquire, distribute, or allow intentional distribution of harmful software like bombs, worms, and computer viruses.

Exhibit 2. The End User's Basic Tenets of Responsible Computing

---

The National Conference on Computing and Values proposed four primary values for computing. These were originally intended to serve as the ethical foundation and guidance for computer security. However, they seem to provide value guidance for all individuals who create, sell, support, use, or depend upon computers. That is, they suggest the values that will tend to improve and stabilize the computer and information world and to make these technologies and systems work more productively and appropriately for society.

The four primary values state that we should strive to:

1. Preserve the public trust and confidence in computers.
2. Enforce fair information practices.
3. Protect the legitimate interests of the constituents of the system.
4. Resist fraud, waste, and abuse.

Exhibit 3. Four Primary Values

In January 1989, the Internet Activities Board (IAB) published a document called Ethics and the Internet (RFC 1087). It proposes that access to and use of the Internet is a privilege and should be treated as such by all users of this system. The IAB "strongly endorses the view of the Division Advisory Panel of the National Science Foundation Division of Network, Communications Research and Infrastructure." That view is paraphrased here. Any activity is characterized as unethical and unacceptable that purposely:

- Seeks to gain unauthorized access to the resources of the Internet.
- Disrupts the intended use of the Internet.
- Wastes resources (people, capacity, computer) through such actions.
- Destroys the integrity of computer-based information.
- Compromises the privacy of users.
- Involves negligence in the conduct of Internetwide experiments.

Exhibit 4. Unacceptable Internet Activities

Donn Parker, who is with SRI International and is the author of "Ethical Conflicts in Information and Computer Science, Technology and Business" (QED Information Sciences, Inc.), defined several principles for resolving ethical conflicts. The following summarizes this work:

You are probably aware of the obvious unethical information activities you should avoid, such as violating others' privacy by accessing their computers and causing others losses by giving away copies of the software others own or sell. But how do you deal with the really tough problems of deciding the best action in complex or unclear situations where a decision may be okay in one respect but not in another? These are the more difficult decisions to make. The following principles of ethical information conduct and examples may help you as a periodic review to make fairer decisions when needed or as a checklist for a methodical approach to solve a problem and reach a decision. You may not remember all of these principles on every occasion, but reading them now and every once in a while or having them handy when making a decision can help you through a difficult process.

1. Try to make sure that those people affected are aware of your planned actions and that they don't disagree with your intentions even if you have rights to do these things (informed consent).
2. Think carefully about your possible alternative actions and select the most beneficial necessary one that would cause the least or no harm under the worst circumstances (higher ethic in the worst case).
3. Consider that an action you take on a small scale or by you alone might result in significant harm if carried out on a larger scale or by many others (change of scale).
4. As a person who owns or is responsible for information, always make sure that the information is reasonably protected and that ownership of it and rights to it are clear to all users (owners' conservation of ownership).
5. As a person who uses information, always assume it is owned by others and their interests must be protected unless you explicitly know it is public or you are free to use it in the way you wish (users' conservation of ownership).

Exhibit 5. Considerations for Conduct

In 1973 the Secretary's Advisory Committee on Automated Personal Data Systems for the U.S. Department of Health, Education & Welfare recommended the adoption of a "Code of Fair Information Practices" to secure the privacy and rights of citizens. The Code is based on four principles:

1. There must be no personal data record-keeping systems whose very existence is secret.
2. There must be a way for a person to find out what information about the person is in a record and how it is used.
3. There must be a way for a person to prevent information about the person that was obtained for one purpose from being used or made available for other purposes without the person's consent.
4. Any organization creating, maintaining, using, or disseminating records of identifiable personal data must assure the reliability of the data for their intended use and must take precautions to prevent misuses of the data.

Exhibit 6. The Code of Fair Information Practices

To meet these purposes, the Computer Ethics Institute conducts seminars, convocations, and the annual National Computer Ethics Conference. The Institute also supports the publication of proceedings and the development and publication of other research. In addition, the Institute participates in projects with other groups with similar interests. The following are ways to contact the institute:

Dr. Patrick F. Sullivan
Executive Director
Computer Ethics Institute
P.O. Box 42672
Washington, D.C. 20015
Voice and fax: 301-469-0615
psullivan@brook.edu

Internet Listserve:cei-1@listserv.american.edu

This is a listserv on the Internet hosted by American University in Washington, D.C., on behalf of the Computer Ethics Institute. Electronic mail sent to this address is automatically forwarded to others interested in computer ethics and in activities surrounding the Computer Ethics Institute. To join the list, a person should send E-mail to:

listserv@american.edu

The subject field should be left blank. The message itself should say:

subscribe cei-1 <yourname>

The sender will receive postings to the list by E-mail (using the return address from the E-mail site used to send the request).

The National Computer Ethics and Responsibilities Campaign (NCERC)

The NCERC is a campaign jointly run by the Computer Ethics Institute and the National Computer Security Association. Its goal is to foster computer ethics awareness and education. The campaign does this by making tools and other resources available for people who want to hold events, campaigns, awareness programs, seminars, and conferences or to write or communicate about computer ethics.

The NCERC itself does not subscribe to or support a particular set of guidelines or a particular viewpoint on computer ethics. Rather, the Campaign is a nonpartisan initiative intended to foster increased understanding of the ethical and moral issues peculiar to the use and abuse of information technologies.

The initial phase of the NCERC was sponsored by a diverse group of organizations, including (alphabetically) The Atterbury Foundation, The Boston Computer Society, The Business Software Alliance, CompuServe,

The Computer Ethics Institute, Computer Professionals for Social Responsibility, Merrill Lynch, Monsanto, The National Computer Security Association, Software Creations BBS, The Software Publisher's Association, Symantec Corporation, and Ziff-Davis Publishing. The principal sponsor of the NCERC is the Computer Ethics Institute.

Other information about the campaign is available on CompuServe (GO CETHICS), where a repository of computer privacy, ethics and similar tools, codes, texts, and other materials are kept.

Computer Ethics Resource Guide

The Resource Guide to Computer Ethics is available for $12. (Send check or credit card number and signature to: NCERC, 10 S. Courthouse Ave., Carlisle, PA, 17013, or call 717-240-0430 and leave credit card information as a voice message.) The guide is meant as a resource for those who wish to do something to increase the awareness of and discussion about computer ethics in their workplaces, schools, universities, user groups, bulletin boards, and other areas.

The National Computer Security Association

The National Computer Security Association (NCSA) provides information and services involving security, reliability, and ethics. NCSA offers information on the following security-related areas: training, testing, research, product certification, underground reconnaissance, help desk, and consulting services. This information is delivered through publications, conferences, forums, and seminars — in both traditional and electronic formats. NCSA manages a CompuServe forum (CIS: GO NCSA) that hosts private online training and seminars in addition to public forums and libraries addressing hundreds of issues concerning information and communications security, computer ethics, and privacy.

The information about computer ethics that is not well suited to electronic distribution can generally be obtained through NCSA's InfoSecurity Resource Catalog, which provides one-stop-shopping for a wide variety of books, guides, training, and tools. (NCSA: 10 S. Courthouse Ave., Carlisle, PA, 17013, 717-258-1816).

SUMMARY

Computer and information technologies have created many new ethical problems. Compounding these problems is the fact that computer users often do not know the full consequences of their behavior.

Several common fallacies cloud the meaning of ethical computing. For example, many computer users confuse behavior that they have a right to perform with behavior that is right to perform and fail to consider the

ramifications of their actions. Another fallacy that is widely held by hackers is that as long as the motivation is to learn and not otherwise profit, any action using a computer is acceptable.

It is up to the system managers to destroy these fallacies and to lead the way in educating end users about policies and procedures and behavior that can clearly be discerned as right or wrong.

Domain 10
Physical Security

The Physical Security Domain discusses the importance of physical security in the protection of valuable information assets of the business enterprise. It provides protection techniques for the entire facility, from the outside perimeter to the inside office space, including the data center or server room.

In the early days of computers, much of the security focus was built on providing physical security protections. Think of the data center that contained the mainframe servers and all the information processed and stored on the system. In this environment, the majority of the protections were for physical protection of that one area, such as restricting personnel from the area, enforcing physical access controls with locks and alarms, and implementing environmental controls to ensure the equipment was protected from heat and moisture. The advent of distributed systems changed this focus; resources and information were now in various places within the organization, and in many cases, not even contained within the building. For example, mobile devices, such as laptops and personal digital assistants, provided the ability to carry information outside a limiting physical environment.

According to many information system security surveys, the majority of threats occur from insiders — that is, those individuals who have physical access to their own resources. Because of this, physical security is just as relevant today as it was 30 years ago. It is still necessary to protect server rooms by limiting access and installing appropriate locks.

Another factor impacting physical security is the new government and private-sector initiatives to protect critical infrastructures, such as power and water supplies. Because information system assets require some type of power source to operate, the need for clean, constant power is a primary physical security concern. Threats to infrastructures are evolving and pose different types of threats. Although this may appear to be dramatic, chemical and biological threats have become increasingly more viable methods of attack.

One of the challenges for information system security professionals is to understand the security challenges associated with the physical environment. Although physical security is documented according to some specific technologies, such as closed-circuit television (CCTV) and alarm systems, there has not been much literature that combines the physical security field with the information system security field. There is also a dichotomy between the "traditional" security professionals who focus primarily on personnel and access controls and the information system security professionals who focus on logical controls. Many organizations still struggle for control over who will provide security — the traditional security divisions or the information management divisions. This lack of coordination and, in many cases, political maneuvering, has created difficulties for organizations to accomplish goals. However, as most security professionals will note, if both sides (security and information management) begin to work together, they will realize that indeed their goals are the same — and what is needed is better communication and coordination about how to achieve those goals. That is, by capitalizing on the strength and knowledge of both functions, they will achieve the goals of information system security — protecting the organization's valuable resources.

Although the challenges have changed along with the technologies, physical security still plays a critical role in protecting the resources of an organization. It requires solidly constructed buildings, emergency preparedness, adequate environmental protection, reliable power supplies, appropriate climate control, and external and internal protection from intruders.

Physical Security: A Foundation for Information Security

Christopher Steinke, CISSP

Physical security can be defined as the measures taken to ensure the safety and material existence of something or someone against theft, espionage, sabotage, or harm. In the context of information security, this means about information, products, and people.

Physical security is the oldest form of protection. For ages, people have been protecting themselves from harm and their valuables from theft or destruction. In the past, physical security was all the protection someone needed to have safety. However, with technology, physical security alone is not effective. Information security is an approach that deploys many different layers of security to achieve its goal; hence the phrase "security in layers." With the common acceptance that nothing is 100 percent secure, information security uses the depth of its layers to achieve the highest form of security. A weakness in any one of these layers will cause security to break. Physical protection is the first step in the layered approach of information security. If it is nonexistent, weak, or exercised in malpractice, information security will fail.

Approaching Physical Security

Physical security is a continuous process that cannot be approached in an unpremeditated manner. The approach must be consistent with the goals of the organization and be applied in accordance with the standards and guidelines set forth in the information security policy.

Because there is little change in the world of physical security (at least not as quickly as the rest of the controls within information security), it is often considered to be boring or unimportant. This misunderstanding often causes physical security to be neglected or practiced haphazardly. Typically, the greatest weakness of any information security control is not the control itself, but the improper application of a control. Physical security must be approached with the same energy, focus, and seriousness as any other information security control. In fact, security controls must be approached and applied in a consistent and predetermined manner to achieve predictable, repeatable, and effective information security.

Locks, guards, surveillance cameras, and identification badges are merely the tools and equipment of physical security. To plan and design physical security, the following questions should be answered:

- What are you protecting?
- How important is the information being protected (in terms of economic, political, or public safety)?
- For whom are you protecting and what is more important to them? Confidentiality, integrity, or availability?
- What and who are you protecting it from?

Granted, not all places need the physical security of Fort Knox (who would want to work there?), but physical security should be applied in proportion to the importance and sensitivity of the people and information it

protects. This chapter discusses the risks posed by common threats and vulnerabilities in information security, and how good physical security can provide a foundation for addressing those risks.

Psychology of Physical Security

When planning and designing physical security, keep in mind that it is as much psychological as it is physical. It is important to consider the advantages that the psychological impact can have. If one can design physical security in such a way as to make it highly visible (while safeguarding the details), one can announce that your organization is well guarded, rendering it less of a target to threatening activity. This is an indirect way to eliminate the desire to commit a crime against that organization. The effectiveness of physical security, as with any security control, is measured in terms of eliminating the opportunity; the psychology of physical security is measured in terms of eliminating the desire.

Facility Physical Security

The diversity of the modern workplace often makes it impractical to establish universal, rigid physical security standards. Nonetheless, adequate physical security at every location is necessary for achieving a complete, secure environment. This chapter section outlines the types of facilities, how they differ, and ways to approach physical security for each.

Facility Classification

Facilities can be grouped into one of these general classifications:

- *Owned facility.* Owned facilities are probably the simplest structure to maintain physical security. The ease of security management is inherent, due to the occupant having complete administrative control over the facility. This allows the flexibility to implement whatever type of physical security control, in any fashion, the owner/occupant feels will accomplish their protection goals. The main downfall of an owned facility is that the owner/occupant must take complete responsibility if physical security fails. A good example of an owned facility is a large corporate headquarters.
- *Nonowned facility.* Nonowned facilities can be a little more challenging to physically protect. The occupant and the owner will have their own lists of responsibilities that hold them liable if physical security fails. For example, if a water pipe bursts and floods a computer room, the occupant may hold the owner liable for the damages if it is discovered that the owner did not adequately maintain the plumbing. In this case, nonowned facilities may offer the advantage of legal recourse for failed physical security. Examples of nonowned facilities are buildings an occupant leases but does not own.
- *Shared facility.* Shared facilities are probably the most diverse and threatening of facilities to occupy, yet they account for the majority of structures. These facilities have more than one occupant, with some of the occupants possibly being competitors. Because the facility must provide equal access to all occupants (in certain areas), physical security becomes very challenging. Good examples of shared facilities could be nonowned facilities with multiple occupants, central offices, and co-locations.

When classifying facilities, one takes the first step in developing a strategy for risk mitigation. By understanding the threats that may be inherent to certain facilities, one gains insight into protecting against the risks. Because some facilities may fit more than one classification description, one is not bound by strict adherence to this classification scheme. What one should then be aware of are any new inherent strengths and weaknesses that these hybrid classes might create.

Facility Location

Not only should one be concerned with what kind of facility one occupies, but also the location. A particular location may harbor more threats than another. Below are some location-based threats to consider when choosing an area for one's facility:

- *Vulnerability to crime, riots, and terrorism.* Research crime and terrorism statistics for each location being considered. If the location of the facility is in an area that is frequented by these activities, the

chances of physical security being breached increases. For example, frequent demonstrations or riots near a facility could erupt into random acts of violence (e.g., fires, crime, etc.) that may threaten the facility, its employees, and possibly its customers. Even in information security, the protection and safety of people should always come before anything else.

- *Adjacent buildings and businesses*. This issue relates to the previously discussed classification of facilities (particularly shared facilities) and the previous issue of crime and riot vulnerability. It is good practice to know who one's neighbors are and what they do. For example, one may not want to locate a corporate data center next to a competitor, a nuclear power plant, or a freeway or railway that is a route for hazardous chemical transportation. Also, these concerns come to mind about connected buildings. Are their physical security controls as strong as yours? Can someone get into the facility if they break into an adjacent building? What about the roof? These should all be in the forefront of one's mind when choosing a location.
- *Emergency support response*. This is simply defined as the time it takes emergency support (i.e., fire, police, and medical personnel) to reach the facility. Know the mileage and time the driving distance (during the heaviest traffic) from emergency support locations to the facility. This information allows one to implement physical security measures that not only will detect and deter, but also delay and minimize damage or harm until emergency support arrives.
- *Environmental support*. Environmental support is the clean air, water, and power that service the facility. Ensure that the location has room for growth in all of these areas. In particular, for high-availability facilities, look for locations from which to draw from two separate power grids.
- *Vulnerability to natural disasters*. Check local geological and weather statistics for patterns of natural disasters in preferred location(s) for the past 100 years. Granted, natural disasters cannot be predicted or totally avoided, but one can minimize their effect by choosing a location where such disasters are less likely to occur.

Facility Threats and Controls

From the previous discussion, one sees how certain locations can harbor more or fewer threats. What follows here is a list of threats and controls in their basic forms. This is to demonstrate that if one can eliminate a threat at its root, one can effectively eliminate several others at the same time. But also notice that the opposite can happen when one threat manifests another. The controls are simple and basic in nature, but keep in mind that controls, as a whole, should be able to deter, detect, delay, and react to a given threat. There are three classes of threats, those being natural, man-made, and environmental failure.

Natural Threats

Good physical security has a psychological advantage against some threats. Unfortunately, natural threats are not one of them. This threat cannot be deterred or discouraged. At one time or another, Mother Nature will threaten the facility. The only option is to implement controls that will minimize the impact and facilitate a quick recovery. Natural threats and some of their controls include:

- Fire causes the following risks:
  - — Heat
  - — Smoke
  - — Suppression agent (e.g., fire extinguishers and water) damage
- Fire controls include:
  - — Installing smoke detectors near equipment
  - — Installing fire extinguishers and training employees in their proper use
  - — Using gaseous (nonliquid) extinguishing systems near information systems
  - — Conducting regular fire evacuation exercises
  - — Storing all backup media offsite (with a bonded third party)
  - — Developing and exercising a disaster recover plan
- Severe Weather causes the following risks:
  - — Lightning

  - Heavy winds
  - Hail
  - Flooding
- Severe weather controls include:
  - Monitoring weather conditions
  - Keeping equipment in areas that are weather-proofed and capable of withstanding strong winds
    - Ensuring equipment is properly grounded
  - Installing surge suppressors and uninterruptible power supplies (UPS) or diesel generators
  - Installing raised flooring
  - Conducting regular weather evacuation exercises
  - Storing all backup media offsite (with a bonded third party)
  - Developing and exercising a disaster recovery plan
- Earthquakes are particularly dangerous because of their ability to spur other natural disasters, such as fires. In addition to collateral damage from quake-induced fires, some additional risks include:
  - Limited or no response from emergency agencies
  - Permanent structural physical damage to facilities and information systems
  - Nullify threat controls (e.g., disables fire-suppression capability)
  - Personnel evacuation is limited
- Earthquake controls include:
  - Keeping information systems equipment off elevated surfaces (without proper mounting)
  - Keeping information systems equipment away from glass windows
  - Installing earthquake-proof or antivibration devices on equipment and infrastructure
  - Conducting routine earthquake drills
  - Storing all backup media offsite (with a bonded third party)
  - Developing and exercising a disaster recovery plan

Natural threats are not always the dramatic events listed above. They can often take a much more subtle and unforeseen form. An example of this is the exposure to dry heat, moisture, and light winds over time. These less-severe threats may not be cause for immediate alarm, yet one should be aware of their potential impact.

Man-Made Threats

The second threat class is called man-made. This type of threat is often the most dynamic and challenging, due to ties in human nature. This is drawn from a conclusion that there are three motivating agents of man-made threats, those being malice, opportunity, and accidental. Man-made threats and some of the controls include:

- Theft/fraud causes the following risks:
  - Reduction or loss of information systems capabilities
  - Loss of sensitive information or trade secrets
  - Loss of revenue
- Theft/fraud controls include:
  - Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - Visible closed circuit television cameras (CCTVs)
  - Security- and safety-conscious employees
  - Identification badges
  - Guards
  - Minimizing the use of location signs
  - Routine audits
  - Good inventory control practices
  - Good lock and key practices
  - Insurance

  - — Separation of duties/job rotation
  - — Employee hiring/termination practices
- Espionage causes the following risks:
  - — Loss of sensitive information or trade secrets
  - — Loss of competitive advantage
  - — Loss of revenue
- Espionage controls include:
  - — Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - — Visible closed circuit television cameras (CCTVs)
  - — Security- and safety-conscious employees
  - — Identification badges
  - — Minimizing the use of location signs
  - — Guards
  - — Employee hiring/termination practices
  - — Separation of duties/job rotation
  - — Routine audits
- Sabotage causes the following risks:
  - — Reduction or loss of information systems capabilities
  - — Loss of sensitive information or trade secrets
  - — Loss of revenue
- Sabotage controls include:
  - — Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - — Visible closed circuit television cameras (CCTVs)
  - — Security- and safety-conscious employees
  - — Minimizing the use of location signs
  - — Identification badges
  - — Guards
  - — Insurance
  - — Separation of duties/job rotation
- Workplace violence causes the following risks:
  - — Harm or death to employees
  - — Loss of productivity
  - — Loss of revenue
- Workplace violence controls include:
  - — Posted signs that state the premises are monitored and persons may be inspected upon leaving or entering the facility
  - — Visible closed circuit television cameras (CCTVs)
  - — Security- and safety-conscious employees
  - — Awareness of warning signs
  - — Guards
  - — Employee hiring/termination practices

The ingenuity and adaptive nature of the human mind makes man-made threats difficult to control. An organization must maintain vigilance with its protection program by conducting routine assessments on the controls implemented against these threats.

Environmental Threats

The third threat class is labeled environmental threats. Environmental controls are important to the operation and safeguarding of information and its systems. Without clean air, water, power, and reliable climate controls, information systems would suffer inconsistent performance or complete failure.

- Climate failure causes the following risks:
  - Equipment and infrastructure malfunction or failure from overheating
  - Damage to storage/backup media
  - Damage to sensitive equipment components
- Climate controls include:
  - Monitoring temperatures of information systems equipment
  - Keeping all rooms containing information systems equipment at reasonable temperatures (60 to 75°F, or 10 to 25°C)
  - Maintaining humidity levels between 20 and 70 percent
  - Considering turning off unnecessary lights in rooms containing information system equipment
  - Conducting routine preventive maintenance and inspections of climate control system
  - Storing all backup media offsite (with a bonded third party)
  - Developing and exercising a disaster recovery plan
- Water and liquid leakage causes the following risks:
  - Equipment and infrastructure failure from excessive exposure to water or other forms of liquid
  - Damage to storage/backup media and critical hardcopy information
  - Damage to critical equipment components
- Water and liquid leakage controls include:
  - Keeping liquid-proof covers near equipment
  - Installing drains, water detectors, and raised flooring in rooms that house critical information systems equipment
  - Conducting routine inspections of plumbing
  - Using gaseous or dry pipe extinguishing systems near information systems
  - Storing all backup media offsite (with a bonded third party)
  - Developing and exercising a disaster recovery plan
- Electrical interruption causes the following risks:
  - Damage to critical equipment components
  - Damage to software and storage/backup media
  - Loss of climate controls
  - Loss of physical access controls and monitoring devices (i.e., surveillance cameras, door alarms, ID/card readers)
- Electrical interruption controls include:
  - Installing and testing uninterruptible power supplies (UPS) or diesel generators
  - Using surge suppressors
  - Installing electrical line filters to control voltage spikes
  - Using static guards and antistatic carpeting where applicable
  - Ensuring that all equipment is properly grounded
  - Having circuit boxes and wiring routinely inspected
  - Drawing power from two separate grids (if possible)
  - Storing all backup media offsite (with a bonded third party)
  - Developing and exercising a disaster recover plan

Environmental failure, in and of itself, is a threat that can cause considerable damage to information systems. However, it can be also be manifested by natural or man-made threats. Therefore, it is important to approach all threats with a layered approach that has defense-in-depth. This not only ensures that controls cover most of the threats, but that those controls are thorough in their coverage as well.

Facility Protection Strategy

Developing an overall strategy for physical protection is one of the many steps taken toward achieving good information security. One's protection strategy will be comprised of many principles and should center on

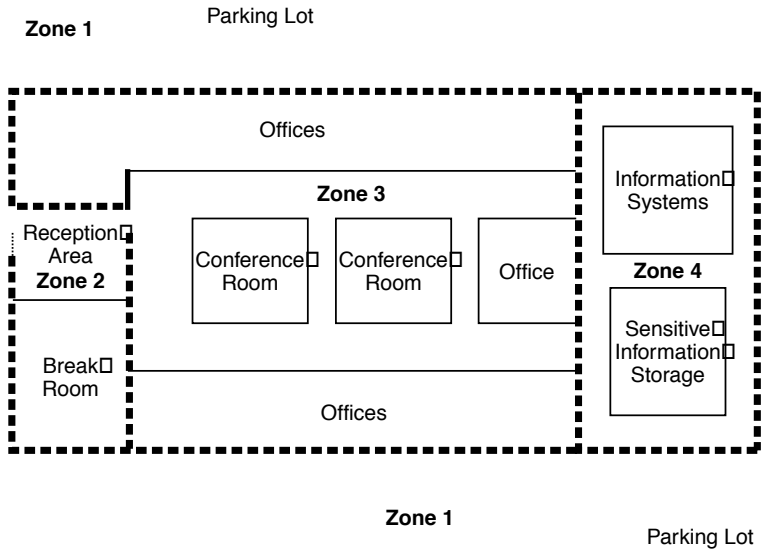

EXHIBIT 158.1 Using zoning for role-based access control.

whether confidentiality, integrity, or availability of the information is of greater importance. Zoning is a strategy that can be used to set a foundation for efficient and effective physical information protection.

Zoning

Zoning is not a new concept. Traditionally, zoning refers to a process used for installing fire detection alarms to identify hidden locations of smoke or fire (above ceiling, under floor, etc.). Additionally, a concept called cross-zoning has been used that allows one to reduce false alarms by requiring two or more alarms to be activated before the fire department is notified.

Zoning is sufficiently flexible to facilitate the simplest to the most detailed security model. Because of this, one can apply all other physical security controls to this concept (e.g., motion detectors, physical intrusion detection alarms, CCTVs, etc.). The biggest advantage is with role-based access control models. In role-based access control schemes, users are assigned access to systems, information, and physical areas according to their role in the organization.

Exhibit 158.1 displays a basic example of the use of zoning for role-based access control. In this example, the zones are labeled 1 through 4, 4 being the most restrictive. In this facility, every employee has access to zones 1, 2, and 3; however, the Information Technology Director, IT staff, and Security Manager, have access to zones 1, 2, 3, and 4 because of their roles.

The natural progression of security is obvious; the zones become more restrictive as one moves further into the facility (from left to right). Once this exercise is completed, the next step would be to determine the controls that should be put in place to support access control zones. Keep in mind that the more restrictive the zone, the stronger and more reliable the controls should be.

By combining physical access controls, role-based models, and zoning, one can build a thorough and centralized system to physically protect one's information and assets. Zoning can be a very important part of one's information security strategy. However, prior to conducting a zoning exercise, one should have already conducted a risk analysis (to understand the threats to and vulnerabilities of one's assets), and developed a risk mitigation strategy. Only then will zoning provide for a solid foundation from which an organization can achieve its information security goals.

Information Systems Physical Security

The second part of physical security is the physical protection of information systems. As discussed, protection should come in layers. If the physical integrity of just one of an organization's computers is com-

promised, information security could be at risk. If someone were to gain unauthorized physical access to a computer, that person could also gain access to all of the information on that computer and possibly any other resource that computer is connected to (including file servers, mainframes, and e-mail).

Information System Classification

Information systems can be classified into three types:

1. *Servers/mainframes:* Usually the most physically secure class of systems. This is due to the common practice of placing them in a location that has some form of access and environmental control. Although this class may be the most physically secure, their overall security is dependent on the physical security of the workstations and portable devices that access them.
2. *Workstations*: Usually located in more open or accessible areas of a facility. Because of their availability within the workplace, workstations can be prone to physical security problems if used carelessly.
3. *Portable devices*: Can be an organization's security nightmare. Although issuing laptops and PDAs to employees facilitates flexibility and productivity in an organization, it poses several serious risks with regard to physical security. With users accessing the company's internal information systems from anywhere, a breach in physical security on one of these devices could undermine an organization's information security. Extreme care must be taken with this class.

Information Systems Physical Threats and Controls

Classifying information systems helps determine which threats pose a greater risk to which systems. This provides a guideline for applying controls. Probably the biggest threat to information systems is that of the user. Keep in mind that if any user fails to practice due diligence in physically protecting their computing assets, nearly all controls will become ineffective, rendering the device vulnerable. This chapter section outlines the basic threats and controls for information systems.

- Loss/theft/destruction poses the following risks:
  - Loss of sensitive information or trade secrets
  - Loss of productivity
  - Loss of revenue
- Loss/theft/destruction controls include:
  - Physical locks for devices
  - Marking and tagging devices
  - Minimize use of location signs
  - Encryption for sensitive information storage
  - Data classification and handing procedures for sensitive information
  - Insurance
  - Awareness training
  - Visible closed circuit television cameras (CCTVs)
  - Guards
  - Alarm systems
  - Routine audits
- Unauthorized access poses the following risks:
  - Loss of sensitive information or trade secrets
  - Information tampering
  - Malware
  - Loss of revenue
- Unauthorized access controls include:
  - Locking consoles
  - Good password practices

— Awareness training
— Data classification and handing procedures for sensitive information
— Minimizing the use of location signs
— Visible closed circuit television cameras (CCTVs)
— Encryption for sensitive information storage
— Strong authentication and access controls

Awareness Training

Although information systems are more prevalent in the world today than ever before (and continue to become ever more so), we nonetheless still live in a physical world. All employees affect physical security, which directly impacts their organization's information security. It is common to find that a majority of physical security failures are due to unaware employees circumventing the controls. Ensuring that all employees receive regular awareness training reduces unintentional security bypasses, while providing an economical way to mitigate risks. No matter how well an information security program is designed and implemented, it only takes one unknowing employee to render it ineffective. Physical security must be among the topics presented in an awareness program, which should also include the following:

- Demonstrate to all employees how even the smallest disregard for physical security can quickly develop into an information security incident or loss of life.
- Educate employees on the security standards and guidelines for the organization. Ensure that employees understand the responsibilities expected of them.
- Distribute monthly publications regarding information security to all employees. Include physical security as a regular topic.
- Provide special orientation for upper management, taking them on tours and offering them a behind-the-scenes look at how information security is done. This rallies support.

Taking the time and effort to provide awareness training will boost the effectiveness of not only one's physical security, but also the entire information security program. By making employees cognizant of the their responsibilities, one can instill a sense of ownership and duty. This transforms the human factor from a disadvantage to an advantage.

Summary

Physical security is more than a niche of information security. In some cases, an organization will have good, strong physical security, but lack many other components of information security. As a practitioner of information security, one must understand the scope and know how to use physical security for protecting assets. Complete physical security will protect all assets, setting a good foundation upon which to build other forms of protection. It is clear that physical security is the foundation for information security.

Physical Security: Contolled Access and Layered Defense

Bruce R. Matthews, CISSP

> *Security* (si kyoor'e tē) *n.*, pl. –ties 1. A feeling secure; freedom from fear, doubt, etc. 2. Protection; safeguard.

The above Webster's definition can be restated for the security practitioner as controlled access. In fact, every aspect of an IT security practitioner's job revolves around the process of defining, implementing, and monitoring access to information. This includes physical access. When to use it, how much, and the best way to integrate it with traditional IT security methods, are concepts the IT security professional must be familiar with. The IT security specialist need not be an expert, someone else will fill that role, but effective policies and strategies should take into account the benefits as well as limitations of physical protection. Success depends on close collaboration with the physical security office; they have more than just IT security on their minds and a mutual respect for each other's duties goes a long way. Thus cross training can prove invaluable, particularly when an incident occurs. In essence, a layered, multidisciplined approach can provide a secure feeling; freedom from fear, doubt, etc. Controlled access is security.

Security Is Controlled Access

When one thinks of security, one often thinks of it only in terms of implementation. In IT security, one thinks of passwords and firewalls. In personal security, one thinks of avoiding rape and muggers by staying away from dark alleys and suspicious-looking characters. However, to place physical security in the context of IT security, one must examine what security is — not just how one implements it. In the simplest of terms, it boils down to: security is controlled access. Implementing security, therefore, is the process of controlling access. Passwords and firewalls control access to network and data resources. Avoiding dark alleys and suspicious characters control access to our bodies and possessions. Likewise, security in the home generally refers to locks on the doors and windows. With the locks, one is controlling the access of persons into the protected area. Everyone is denied entry unless they can produce the proper key. By issuing keys to only those persons one desires, one is controlling access. Because one normally does not want anyone entering through the windows after-hours (although a teenager may have a different viewpoint), there is typically no key lock on windows and the level of control is total denial of access. Home alarm systems are gaining increased popularity these days. They also control access by restricting the movements of an intruder who is trying to avoid detection.

The definition — security is controlled access — also holds true for the familiar information security concepts of availability, integrity, and confidentiality. Availability is ensuring access to the data when needed. Integrity implies that the data has been unmodified; thus, access to change the data is limited to only authorized persons or programs.

Confidentiality implies that the information is seen only by those authorized. Thus, confidentiality is controlling access to read the data. All of these concepts are different aspects of controlling access to the data. In a perfect world, one could equate assurance with the degree of control one has over access. However, this is not a perfect world, and it may be more appropriate to equate assurance with the level of confidence one has in the controls. A high level of assurance equates to a high level of confidence that the access controls are working and vice versa. For example, locking the window provides only moderate assurance because one knows that a determined intruder can easily break the window. But a degree of access control is gained because the intruder risks detection from the sound of breaking glass.

Bear in mind, and this is important, that more security is not necessarily less access. That is, controlled access does not equal denied access. The locked window is certainly a control that denies access — totally (with respect to intent, not assurance). On the other hand, Social Security provides security by guaranteeing access to a specified sum of money in old age, or should one say the "golden years." (However, the degree of confidence that this access control will provide the requisite security is left as an exercise for the reader.) It is obvious that practically all controls fall somewhere in between providing complete access and total denial. Thus, it is the level of control over access — not the amount of access — that provides security. Confidence in those controls provides assurance.

This leads to the next topic: a layered defense.

A Layered Defense

A layered defense boosts the confidence level in access controls by providing some redundancy and expanded protection. The details of planning a layered defense for physical security is beyond the scope of this chapter and should be handled by an experienced physical security practitioner. However, the IT security specialist should be able to evaluate the benefits of a layered defense and the security it will and will not provide. When planning a layered defense, the author breaks it into three basic principles: breadth, depth, and deterrence.

Think of applying "breadth" as plugging the holes across a single wall. Each hole represents a different way in or different type of vulnerability. Breadth is used because a single type of control rarely eliminates all vulnerabilities. Relating this first in the familiar IT world, suppose one decides to control read access to data by using a log-on password. But the log-on password does not afford protection if one sends the data over the Internet. A different type of control (i.e., encryption) would therefore provide the additional coverage needed. Physical security works much the same way. For example, suppose one needs to control access to a hot standby site housed in a small one-story warehouse. The facility has a front door, a rear door, a large garage door, and fixed windows that do not open. Locks on the doors control one type of pathway to the inside, but offer no protection for the breakable windows. Thus, bars would be/could be an additional control to provide complete coverage.

The second principle, depth, is commonly ignored yet often the most important aspect for a layered defense. To be realistic with security, one must believe in failure. Any given control is not perfect and will fail, sooner or later. Thus, for depth, one adds layers of additional access controls as a backstop measure. In essence, the single wall becomes several walls, one behind the other. To illustrate on the familiar ground, take a look at the user password. The password will not stay secret forever, often not for a single day, because users have a habit of writing them down or sharing them. Face it; everyone knows that no amount of awareness briefings or admonishments will make the password scheme foolproof. Thus, we embrace the common dictum, "something you have, something you know, and something you are." The password is the "something you know" part; the others provide some depth to the authentication scheme. Depth is achieved by adding additional layers of protection such as a smart card — "something you have." If the password alone is compromised, access control is still in place. But recognize that this too has limitations, so one invokes auditing to verify the controls. Again, physical security works the same way.

For physical security, depth usually works from the outer perimeter, areas far away from the object to be protected, to the center area near the object to be protected. In theory, each layer of access control forms a concentric ring toward the center (although very few facilities are entirely round). The layers are often defined at the perimeter of the grounds, the building entrance and exterior, the building floors, the office suites, the individual office, and the file cabinets or safes.

Deterrence, the third principle, is simply putting enough controls in place that the cost or feasibility of defeating them without getting caught is more than the prize is worth. If the prize to be stolen is a spare $5000

server that could be sold (fenced) in the back alleys for only $1000, it may not be worth it to an employee to try sneaking it out it out a back door with a camera on it when loss of the job and jail time may cost that employee $50,000. Notice here that the deterring factor was the potential cost to the employee, not to the company. A common mistake made even by physical security managers is to equate value only to the owner. Owner value of the protected item is needed for risk analysis to weigh the cost of protection to the cost of recovery/replacement. One does not want to spend $10,000 protecting a $5000 item. However, the principle of deterrence must also consider the value to the perpetrator with respect to their capability — the bad guy's own risk assessment. In this case, maybe an unmonitored $300 camera at the back door instead of a $10,000 monitored system would suffice.

A major challenge is determining how much of the layered defense is breadth and depth in contrast to deterrence. One must examine each layer's contribution to detection, deterrence, or delay, and then factor in a threat's motivation and capabilities. The combined solution is a balancing act called analytical risk management.

Physical Security Technology

Security Components

Locks

Physical security controls are largely comprised of locks (referred to as locking devices by the professionals). In terms of function, there are day access locks, after-hours locks, and emergency egress locks. Day locks permit easy access for authorized persons — such as a keypad or card swipe. After-hours locks are not intended to be opened and closed frequently and are often more substantial. Examples are key locks, locked deadbolts, padlocks, combination padlocks, or high-security combination locks like one would see on safes or vault doors. Emergency egress locks allow easy access in one direction (i.e., away from the fire), but difficult access in the other direction. A common example is the push or "crash" bar style seen at emergency exits in public facilities. Just push the bar to get out, but one needs a key to get back in.

In terms of types, locks can be mechanical or electrical. A mechanical lock requires no electric power. Most of the locks used daily with a key or combination are mechanical. An electric lock requires electricity to move the locking mechanism, usually with a component called a solenoid. A solenoid is a coil of wire around a shaft. The shaft moves in or out when electric current flows through the coil. Another type of electric lock uses a large electromagnet to hold a door closed. The advantage is few moving parts with considerable holding power.

The way people authenticate themselves to a lock (to use an IT term) is becoming more sophisticated each day. Traditionally, people used a key or mechanical combination. Now there are combination locks that generate electricity when one spins the dial to power internal microprocessors and circuits. There are also electronic keypads, computers, biometrics, and card keys to identify people. Although this is more familiar territory to the IT security professional, it all boils down to activating a locking device. Collectively, authentication combined with door locking devices is referred to as a "door control system."

Barriers

Barriers include walls, fences, doors, bollards, and gates. A surprising amount of technology and thought goes into the design of barriers. The physics behind barriers can involve calculations for bomb blasts, fire resistance, and forced entry. Installation concerns such as floor loading, wind resistance, and aesthetics can play a role as well. Making sense of the myriad of options requires the answer to the following question: Who or what is the barrier intended to stop, and for how long?

To supply the answer, think of the barrier as an element of access control. It is not a door to the office, but something to control "whom" or "what" is allowed into the office. Is valuable data stored in the office, such as backup tapes, or is the concern with theft of hardware? Is the supposed thief an employee, or is it a small company where a break-in is more likely? Is the office in a converted wooden house where liability for data lost in fire is the primary concern? If so, how long does one need to keep the fire at bay (i.e., what is the fire department response time)? Know these answers.

Alarms

Barriers and the locks that secure them directly control access. Alarms are primarily for letting us know if that control is functioning properly — that is, has it been breached? Alarms tell us when some sort of action must

be taken, usually by a human. A fire alarm may automatically activate sprinklers as well as the human response by the fire department. In terms of a layered defense, the presence of alarms also adds to the deterrence. Alarms are usually divided into two parts: the controller and the sensors. The sensors detect the alarm condition, such as an intruder's movements or the heat from a fire, and report it to the controller. The controller then initiates the response, such as an alarm bell or dialing the police department. A facility that monitors several control units is referred to as a "central monitoring" facility.

As indicated, sensors usually detect environmental conditions or intrusion. Environmental conditions include temperature, moisture, and vibration. Temperature not only protects against fire, but can alert us to the air conditioner failing in a server room. Moisture may indicate flooding due to rains or broken plumbing. Vibration sensors are used both in environmental sensors, to protect sensitive hardware, and in intrusion detectors such as glass breakage sensors or on fences to detect climbing. Other intrusion sensors detect human motion by measuring changes in heat or ultrasonic sound within a room. In fact, many intrusion sensors are really just environmental sensors configured for human activity. Thus, innocuous items such as coffee pots not turned off or room fans can generate false alarms.

Doors are usually monitored with magnetic switches. A magnet is mounted on the door, and a switch made of thin metal strips is mounted on the doorframe. When the door is shut, the magnet pulls the metal strips closed, completing a circuit (or pushes them open to break a circuit).

The perimeter of an area can be monitored with microwave or infrared beams that are broken when a person passes through them. Cables can be buried in the ground that detect people passing overtop. Animals are a source of false detection for these perimeter sensors.

An important feature of many alarm systems is how the sensors communicate with the controller — wireless or wired. Wireless systems are generally cheaper to install, but can suffer radio frequency interference or intentional jamming. Wired systems can be expensive or impractical to install but can be made quite secure, especially if the wires are in conduit. Whether wired or wireless, the better systems will incorporate some method for the controller to monitor the integrity of the system. The sensors can be equipped with tamper switches and the communication links can be verified through "line monitoring."

The key question for alarms is: who and what is it supposed to detect, and what is the intended response? The "who" will define the sophistication of the alarm system, and the "what" may dictate the sensitivity of the sensors. Provided with this, the alarm specialist can then determine the appropriate mix and placement of sensors.

A major task of the alarm controller is to arm and disarm the system, which really means to act upon or ignore the information from the sensors. With such a vital function, one must have some means to authenticate the person's authority to turn off the alarm system. Like the locks in the previous chapter section, the methods to do this are essentially the same as for authenticating to any information system, ranging from passwords to smart cards to biometrics, with all the same pros and cons.

Lights and Cameras

Lights and cameras are combined because they serve essentially the same function: they allow us to see. In addition, lighting is a critical element for cameras. Poor light or too much light, such as glare, can mean not seeing something as big as a truck. Proper camera lighting is a field unto itself; and for high-security situations, data from lighting and camera manufacturers should be consulted. A common misuse of cameras is assuming that they will detect an intruder. With a camera, the possibility certainly exists; in terms of deterrence, both lights and cameras increase the risk to perpetrators that they will be seen. For many low-threat situations, this is sufficient; however, as threat or risk increases, they cannot be relied upon. If a guard's attention is focused elsewhere (and often is), the event will go unnoticed. If ever in doubt, try putting a camera outside an access door without a buzzer for people to ring. People will become rapidly annoyed that the guard does not notice them and open the door fast enough. Cameras are best suited for assessing a situation — a tool to extend the eyes (and sometimes ears) of the guard force.

Antitheft, Antitamper, and Inventory Controls

It is obvious that the theft of computers and peripherals can directly affect the availability and confidentiality of data. However, tampering is also an issue, particularly with data integrity. Physical access affords the opportunity to bypass many traditional IT security measures by inserting modems, wireless network cards, or additional hard drives to steal password files, boot up on alternate operating systems, and allow unauthorized

network access — the list goes on and on. Physical access to security peripherals such as routers may enable someone to log in locally and modify the settings.

The retail and warehouse industries have created a wide range of products to prevent theft and tampering. Antitamper devices control access to ensure the integrity of the protected asset, whereas antitheft devices and inventory controls are intended to limit movement to a confined area. The technologies behind these products have rapidly spilled over into new product lines designed to protect IT assets.

Antitheft devices include locked cages, cabinets, housings, cables, and anchors. Labels and inventory controls such as barcodes discourage theft. More sophisticated devices include vibration or motion sensors, power line monitoring, and electronic article surveillance (EAS) systems. Power line monitoring alerts us when someone has unplugged the power cord of a computer or other protected asset. EAS systems alert us when a protected asset is moved from a designated area. The most familiar EAS devices are probably those little tags attached to clothes or merchandise in retail stores. They cause that annoying alarm when one departs the store if the clerk forgets to disable it.

Antitamper devices include locked cabinets, locking covers, microswitches, vibration or motion sensors, and antitamper screws.

The Role of Physical Security

A basic role of physical security is to keep unwanted people out, and to keep "insiders" honest. In terms of IT security, the role is not that much different. One could change "people" to "things" to include fire, water, etc., but the idea is the same. The greatest difference is expanding the assets to be protected. Physical security must not only protect people, paper, and property, but it must also protect data in forms other than paper.

So where does one start? Recall the above descriptions of depth in a layered defense where one countermeasure or barrier backstops the preceding one. In a textbook analysis, sufficient depth is determined by security response time. The physical security practitioners view each control or countermeasure as a delaying action. The amount of the time it takes for the guard force to respond is equivalent to the minimum delay needed. Although a tried and true strategy in the physical security realm, it was only recently proposed as an IT security strategy.[1]

For the physical world, it works like this. Suppose one has an estimated response time of ten minutes by the local police. One discounts the perimeter wall as only a deterrent because there are no alarms there. The first alarm is at the front door, which one estimates will take two minutes to get past. Thus, one needs an additional eight minutes worth of inside layers between the door and the cash for the police to apprehend the thief.

For the IT world, layering brings to mind firewalls backed up by routers, backed up by proxies, etc. Notice that physical controls were backed up by additional physical controls and "cyber" controls were backed up by more cyber controls. This is okay to a point; but for data security, the roles of physical and cyber controls should be to complement one another. They become interleaved in a multidisciplinary defense.

A Multidisciplinary Defense

In a multidisciplinary defense, more than one skill set or expertise is brought to bear on the security problem. Physical security is comprised of several disciplines, ranging from barrier technology to antitamper devices. Each discipline aids another. Each component has a purpose to be used in concert with another. The basic relationship between components at each layer is the need to prevent a security event, detect a security event, and assess a security event. For example, there is a locked door with alarm contacts and a camera. The door blocks the way to prevent entry. If the door is opened, the alarm alerts the guard. The guard then uses the camera to assess the situation and decide on an appropriate response. Multiple technologies are integrated to prevent, detect, and assess.

Now take a broader view and consider physical security as a single discipline and IT security as a single discipline. Although separate disciplines, one cannot have one without the other. For example, the payroll office is using Windows NT. The administrator has installed the password filter to ensure that users create quality passwords. Auditing is turned on; file and directory permissions are set. The administrator is aware that the passwords, and hence the network, are still vulnerable because the computer can be booted from removable media (i.e., the floppy drive or CD-ROM). Once booted from a floppy, the password files can be

stolen and cracked. There are always a number of people working late at the company, with a night shift on the factory floor, but payroll employees are generally gone by 4 p.m. (except before payday).

One solution is to disable the floppy and CD-ROM. But this idea is met with a polite yet firm "not if you value your job…" from management. One could modify the boot function from the bios, install a switch and use the tamper alarm option on the motherboard, and replace the computer case screws with a tamper-resistant type. That is one example of a multidisciplinary approach; but considering the number of clients, one does not relish the extra work — particularly when one is constantly servicing the machines. So think more physical security and back up one layer. Put a high-security deadbolt on the payroll office door. Okay, this example seems fairly intuitive, but are we finished? If one has a guard service, then one would want to brief them on the importance of ensuring that the door is closed after normal hours and to make note of a nonpayroll employee who seems to be rebooting or using a payroll computer. How does the guard know who is an authorized payroll (or systems admin) employee? Provide a list. These "extra" physical security details can be easily forgotten.

Now turn the tables. You are chatting with the guards who are quite happy with the new card-access system (the result of a backroom deal with payroll). They have absolute accountability and control over who enters the various sensitive offices. You are happy; your payroll information is secure. Physical security is quite impressive with this set up-and-forget security wonder. There are fewer guards (okay, not all the guards were so happy) and they no longer wander the hallways all night. But then you begin to wonder, where is this card-access system computer located? You learn it is in a closet down the hall and it too is running Windows NT — with a blank password administrator account and no auditing. Hmm, are your payroll files still safe from a computer-savvy, disgruntled employee? From an ex-guard who is now working in janitorial? Perhaps the remaining guards need some IT security assistance.

The Economic Espionage Act of 1996 brings to bear the importance of protecting data, both physically and electronically. The act makes the theft of trade secrets an act of espionage if the benefactor is a foreign government. However, contained in the definition of "trade secret" is the following statement:

> (A) the owner thereof has taken reasonable measures to keep such information secret; unfortunately, there is no firm legal definition of "reasonable measures," but as a starting point, Mr. Patrick W. Kelley, J.D., LL.M., M.B.A, FBI's chief of the Administrative Law Unit, Office of General Counsel, at FBI Headquarters in Washington, D.C., in 1997 provided the following guidance to their field agents: Advise businesses that "owners must take affirmative steps to mark clearly information or materials that they regard as proprietary, protect the physical property in which trade secrets are stored, limit employees' access to trade secrets to only those who truly have a need to know in connection with the performance of their duties, train all employees on the nature and value of the firm's trade secrets, and so on."[2]

This is good advice to protect any valuable information, trade secret or not. In fact, Mr. Kelley's advice is common-sense security practice. One can capture this common sense with the following tenets: identify it, label it, secure it, track it, and know it. These tenets represent the practical side of controlling access. Below are some common physical security implementations, along with their IT security counterparts.

1. Identify it.
   a. *Physical security.* The U.S. government refers to this as classification guidelines. Decide what needs to be protected, and create guidelines on how to recognize it by subject matter or keywords. The guidelines should enable a company novice to determine, based on content, the sensitivity of a document. For example, perhaps any document that describes the project goal or the name of the client is "company confidential" whereas the project name is not sensitive.
   b. *IT security.* The same as physical security, except create an electronic classification guide. Hyperlink it by subject and keyword so a user can easily determine (by answering a series of questions) the material's sensitivity and what is required in terms of the policies.
2. Label it.
   a. *Physical security.* Use a rubber stamp or stickers to identify sensitive documents. Document folders should be distinctive (color or colored band) and labeled. Labels should indicate special handling requirements, dates for downgrading sensitivity, and who has authorized access to it.
   b. *IT security.* Use automatic document headers/footers or cover pages for sensitive data. Automatically print out cover pages.

3. Secure it.
    a. *Physical security.* Create the physical layers of defense based on risk. The following is a list of possibilities for each physical security layer; it does not imply that everyone needs all this stuff. Working from the outer ring inward, these are common options that form layers of physical security that the IT security practitioner should be aware of.
        i. *Perimeter.* Perimeter access controls include physical barriers such as fences, walls, barbed wire, gates, and ID checks. Alarms and cameras are used at the perimeter.
        ii. *Building grounds.* Within the building grounds, cameras, lights, alarms, and roving guards can be deployed, along with physical barriers to control traffic flow (foot or vehicle).
        iii. *Building entrance.* In closer is the facility building where there are doors, locks, barred windows, cameras, alarms, and perhaps another ID check or a card-access system (common in many hotels to gain entry to a room instead of a key).
        iv. *Building floors.* Deeper into the building one might have access limited by floor, with special keys for the elevator as in some hotels and alarmed stairwells. Stairwells and hallways may be monitored with cameras.
        v. *Office suites.* Access controls for the office suite include card-access systems, locks, and keypads that require a code to be entered, human receptionists, and steel or solid-core doors. Wooden doors are typically hollow inside to reduce weight, making them easier to swing and providing less wear-and-tear on the hinges. However, the locks, including deadbolts, do not have much to grab onto and are easily pushed open. Solid cores strengthen the doors considerably. Within the suite may be individual offices with keypads, cards, or regular locks.
        vi. *Office physical security.* Once inside the office, there may be lockable file cabinets, safes, vaults, antitheft/tamper devices, and alarm systems. Lock up any sensitive disks, CD-ROMs, or media. Consider fire/water-resistant storage containers. Use paper shredders.
        vii. *IT security.* Create the IT layers of defense based on risk. Make use of firewalls, proxy servers, routers, network address translation, switches, network monitoring, etc. Use passwords or user authentication, invoke file rights and permissions, anti-virus, data backups, data encryption, or overwrite utilities. Monitors away from observable windows, emergency power source (UPS or generator), spare equipment.
4. Track it.
    a. *Physical security.* Access lists (need-to-know), checkout lists, inventory controls, audits, and registered or insured mail.
    b. *IT security.* Auditing, digital certificates/signatures, file permissions, etc.
5. Know it.
    a. For both physical and IT security, make sure people know what to do and why. Create the policies to implement the protection. Policies should spell out the required access controls and handling procedures. Different jobs have different responsibilities, so vary the presentations and training accordingly.
    b. *Physical security.* Handling procedures should cover issues such as copying, mailing, how long material will be sensitive, and destruction requirements.
    c. *IT security.* Policies for electronic handling, such as copying, e-mailing, posting on Web sites, and deleting files, should be created.

Integrating Physical Security with IT Security Policy

Policies created to fulfill the "know it" tenet provide the necessary roadmaps to implement the other tenets. Policies instruct us to take the steps outlined in the other tenets. With each tenet, there were physical security examples and corresponding IT security examples. Thus, the policies to protect information must address both physical and IT security requirements. Why protect information in digital form, and then not write policy to protect it in paper form? Policy should cover both. They should be consistent in approach, but not always identical in application. For example, suppose there is a policy to ensure that project confidential information is delivered securely to project partners. For the paper world, a sealed envelope might be sufficient; but for the digital world, robust encryption is needed. So why not encrypt the envelope as well? Certainly, the delivery cyclist is capable of tearing open an envelope; so should it not have the same protection? The reason is the

scale of risk. The cyclist can be identified, is probably bonded, and if he or she should drop it, very few people would likely ever see the contents. However, when sending data across the Internet, one has no idea who might come in contact with it, and it can be replicated and redistributed in enormous quantities with amazing speed at virtually no cost to an unethical person. The approach to the "secure it" tenet is the same for digital and nondigital information: deliver it securely; however, the implementations for each are tailored to individual risk.

On the digital side of policy, one cannot divorce oneself from physical access control. For example, a high-level policy states: "Users must be uniquely identified for gain network access." From this emerge standards for passwords, password receipts, and password storage. However, as illustrated previously in the payroll scenario, success for the high-level policy is not assured until one includes standards for protecting physical access to the computer, be it disabling floppy drives or locking the office door. Ensure that IT security policies and standards address avenues of access control in both the physical and digital worlds; this enhances the depth and breadth. Breadth is also improved if standards and policies are applied across the board. If the standards were applied to all networked computing assets in the payroll scenario, the alarm system computer would be covered as well.

Pitfalls of Physical Security

When implementing physical security, be aware of some common limitations and failings.

1. *Social engineering*. As in IT security, social engineering works quite well to bypass physical security controls. Typically, as long as a person appears to belong, no one will question him. If the person provides a plausible story, a guard may concede. Day-access combination locks and electronic card key systems do not suffer guilt when denying access. However, someone can be conned into sharing the combination or opening the door.
2. *Compromise of combinations*. Like passwords, combinations are often written down or posted. They can be also observed by "shoulder surfing."
3. *Tailgating*. A common practice is to "tailgate" into a facility. To tailgate, just wait until an authorized person enters, then walk in behind that person before the door shuts. Often, that person will even hold the door for the tailgater. Following a group is even easier; just feign impatience with them as they take time to get through in front of you. They might let you go first!
4. *Weather/environmental conditions*. Foul weather, bright sunlight, reflections, fog, etc. can render cameras useless or generate false alarms in the sensors. Like a dirty automobile windshield, dust and dirt on a camera lens compound the glare when looking toward the sun. Excessive heat or cold can cause equipment to malfunction. Trees or branches can interfere with perimeter alarms, as can animals and birds.
5. *Appliances*. Appliances that get hot or cold can affect motion detectors and give unwanted alarms. Therefore, take particular care to turn off coffee pots and hotplates after work hours. Moving appliances (fans) or furnishings (window blinds blowing around) generate unwanted alarms, as can a cold wind blowing into a warm room. Interference from electrical noise, like that generated by faulty refrigerator compressors, or acoustical sound such as steam escaping from heating radiators, can cause false indications in sensors.
6. *Complacency*. Either unwanted alarms or false alarms intentionally induced by bad guys creates a loss of faith in the alarm system. For example, whacking a fence equipped with a vibration sensor would generate alarms. After repeated checking and finding no one climbing a fence, the alarms are soon ignored. Long periods of inactivity can also cause complacency or slow response. Occasional drills or competitions may help break the monotony.
7. *Notification of video surveillance*. Similar to notifying users of their lack of privacy when on the company computer system, people should be informed that they are under video surveillance. If the camera and view is not in a public area, it may be a legal requirement. Consult an attorney.
8. *User acceptance*. Users might balk at security measures they feel are too intrusive, difficult, or unsafe — whether their concern is justified or not. If they consider something as ugly, it might be vandalized or management might elect to remove it (or not approve it in the first place). One may have to gain approval from a labor union as well. If they will not accept it, despite efforts at education, one might have to rely on a different security layer or become very creative. At times, it may be a risk deemed acceptable.

IT and Physical Security Teamwork

"Hey! That is the least of my concerns." "Take a number." "Ooh, he is armed and dangerous with a floppy." "<sigh>, Rent-a-Cops. They just do not get it." "<sigh> Computer dweebs. They just do not get it." In fact, none of us ever truly "gets it." If we did, we would be doing the other guy's job. Granted, in small organizations, we probably will be doing the other guy's job; but in larger organizations, with separate physical and IT security personnel, there must be teamwork. Okay, that is a cliché, but teamwork is more than understanding each other's needs and expounding on the virtues of synergy. Teamwork means starting with the understanding that one will never be at the top of another person's priority list. Seek to understand where you *should* fit into each other's priority list. If one works within that framework, then maybe one can achieve some realistic progress.

Well-written policies establish a starting point for teamwork. The policies will identify the specific roles and responsibilities for the physical security team and security officers. A comparison of the physical and IT security requirements articulated in policies may reveal areas of common ground between the two, such as incident response. Whether or not clear policies exist, one can build teamwork on the following triad: education, collaboration, and implementation.

Education

Invite the physical security practitioners, both designers and officers, to attend some computer security courses. Encourage them into the IT world so they can understand where they fit in. A classroom environment is a great place for sharing perceptions and becoming accustomed to the IT practitioner's mindset. Bring them into the courses as mentors, not just as students; they bring a different perspective to the classroom problems. Professional security officers can be quite creative (read "devious") when challenged to think like the opposition; a challenge they frequently engage.

In addition to coursework, educate the physical security crew to in-house IT vulnerabilities that are closely related to their work, such as the susceptibility of outside diskettes to introducing viruses or the potential theft of backup tapes of sensitive data. Do not merely tell them that it is a bad thing and could wipe out the entire corporate profits if taken. Be specific. Show them exactly where the vulnerability exists. If possible, demonstrate it so that they understand the time involved for someone to pull off the crime and what resources they would need. For example, if modems are not permitted in a particular facility, or if breaking into the operating system requires removing the computer case, let them know. Show them what a modem looks like, in comparison to a network interface card. Keep it in their language without being condescending; that is, "You know that little jack on the wall your phone plugs into? Well, a modem card at the rear of a computer will have two of those, one for the telephone and one for the phone line. If it has just one, it is probably the network card, which is okay."

Collaboration

Developing procedures and access controls is enhanced by close collaboration between IT and physical security personnel. If consistency is apparent to users, there will be a greater buy-in on their part. If one labels sensitive documents with a specific color, then labels for diskettes containing the electronic version of those documents should also be the same color. If one requires sensitive documents to be stored in a specific locked file cabinet, perhaps keep the electronic versions in the same or similar locked cabinet.

Collaboration is also helpful for the risk assessments. Applying the principles of a layered defense can become quite complicated and, at times, quite expensive. To design physical protection that is appropriate and creative, a risk management exercise should be completed. In practice, a physical security practitioner may not understand the true value of an item such as a spare server, and the tendency will be to look at the cost of hardware replacement. What if the spare server contained corporate data? What if it was staged for use as a warm standby situation? On the other hand, the IT security practitioner may not recognize creative ways to implement or bypass physical security controls or the extent of insider pilfering. The physical security practitioner generally has a better handle on the costs and practicality of security systems. Maybe a perimeter alarm system sounds great until one finds out too late the additional costs of burying cables under a driveway. Thus, if a company or organization is large enough to have a physical security office or manager, ensure they take part in the process. If hiring a risk assessment company, or providing those services, make sure there is a physical security

expert on staff and that they consult with the client security officers. The security officers may have on-site knowledge of vulnerabilities, emergency service response times, and threats unknown to the hired consultant.

During collaboration, do not forget to address issues such as incident response, particularly with respect to laws and statutes, and contingency plans. Agree on what types of incidents will be pursued aggressively and which will be dealt with at a lower level or as time permits. One does not want one office jumping up and down while the other puts it on the back burner. Identifying competing priorities is also important to identify and iron out at this stage. Maybe the theft of a spare server becomes a low-priority incident to the IT office when it confirms the thief did not intrude on the network and the server had no data. But when the physical security office discovers that the thief broke a fire door, rendering the alarm system inoperable, it becomes a huge life-safety issue. The security office needs to let the IT staff know their priority on pursuing an investigation or prosecution because it may affect issues of evidence where the server was stored. Establish a process for communicating these tactical issues.

Implementation

Whatever is decided during collaboration, make it happen. Test it. See what does not work well; then jump back to the education and collaboration steps to resolve it. Fine-tuning the implementation is a continual process.

Shopping for More Information

A good place to start is with the American Society for Industrial Security (ASIS); it can be found at www.asisonline.org. The ASIS promotes education in security management and offers an ASIS Certified Protection Professional (CPP) Program. At its Web page, one will find an abundance of reference material and publications.

Another organization is the Overseas Security Advisory Council (OSAC). OSAC, established in 1985 by the Department of State, is a joint venture between the U.S. government and the American private sector operating abroad to foster the exchange of security-related information. Administered by the Bureau of Diplomatic Security, the OSAC provides information to organizations to help them protect their investment, facilities, personnel, and intellectual property abroad. Additional information can be found at www.ds-osac.org.

When hiring a physical security consultant, look for the CPP certification combined with experience in the IT sector. A certification that includes expertise in both IT and physical security is the Certified Information Systems Security Professional (CISSP). If a consultant is not professionally certified, look at his or her experience and background. Former law enforcement, military, federal or government investigators, and security engineers are examples of good backgrounds for a consultant. These backgrounds coupled, with professional certification, can make a great package.

The National Center for Education Statistics has some good tips and a checklist for physical security at http://nces.ed.gov/pubs98/safetech/chapter5.html. Although it is intended for schools, which are often strapped for cash and security resources, many of the tips are applicable anywhere.

If one is interested in locks, there is a nice beginner tutorial at http://www.rc3.org/archive/inform/5/4.html. Originally published in a now-defunct hacking zine, *Informatik*, it covers basic lock types and methods of defeating them. It is about ten years old and does not cover high-security locking devices, but it is a quick read and informative.

Infosyssec.org, http://www.infosyssec.org/infosyssec/physfac1.htm, lists a dizzying array of links to physical security companies and information. This should not be the first stop for the physical security novice; but for experienced practitioners, this is a good place to locate a particular vendor or seek specific information.

Conclusion

When challenged to secure data, a wise IT security manager will heed the contributions of physical security. Understand that security is controlled access and that it is best implemented through a layered defense. The layered defense features breadth, depth, and deterrence to ensure that all areas are covered, and that the coverage has fallback contingencies. There is an abundance of technologies to draw upon for each layer. For small or low-equity assets, the choices may be as simple as a lock on the door; but as the value and associated risk

increase, the role of each component becomes more important. Is there a need to detect or assess a situation, or is deterrence the primary objective? If one knows the roles, one can determine how they complement one's IT security strategy and where one's security strategies still fall short or need shoring up. Using the simple tenets — identify it, label it, secure it, track it, and know it — as a template against an existing strategy or to create a new one, will help in assessing how physical and digital security complement each other and help root out those remaining gaps as well. None of the gaps, however, will be adequately filled in practice unless there is detailed collaboration and cooperation between those responsible for physical and digital security. Policies and procedures should establish the relationship, and cross-training should foster it. The benefits and, perhaps more importantly, the limitations of each discipline can be derived from cross-training. Remember: the common goal is to control access. Achieving this, both physically and digitally, gets us much closer to providing a feeling secure; freedom from fear, doubt, etc.

Note

This chapter is dedicated to my father, Floyd V. Matthews, Jr., Professor Emeritus, Cal Poly University, Pomona, California.

Computing Facility Physical Security

Alan Brusewitz, CISSP, CBCP

Most information security practitioners are experienced in and concentrate on logical issues of computer and telecommunications security while leaving physical security to another department. However, most of us would agree that a knowledgeable person with physical access to a console could bypass most of our logical protective measures by simply rebooting the system or accessing the system that is already turned on with root or administrator access in the computer room. Additionally, an unlocked wiring closet could provide hidden access to a network or a means to sabotage existing networks.

Physical access controls and protective measures for computing resources are key ingredients to a well-rounded security program. However, protection of the entire facility is even more important to the well-being of employees and visitors within the workplace. Also, valuable data is often available in hard copy on the desktop, by access to applications, and by using machines that are left unattended. Free access to the entire facility during or after work hours would be a tremendous asset to competitors or people conducting industrial espionage. There is also a great risk from disgruntled employees who might wish to do harm to the company or to their associates.

As demonstrated in the September 11, 2001 attack on the World Trade Center, greater dangers now exist than we may have realized. External dangers seem more probable than previously thought.

Physical access to facilities, lack of control over visitors, and lack of identification measures may place our workplaces and our employees in danger. Additionally, economic slowdowns that cause companies to downsize may create risks from displaced employees who may be upset about their loss of employment.

Physical security is more important than ever to protect valuable information and even more valuable employees. It must be incorporated into the total information security architecture. It must be developed with several factors in mind such as cost of remedies versus value of the assets, perceived threats in the environment, and protective measures that have already been implemented. The physical security plan must be developed and sold to employees as well as management to be successful. It must also be reviewed and audited periodically and updated with improvements developed to support the business of the organization.

Computing Centers

Computing centers have evolved over the years, but they still remain as the area where critical computing assets are enclosed and protected from random or unauthorized access. They have varying degrees of protection and protective measures, depending on the perceptions of management and the assets they contain.

Members of the technical staff often demand computing center access during off-hours, claiming that they might have to reboot systems. Members of management may also demand access because their position in the company requires that they have supervisory control over company assets. Additionally, computer room access is granted to nonemployees such as vendors and customer engineers to service the systems. Keeping track of authorized access and ensuring that it is kept to a minimum is a major task for the information security

department. Sometimes, the task is impossible when the control mechanisms consist of keys or combination locks.

Computing Center Evolution

In the days of large mainframes, computing centers often occupied whole buildings with some space left around for related staff. Those were the days of centralized computing centers where many people were required to perform a number of required tasks. Operators were required to run print operations, mount and dismount tapes, and manage the master console. Production control staffs were required to set up and schedule jobs. In addition, they required staffs of system programmers and, in some cases, system developers. Computer security was difficult to manage, but some controls were imposed with physical walls in place to keep the functions separate. Some of these large systems still remain; however, physical computer room tasks have been reduced through automation and departmental printing.

As distributed systems evolved, servers were installed and managed by system administrators who often performed all system tasks. Many of these systems were built to operate in office environments without the need for stringent environmental controls over heat and humidity. As a result, servers were located in offices where they might not be placed behind a locked door. That security was further eroded with the advent of desktop computing, when data became available throughout the office. In many cases, the servers were implemented and installed in the various departments that wanted control over their equipment and did not want control to go back to the computing staff with their bureaucratic change controls, charge-backs, and perceived slow response to end-user needs.

As the LANs and distributed systems grew in strategic importance, acquired larger user bases, needed software upgrades and interconnectivity, it became difficult for end-user departments to manage and control the systems. Moreover, the audit department realized that there were security requirements that were not fulfilled in support of these critical systems. This resulted in the migration of systems back to centralized control and centralized computer rooms.

Although these systems could withstand environmental fluctuations, the sheer number of servers required some infrastructure planning to keep the heat down and to provide uninterruptible power and network connectivity. In addition, the operating systems and user administration tasks became more burdensome and required an operations staff to support. However, these systems no longer required the multitudes of specialized staffs in the computer rooms to support them. Print operations disappeared for the most part, with data either displayed at the desktop or sent to a local printer for hard copy.

In many cases, computer centers still support large mainframes but they take up a much smaller footprint than the machines of old. Some of those facilities have been converted to support LANs and distributed UNIX-based systems. However, access controls, environmental protections, and backup support infrastructure must still be in place to provide stability, safety, and availability. The security practitioner must play a part ensuring that physical security measures are in place and effective.

As stated before, the computing center is usually part of a facility that supports other business functions. In many cases, that facility supports the entire business. Physical security must be developed to support the entire facility with special considerations for the computing center that is contained within. In fact, protective measures that are applied in and around the entire facility provide additional protection to the computing center.

Environmental Concerns

Most of us do not have the opportunity to determine where our facilities will be located because they probably existed prior to our appointment as an information security staff member. However, that does not prevent us from trying to determine what environmental risks exist and taking action to reduce them. If lucky, you will have some input regarding relocation of the facilities to areas with reduced exposure to threats such as airways, earthquake faults, and floodplains.

Community

The surrounding community may contribute to computer room safety as well as risks. Communities that have strong police and fire services will be able to provide rapid response to threats and incidents. Low crime rates

and strong economic factors provide safety for the computing facilities as well as a favorable climate for attracting top employees.

It is difficult to find the ideal community, and in most cases you will not have the opportunity to select one. Other businesses in that community may provide dangers such as explosive processes, chemical contaminants, and noise pollution. Community airports may have landing and takeoff flight paths that are near the facility. High crime rates could also threaten the computing facility and its inhabitants. Protective measures may have to be enhanced to account for these risks.

The security practitioner can enhance the value of community capabilities by cultivating a relationship with the local police and fire protection organizations. A good relationship with these organizations not only contributes to the safety of the facilities, but also will be key to safety of the staff in the event of an emergency. They should be invited to participate in emergency drills and to critique the process.

The local police should be invited to tour the facilities and understand the layout of the facilities and protective measures in place. In fact, they should be asked to provide suggested improvements to the existing measures that you have employed. If you have a local guard service, it is imperative that they have a working relationship with the local police officials.

The fire department will be more than happy to review fire protection measures and assist in improving them. In many cases, they will insist with inspecting such things as fire extinguishers and other fire suppression systems. It is most important that the fire department understand the facility layout and points of ingress and egress. They must also know about the fire suppression systems in use and the location of controls for those systems.

Acts of Nature

In most cases we cannot control the moods of Mother Nature or the results of her wrath. However, we can prepare for the most likely events and try to reduce their effects. Earthquake threats may require additional bracing and tie-down straps to prevent servers and peripheral devices from destruction due to tipping or falling. Flooding risks can be mitigated with the installation of sump pumps and locating equipment above the ground floor. Power outages resulting from tornadoes and thunderstorms may be addressed with uninterruptible power supply (UPS) systems and proper grounding of facilities.

The key point with natural disasters is that they cannot be eliminated in most cases. Remedies must be designed based on the likelihood that an event will occur and with provisions for proper response to it. In all cases, data backup with off-site storage or redundant systems are required to prepare for manmade or natural disasters.

Other External Risks

Until the events that occurred on September 11, 2001, physical security concerns related to riots, workplace violence, and local disruptions. The idea of terrorist acts within the country seemed remote but possible. Since that date, terrorism is not only possible, but also probable. Measures to protect facilities by use of cement barriers, no-parking zones, and guarded access gates have become understandable to both management and staff. The cost and inconvenience that these measures impose are suddenly more acceptable.

Many of our facilities are located in areas that are considered out of the target range that terrorists might attack. However, the Oklahoma City bombing occurred in a low-target area. The anthrax problems caused many unlikely facilities to be vacated. The risks of bioterrorism or attacks on nuclear power plants are now considered real and possible, and could occur in almost any city. Alternate site planning must be considered in business continuity and physical security plans.

Facility

The facilities that support our computing environments are critical to the organization in providing core business services and functions. There are few organizations today that do not rely on computing and telecommunications resources to operate their businesses and maintain services to their customers. This requires security over both the physical and logical aspects of the facility. The following discussion concentrates on the physical protective measures that should be considered for use in the computing center and the facilities that surround it.

Layers of Protection

For many computing facilities, the front door is the initial protection layer that is provided to control access and entry to the facility. This entry point will likely be one of many others such as back doors, loading docks, and other building access points. A guard or a receptionist usually controls front-door access. Beyond that, other security measures apply based on the value of contents within. However, physical security of facilities may begin outside the building.

External Protective Measures

Large organizations may have protective fences surrounding the entire campus with access controlled by a guard-activated or card-activated gate. The majority of organizations will not have perimeter fences around the campus but may have fences around portions of the building. In most of those cases, the front of the building is not fenced due to the need for entry by customers, visitors, and staff. These external protective measures may be augmented through the use of roving guards and closed-circuit television (CCTV) systems that provide a 360-degree view of the surrounding area.

Security practitioners must be aware of the risks and implement cost-effective measures that provide proper external protection. Measures to consider are:

- Campus perimeter fences with controlled access gates
- Building perimeter fences with controlled access gates
- Building perimeter fences controlling rear and side access to the building
- Cement barriers in the front of the building
- Restrict parking to areas away from the building
- CCTV viewing of building perimeters

External Walls

Facilities must be constructed to prevent penetration by accidental or unlawful means. Windows provide people comforts for office areas and natural light, but they can be a means for unauthorized entry. Ground floors may be equipped with windows; however, they could be eliminated if that floor were reserved for storage and equipment areas. Loading docks may provide a means of unauthorized entry and, if possible, should be located in unattached buildings or be equipped with secured doors to control entry. Doors that are not used for normal business purposes should be locked and alarmed with signs that prohibit their use except for emergencies.

Internal Structural Concerns

Critical rooms such as server and telecommunications areas should be constructed for fire prevention and access controls. Exterior walls for these rooms should not contain windows or other unnecessary entry points. They should also be extended above false ceilings and below raised floors to prevent unlawful entry and provide proper fire protection. Additional entry points may be required for emergency escape or equipment movement. These entrances should be locked when not in use and should be equipped with alarms to prevent unauthorized entry.

Ancillary Structures (Wiring Cabinets and Closets)

Wiring cabinets may be a source of unauthorized connectivity to computer networks and must be locked at all times unless needed by authorized personnel. Janitor closets should be reserved for that specific purpose and should not contain critical network or computing connections. They must be inspected on a regular basis to ensure that they do not contain flammable or other hazardous materials.

Facility Perils and Computer Room Locations

Computer rooms are subject to hazards that are created within the general facility. These hazards can be reduced through good facility design and consideration for critical equipment.

Floor Locations

Historically, computing equipment was added to facilities that were already in use for general business processes. Often, the only open area left for computing equipment was the basement. In many cases, buildings were not built to support heavy computers and disk storage devices on upper floors, so the computer room was

constructed on the ground floor. In fact, organizations were so proud of the flashy computer equipment that they installed observation windows for public viewing, with large signs to assist them in getting there.

Prudent practices along with a realization that computing resources were critical to the continued operation of the company have caused computing facilities to be relocated to more protected areas with minimum notification of their special status. Computer rooms have been moved to upper floors to mitigate flooding and access risks. Freight elevators have been installed to facilitate installation and removal of computing equipment and supplies. Windows have been eliminated and controlled doors have been added to ensure only authorized access.

Rest Rooms and Other Water Risks

Water hazards that are located above computer rooms could cause damage to critical computing equipment if flooding and leakage occurs. A malfunctioning toilet or sink that overflows in the middle of the night could be disastrous to computer operations. Water pipes that are installed in the flooring above the computer room could burst or begin to leak in the event of earthquakes or corrosion. A well-sealed floor will help, but the best prevention is to keep those areas clear of water hazards.

Adjacent Office Risks

Almost all computing facilities have office areas to support the technical staff or, in many cases, the rest of the business. These areas can provide risks to the computing facility from fire, unauthorized access, or chemical spills. Adjacent office areas should be equipped with appropriate fire suppression systems that are designed to control flammable material and chemical fires. Loading docks and janitor rooms can also be a source of risk from fire and chemical hazards. Motor-generated UPS systems should be located in a separate building due to their inherent risks of fire and carbon monoxide. The local fire department can provide assistance to reduce risks that may be contained in other offices as well as the computing center.

Protective Measures

Entrances to computing facilities must be controlled to protect critical computing resources, but they must also be controlled to protect employees and sensitive business information. As stated before, valuable information is often left on desks and in unlocked cabinets throughout the facility. Desktop computers are often left on overnight with valuable information stored locally. In some cases, these systems are left logged on to sensitive systems. Laptops with sensitive data can be stolen at night and even during business hours.

To protect valuable information resources, people, and systems, various methods and tools should be considered. Use of any of these tools must be justified according to the facility layout and the value of the resources contained within.

Guard Services

There are many considerations related to the use of guard services. The major consideration, other than whether to use them, is employee versus purchased services. The use of employee guards may be favored by organizations with the idea that employees are more loyal to the organization and will be trustworthy. However, there are training, company benefit, and insurance considerations that accompany that decision. Additionally, the location may not have an alternative guard source available. If the guards are to be armed, stringent controls and training must be considered.

There are high-quality guard services available in most areas that will furnish trained and bonded guards who are supervised by experienced managers. Although cost is a factor in the selection of a contract guard service, it should not be the major one. The selection process should include a request for proposal (RFP) that requires references and stringent performance criteria. Part of the final selection process must include discussions with customer references and a visit to at least two customer sites. Obviously, the guard service company should be properly licensed and provide standard business documentation.

The guard service will be operating existing and planned security systems that may include CCTV, card access systems, central control rooms, and fire suppression systems. Before contracting with an organization, that organization must demonstrate capabilities to operate existing and planned systems. It should also be able to provide documented operating procedures that can be modified to support the facility needs.

Intrusion Monitoring Systems

Closed-circuit television (CCTV) systems have been used for years to protect critical facilities. These systems have improved considerably over the years to provide digital images that take up less storage space and be transmitted over TCP/IP-based networks. Their images can be combined with other alarm events to provide a total picture for guard response as well as event history. Digital systems that are activated in conjunction with motion detection or other alarms may be more effective because their activation signals a change to the guard who is assigned to watch them.

CCTV systems allow guards to keep watch on areas that are located remotely, are normally unmanned, or require higher surveillance, such as critical access points. These systems can reduce the need for additional manpower to provide control over critical areas. In many cases, their mere presence serves as a deterrent to unwanted behavior.

They may also contribute to employee safety by providing surveillance over parking areas, low traffic areas, and high-value functions such as cashier offices. A single guard in a central control center can spot problems and dispatch roving manpower to quickly resolve threats. In addition to the above, stored images may be used to assist law enforcement in apprehending violators and as evidence in a court of law.

Security requirements will vary with different organizations; however, CCTV may be useful in the following areas:

- Parking lots for employee and property safety
- Emergency doors where access is restricted
- Office areas during nonworking hours
- Server and telecommunications equipment rooms during nonworking hours
- Loading docks and delivery gates
- Cashier and check-processing areas
- Remote facilities where roving guards would be too costly
- Executive office areas in support of executive protection programs
- Mantrap gates to ensure all entry cards have been entered

Alarms and motion-detection systems are designed to signal the organization that an unusual or prohibited event has occurred. Doors that should not be used during normal business activity may be equipped with local sound alarms or with electronic sensors that signal a guard or activate surveillance systems. Motion detectors are often installed in areas that are normally unmanned. In some systems, motion detection is activated during nonbusiness hours and can be disabled or changed to allow for activities that are properly scheduled in those areas.

Many systems can be IP addressable over the backbone TCP/IP network, and alarm signals can be transmitted from multiple remote areas. It is important to note that IP-based systems may be subject to attack. The vendor of these systems must ensure that these systems are hack-protected against covert activities by unauthorized people.

Physical Access Control Measures

Physical access controls are as important as logical access controls to protect critical information resources. Multiple methods are available, including manual and automated systems. Often, cost is the deciding factor in their selection despite the risks inherent in those tools.

Access Policies

All good security begins with policies. Policies are the drivers of written procedures that must be in place to provide consistent best practices in the protection of people and information resources. Policies are the method by which management communicates its wishes. Policies are also used to set standards and assign responsibility for their enforcement. Once policies are developed, they should be published for easy access and be part of the employee awareness training program.

Policies define the process of granting and removing access based on need-to-know. If badges are employed, policies define how they are to be designed, worn, and used. Policies define who is allowed into restricted areas or how visitors are to be processed. There is no magic to developing policies, but they are required as a basic tool to protect information resources.

Keys and Cipher Locks

Keys and cipher (keypad) locks are the simplest to use and hardest to control in providing access to critical areas. They do not provide a means of identifying who is accessing a given area, nor do they provide an audit trail. Keys provide a slightly better security control than keypad locks in that the physical device must be provided to allow use. While they can be copied, that requires extra effort to accomplish. If keys are used to control access, they should be inventoried and stamped with the words *Do Not Duplicate*.

Cipher locks require that a person know the cipher code to enter an area. Once given out, use of this code cannot be controlled and may be passed throughout an organization by word of mouth. There is no audit trail for entry, nor is there authentication that it is used by an authorized user. Control methods consist of periodic code changes and shielding to prevent other people from viewing the authorized user's code entry. Use of these methods of entry control could be better protected through the use of CCTV.

Card Access Controls

Card access controls are considerably better tools than keys and cipher locks if they are used for identification and contain a picture of the bearer. Without pictures, they are only slightly better than keys because they are more difficult to duplicate. If given to another person to gain entry, the card must be returned for use by the authorized cardholder. Different types of card readers can be employed to provide ease of use (proximity readers) and different card identification technology. Adding biometrics to the process would provide added control along with increased cost and inconvenience that might be justified to protect the contents within.

The most effective card systems use a central control computer that can be programmed to provide different access levels depending on need, time zone controls that limit access to certain hours of the day, and an audit trail of when the card was used and where it was entered. Some systems even provide positive in and out controls that require a card to be used for both entry and exit. If a corresponding entry/exit transaction is not in the system, future entry will be denied until management investigation actions are taken.

Smart card technology is being developed to provide added security and functionality. Smart cards can have multiple uses that expand beyond mere physical access. Additional uses for this type of card include computer access authentication, encryption using digital certificates, and debit cards for employee purchases in the cafeteria or employee store. There is some controversy about multiple-use cards because a single device can be used to gain access to many different resources. If the employee smart card provides multiple access functions as well as purchasing functions, the cardholder will be less likely to loan the badge to an unauthorized person for use and will be more likely to report its loss.

Mantraps and Turnstiles

Additional controls can be provided through the use of mantraps and turnstiles. These devices prevent unauthorized tailgating and can be used to require inspection of parcels when combined with guard stations. These devices also force the use of a badge to enter through a control point and overcome the tendency for guards to allow entry because the person looks familiar to them. Mantraps and turnstiles can control this weakness if the badge is confiscated upon termination of access privileges. The use of positive entry/exit controls can be added to prevent card users from passing their card back through the control point to let a friend enter.

Fire Controls

Different fire control mechanisms must be employed to match the risks that are present in protected areas. Fire control systems may be as simple as a hand-held fire extinguisher or be combined with various detection mechanisms to provide automated activation. Expert advice should be used to match the proper system to the existing threats. In some cases, multiple systems may be used to ensure that fires do not reignite and cause serious damage.

Detectors and Alarms

Smoke and water detectors can provide early warning and alarm the guards that something dangerous may be happening. Alarms may also trigger fire prevention systems to activate. To be effective, they must be carefully placed and tested by experts in fire prevention.

Water-Based Systems

Water-based systems control fires by reducing temperatures below the combustion point. They are usually activated through overhead sprinklers to extinguish fires before they can spread. The problem with water-based systems is that they cause a certain amount of damage to the contents of areas they are designed to protect. In addition, they may cause flooding in adjacent areas if they are not detected and shut off quickly following an event.

Water-based systems may be either dry pipe or wet pipe systems. Wet pipe systems are always ready to go and are activated when heat or accidental means open the sprinkler heads. There is no delay or shut-off mechanism that can be activated prior to the start of water flow. Water in the pipes that connect to the sprinkler heads may become corroded, causing failure of the sprinkler heads to activate in an emergency.

Dry pipe systems are designed to allow some preventive action before they activate. These types of systems employ a valve to prevent the flow of water into the overhead pipes until a fire alarm event triggers water release. Dry pipe systems will not activate and cause damage if a sprinkler head is accidentally broken off. They also allow human intervention to override water flow if the system is accidentally activated.

Gas-Based Fire Extinguishing Systems

Halon-type systems are different from water-based systems in that they control fires by interrupting the chemical reactions needed to continue combustion. They replaced older gas systems such as carbon dioxide that controlled fires by replacing the oxygen with a gas (CO_2) that did not support the combustion process. Oxygen replacement systems were effective, but they were toxic to humans who might be in the CO_2-activated room due to the need for oxygen to survive.

Throughout the 1970s and 1980s, halon systems were the preferred method to protect computer and telecommunication rooms from fire damage because they extinguished the fire without damaging sensitive electronic equipment. Those systems could extinguish fires and yet allow humans to breathe and survive in the flooded room. The problem with halon is that it proved unfriendly to the ozone layer and was banned from new implementations by an international agreement (Montreal Protocol). There are numerous Clean Air Act and EPA regulations now in effect to govern the use of existing halon systems and supplies. Current regulations and information can be obtained by logging onto www.epa.gov/docs/ozone/ title6/snap/hal.html. This site also lists manufacturers of halon substitute systems.

Today, halon replacement systems are available that continue to extinguish fires, do not harm the ozone layer, and, most important, do not harm humans who may be in the gas-flooded room. Although these systems will not kill human inhabitants, most system manufacturers warn that people should leave the gas-flooded area within one minute of system activation. Current regulations do not dictate the removal of halon systems that are in place; however, any new or replacement halon systems must employ the newer ozone-friendly gas (e.g., FM 200).

Utility and Telecommunications Backup Requirements

Emergency Lighting

As stated before, modern computer rooms are usually lacking in windows or other sources of natural light. Therefore, when a power outage occurs, these rooms become very dark and exits become difficult to find. Even in normal offices, power outages may occur in areas that are staffed at night. In all of these cases, emergency lighting with exit signs must be installed to allow people to evacuate in an orderly and safe manner. Emergency lighting is usually provided by battery-equipped lamps that are constantly charged until activated.

UPS Systems

Uninterruptible power supply (UPS) systems ensure that a computing system can continue to run, or at least shut down in an orderly manner, if normal power is lost. Lower cost systems rely on battery backup to provide an orderly shutdown; motor generator backup systems used in conjunction with battery backup can provide continuous power as long as the engines receive fuel (usually diesel). As usual, cost is the driver for choosing the proper UPS system. More enlightened management will insist on a business impact analysis prior to making that decision to ensure that critical business needs are met.

Regardless of the type of system employed, periodic testing is required to ensure that the system will work when needed. Diesel systems should be tested weekly to ensure they work and to keep the engines properly lubricated.

Redundant Connections

Redundancy should be considered for facility electrical power, air conditioning, telecommunications connections, and water supplies. Certain systems such as UPS can be employed to mitigate the need for electrical redundancy. Telecommunications connectivity should be ensured with redundant connections. In this E-commerce world, telecommunications redundancy should also include connections to the Internet. Water is important to the staff, but environmental systems (cooling towers) may also depend on a reliable supply. In most cases, this redundancy can be provided with separate connections to the water main that is provided by the supporting community.

Summary

Physical security must be considered to provide a safe working environment for the people who visit and work in a facility. Although physical access controls must be employed for safety reasons, they also should prevent unauthorized access to critical computing resources.

Many tools are available to provide physical security that continues to be enhanced with current technology. Backbone networks and central control computers can support the protection of geographically separated facilities and operations. IP-supported systems can support the collection of large amounts of data from various sensors and control mechanisms and provide enhanced physical security while keeping manpower at a minimum.

The information security practitioner must become aware of existing physical security issues and be involved. If a separate department provides physical security, coordination with them becomes important to a total security approach. If information security organizations are assigned to provide physical security, they must become aware of the tools that are available and determine where to employ them.

Computing Facility Physical Security

Alan Brusewitz, CISSP, CBCP

Most information security practitioners are experienced in and concentrate on logical issues of computer and telecommunications security while leaving physical security to another department. However, most of us would agree that a knowledgeable person with physical access to a console could bypass most of our logical protective measures by simply rebooting the system or accessing the system that is already turned on with root or administrator access in the computer room. Additionally, an unlocked wiring closet could provide hidden access to a network or a means to sabotage existing networks.

Physical access controls and protective measures for computing resources are key ingredients to a well-rounded security program. However, protection of the entire facility is even more important to the well-being of employees and visitors within the workplace. Also, valuable data is often available in hard copy on the desktop, by access to applications, and by using machines that are left unattended. Free access to the entire facility during or after work hours would be a tremendous asset to competitors or people conducting industrial espionage. There is also a great risk from disgruntled employees who might wish to do harm to the company or to their associates.

As demonstrated in the September 11, 2001 attack on the World Trade Center, greater dangers now exist than we may have realized. External dangers seem more probable than previously thought.

Physical access to facilities, lack of control over visitors, and lack of identification measures may place our workplaces and our employees in danger. Additionally, economic slowdowns that cause companies to downsize may create risks from displaced employees who may be upset about their loss of employment.

Physical security is more important than ever to protect valuable information and even more valuable employees. It must be incorporated into the total information security architecture. It must be developed with several factors in mind such as cost of remedies versus value of the assets, perceived threats in the environment, and protective measures that have already been implemented. The physical security plan must be developed and sold to employees as well as management to be successful. It must also be reviewed and audited periodically and updated with improvements developed to support the business of the organization.

Computing Centers

Computing centers have evolved over the years, but they still remain as the area where critical computing assets are enclosed and protected from random or unauthorized access. They have varying degrees of protection and protective measures, depending on the perceptions of management and the assets they contain.

Members of the technical staff often demand computing center access during off-hours, claiming that they might have to reboot systems. Members of management may also demand access because their position in the company requires that they have supervisory control over company assets. Additionally, computer room access is granted to nonemployees such as vendors and customer engineers to service the systems. Keeping track of authorized access and ensuring that it is kept to a minimum is a major task for the information security

department. Sometimes, the task is impossible when the control mechanisms consist of keys or combination locks.

Computing Center Evolution

In the days of large mainframes, computing centers often occupied whole buildings with some space left around for related staff. Those were the days of centralized computing centers where many people were required to perform a number of required tasks. Operators were required to run print operations, mount and dismount tapes, and manage the master console. Production control staffs were required to set up and schedule jobs. In addition, they required staffs of system programmers and, in some cases, system developers. Computer security was difficult to manage, but some controls were imposed with physical walls in place to keep the functions separate. Some of these large systems still remain; however, physical computer room tasks have been reduced through automation and departmental printing.

As distributed systems evolved, servers were installed and managed by system administrators who often performed all system tasks. Many of these systems were built to operate in office environments without the need for stringent environmental controls over heat and humidity. As a result, servers were located in offices where they might not be placed behind a locked door. That security was further eroded with the advent of desktop computing, when data became available throughout the office. In many cases, the servers were implemented and installed in the various departments that wanted control over their equipment and did not want control to go back to the computing staff with their bureaucratic change controls, charge-backs, and perceived slow response to end-user needs.

As the LANs and distributed systems grew in strategic importance, acquired larger user bases, needed software upgrades and interconnectivity, it became difficult for end-user departments to manage and control the systems. Moreover, the audit department realized that there were security requirements that were not fulfilled in support of these critical systems. This resulted in the migration of systems back to centralized control and centralized computer rooms.

Although these systems could withstand environmental fluctuations, the sheer number of servers required some infrastructure planning to keep the heat down and to provide uninterruptible power and network connectivity. In addition, the operating systems and user administration tasks became more burdensome and required an operations staff to support. However, these systems no longer required the multitudes of specialized staffs in the computer rooms to support them. Print operations disappeared for the most part, with data either displayed at the desktop or sent to a local printer for hard copy.

In many cases, computer centers still support large mainframes but they take up a much smaller footprint than the machines of old. Some of those facilities have been converted to support LANs and distributed UNIX-based systems. However, access controls, environmental protections, and backup support infrastructure must still be in place to provide stability, safety, and availability. The security practitioner must play a part ensuring that physical security measures are in place and effective.

As stated before, the computing center is usually part of a facility that supports other business functions. In many cases, that facility supports the entire business. Physical security must be developed to support the entire facility with special considerations for the computing center that is contained within. In fact, protective measures that are applied in and around the entire facility provide additional protection to the computing center.

Environmental Concerns

Most of us do not have the opportunity to determine where our facilities will be located because they probably existed prior to our appointment as an information security staff member. However, that does not prevent us from trying to determine what environmental risks exist and taking action to reduce them. If lucky, you will have some input regarding relocation of the facilities to areas with reduced exposure to threats such as airways, earthquake faults, and floodplains.

Community

The surrounding community may contribute to computer room safety as well as risks. Communities that have strong police and fire services will be able to provide rapid response to threats and incidents. Low crime rates

and strong economic factors provide safety for the computing facilities as well as a favorable climate for attracting top employees.

It is difficult to find the ideal community, and in most cases you will not have the opportunity to select one. Other businesses in that community may provide dangers such as explosive processes, chemical contaminants, and noise pollution. Community airports may have landing and takeoff flight paths that are near the facility. High crime rates could also threaten the computing facility and its inhabitants. Protective measures may have to be enhanced to account for these risks.

The security practitioner can enhance the value of community capabilities by cultivating a relationship with the local police and fire protection organizations. A good relationship with these organizations not only contributes to the safety of the facilities, but also will be key to safety of the staff in the event of an emergency. They should be invited to participate in emergency drills and to critique the process.

The local police should be invited to tour the facilities and understand the layout of the facilities and protective measures in place. In fact, they should be asked to provide suggested improvements to the existing measures that you have employed. If you have a local guard service, it is imperative that they have a working relationship with the local police officials.

The fire department will be more than happy to review fire protection measures and assist in improving them. In many cases, they will insist with inspecting such things as fire extinguishers and other fire suppression systems. It is most important that the fire department understand the facility layout and points of ingress and egress. They must also know about the fire suppression systems in use and the location of controls for those systems.

Acts of Nature

In most cases we cannot control the moods of Mother Nature or the results of her wrath. However, we can prepare for the most likely events and try to reduce their effects. Earthquake threats may require additional bracing and tie-down straps to prevent servers and peripheral devices from destruction due to tipping or falling. Flooding risks can be mitigated with the installation of sump pumps and locating equipment above the ground floor. Power outages resulting from tornadoes and thunderstorms may be addressed with uninterruptible power supply (UPS) systems and proper grounding of facilities.

The key point with natural disasters is that they cannot be eliminated in most cases. Remedies must be designed based on the likelihood that an event will occur and with provisions for proper response to it. In all cases, data backup with off-site storage or redundant systems are required to prepare for manmade or natural disasters.

Other External Risks

Until the events that occurred on September 11, 2001, physical security concerns related to riots, workplace violence, and local disruptions. The idea of terrorist acts within the country seemed remote but possible. Since that date, terrorism is not only possible, but also probable. Measures to protect facilities by use of cement barriers, no-parking zones, and guarded access gates have become understandable to both management and staff. The cost and inconvenience that these measures impose are suddenly more acceptable.

Many of our facilities are located in areas that are considered out of the target range that terrorists might attack. However, the Oklahoma City bombing occurred in a low-target area. The anthrax problems caused many unlikely facilities to be vacated. The risks of bioterrorism or attacks on nuclear power plants are now considered real and possible, and could occur in almost any city. Alternate site planning must be considered in business continuity and physical security plans.

Facility

The facilities that support our computing environments are critical to the organization in providing core business services and functions. There are few organizations today that do not rely on computing and telecommunications resources to operate their businesses and maintain services to their customers. This requires security over both the physical and logical aspects of the facility. The following discussion concentrates on the physical protective measures that should be considered for use in the computing center and the facilities that surround it.

Layers of Protection

For many computing facilities, the front door is the initial protection layer that is provided to control access and entry to the facility. This entry point will likely be one of many others such as back doors, loading docks, and other building access points. A guard or a receptionist usually controls front-door access. Beyond that, other security measures apply based on the value of contents within. However, physical security of facilities may begin outside the building.

External Protective Measures

Large organizations may have protective fences surrounding the entire campus with access controlled by a guard-activated or card-activated gate. The majority of organizations will not have perimeter fences around the campus but may have fences around portions of the building. In most of those cases, the front of the building is not fenced due to the need for entry by customers, visitors, and staff. These external protective measures may be augmented through the use of roving guards and closed-circuit television (CCTV) systems that provide a 360-degree view of the surrounding area.

Security practitioners must be aware of the risks and implement cost-effective measures that provide proper external protection. Measures to consider are:

- Campus perimeter fences with controlled access gates
- Building perimeter fences with controlled access gates
- Building perimeter fences controlling rear and side access to the building
- Cement barriers in the front of the building
- Restrict parking to areas away from the building
- CCTV viewing of building perimeters

External Walls

Facilities must be constructed to prevent penetration by accidental or unlawful means. Windows provide people comforts for office areas and natural light, but they can be a means for unauthorized entry. Ground floors may be equipped with windows; however, they could be eliminated if that floor were reserved for storage and equipment areas. Loading docks may provide a means of unauthorized entry and, if possible, should be located in unattached buildings or be equipped with secured doors to control entry. Doors that are not used for normal business purposes should be locked and alarmed with signs that prohibit their use except for emergencies.

Internal Structural Concerns

Critical rooms such as server and telecommunications areas should be constructed for fire prevention and access controls. Exterior walls for these rooms should not contain windows or other unnecessary entry points. They should also be extended above false ceilings and below raised floors to prevent unlawful entry and provide proper fire protection. Additional entry points may be required for emergency escape or equipment movement. These entrances should be locked when not in use and should be equipped with alarms to prevent unauthorized entry.

Ancillary Structures (Wiring Cabinets and Closets)

Wiring cabinets may be a source of unauthorized connectivity to computer networks and must be locked at all times unless needed by authorized personnel. Janitor closets should be reserved for that specific purpose and should not contain critical network or computing connections. They must be inspected on a regular basis to ensure that they do not contain flammable or other hazardous materials.

Facility Perils and Computer Room Locations

Computer rooms are subject to hazards that are created within the general facility. These hazards can be reduced through good facility design and consideration for critical equipment.

Floor Locations

Historically, computing equipment was added to facilities that were already in use for general business processes. Often, the only open area left for computing equipment was the basement. In many cases, buildings were not built to support heavy computers and disk storage devices on upper floors, so the computer room was

constructed on the ground floor. In fact, organizations were so proud of the flashy computer equipment that they installed observation windows for public viewing, with large signs to assist them in getting there.

Prudent practices along with a realization that computing resources were critical to the continued operation of the company have caused computing facilities to be relocated to more protected areas with minimum notification of their special status. Computer rooms have been moved to upper floors to mitigate flooding and access risks. Freight elevators have been installed to facilitate installation and removal of computing equipment and supplies. Windows have been eliminated and controlled doors have been added to ensure only authorized access.

Rest Rooms and Other Water Risks

Water hazards that are located above computer rooms could cause damage to critical computing equipment if flooding and leakage occurs. A malfunctioning toilet or sink that overflows in the middle of the night could be disastrous to computer operations. Water pipes that are installed in the flooring above the computer room could burst or begin to leak in the event of earthquakes or corrosion. A well-sealed floor will help, but the best prevention is to keep those areas clear of water hazards.

Adjacent Office Risks

Almost all computing facilities have office areas to support the technical staff or, in many cases, the rest of the business. These areas can provide risks to the computing facility from fire, unauthorized access, or chemical spills. Adjacent office areas should be equipped with appropriate fire suppression systems that are designed to control flammable material and chemical fires. Loading docks and janitor rooms can also be a source of risk from fire and chemical hazards. Motor-generated UPS systems should be located in a separate building due to their inherent risks of fire and carbon monoxide. The local fire department can provide assistance to reduce risks that may be contained in other offices as well as the computing center.

Protective Measures

Entrances to computing facilities must be controlled to protect critical computing resources, but they must also be controlled to protect employees and sensitive business information. As stated before, valuable information is often left on desks and in unlocked cabinets throughout the facility. Desktop computers are often left on overnight with valuable information stored locally. In some cases, these systems are left logged on to sensitive systems. Laptops with sensitive data can be stolen at night and even during business hours.

To protect valuable information resources, people, and systems, various methods and tools should be considered. Use of any of these tools must be justified according to the facility layout and the value of the resources contained within.

Guard Services

There are many considerations related to the use of guard services. The major consideration, other than whether to use them, is employee versus purchased services. The use of employee guards may be favored by organizations with the idea that employees are more loyal to the organization and will be trustworthy. However, there are training, company benefit, and insurance considerations that accompany that decision. Additionally, the location may not have an alternative guard source available. If the guards are to be armed, stringent controls and training must be considered.

There are high-quality guard services available in most areas that will furnish trained and bonded guards who are supervised by experienced managers. Although cost is a factor in the selection of a contract guard service, it should not be the major one. The selection process should include a request for proposal (RFP) that requires references and stringent performance criteria. Part of the final selection process must include discussions with customer references and a visit to at least two customer sites. Obviously, the guard service company should be properly licensed and provide standard business documentation.

The guard service will be operating existing and planned security systems that may include CCTV, card access systems, central control rooms, and fire suppression systems. Before contracting with an organization, that organization must demonstrate capabilities to operate existing and planned systems. It should also be able to provide documented operating procedures that can be modified to support the facility needs.

Intrusion Monitoring Systems

Closed-circuit television (CCTV) systems have been used for years to protect critical facilities. These systems have improved considerably over the years to provide digital images that take up less storage space and be transmitted over TCP/IP-based networks. Their images can be combined with other alarm events to provide a total picture for guard response as well as event history. Digital systems that are activated in conjunction with motion detection or other alarms may be more effective because their activation signals a change to the guard who is assigned to watch them.

CCTV systems allow guards to keep watch on areas that are located remotely, are normally unmanned, or require higher surveillance, such as critical access points. These systems can reduce the need for additional manpower to provide control over critical areas. In many cases, their mere presence serves as a deterrent to unwanted behavior.

They may also contribute to employee safety by providing surveillance over parking areas, low traffic areas, and high-value functions such as cashier offices. A single guard in a central control center can spot problems and dispatch roving manpower to quickly resolve threats. In addition to the above, stored images may be used to assist law enforcement in apprehending violators and as evidence in a court of law.

Security requirements will vary with different organizations; however, CCTV may be useful in the following areas:

- Parking lots for employee and property safety
- Emergency doors where access is restricted
- Office areas during nonworking hours
- Server and telecommunications equipment rooms during nonworking hours
- Loading docks and delivery gates
- Cashier and check-processing areas
- Remote facilities where roving guards would be too costly
- Executive office areas in support of executive protection programs
- Mantrap gates to ensure all entry cards have been entered

Alarms and motion-detection systems are designed to signal the organization that an unusual or prohibited event has occurred. Doors that should not be used during normal business activity may be equipped with local sound alarms or with electronic sensors that signal a guard or activate surveillance systems. Motion detectors are often installed in areas that are normally unmanned. In some systems, motion detection is activated during nonbusiness hours and can be disabled or changed to allow for activities that are properly scheduled in those areas.

Many systems can be IP addressable over the backbone TCP/IP network, and alarm signals can be transmitted from multiple remote areas. It is important to note that IP-based systems may be subject to attack. The vendor of these systems must ensure that these systems are hack-protected against covert activities by unauthorized people.

Physical Access Control Measures

Physical access controls are as important as logical access controls to protect critical information resources. Multiple methods are available, including manual and automated systems. Often, cost is the deciding factor in their selection despite the risks inherent in those tools.

Access Policies

All good security begins with policies. Policies are the drivers of written procedures that must be in place to provide consistent best practices in the protection of people and information resources. Policies are the method by which management communicates its wishes. Policies are also used to set standards and assign responsibility for their enforcement. Once policies are developed, they should be published for easy access and be part of the employee awareness training program.

Policies define the process of granting and removing access based on need-to-know. If badges are employed, policies define how they are to be designed, worn, and used. Policies define who is allowed into restricted areas or how visitors are to be processed. There is no magic to developing policies, but they are required as a basic tool to protect information resources.

Keys and Cipher Locks

Keys and cipher (keypad) locks are the simplest to use and hardest to control in providing access to critical areas. They do not provide a means of identifying who is accessing a given area, nor do they provide an audit trail. Keys provide a slightly better security control than keypad locks in that the physical device must be provided to allow use. While they can be copied, that requires extra effort to accomplish. If keys are used to control access, they should be inventoried and stamped with the words *Do Not Duplicate*.

Cipher locks require that a person know the cipher code to enter an area. Once given out, use of this code cannot be controlled and may be passed throughout an organization by word of mouth. There is no audit trail for entry, nor is there authentication that it is used by an authorized user. Control methods consist of periodic code changes and shielding to prevent other people from viewing the authorized user's code entry. Use of these methods of entry control could be better protected through the use of CCTV.

Card Access Controls

Card access controls are considerably better tools than keys and cipher locks if they are used for identification and contain a picture of the bearer. Without pictures, they are only slightly better than keys because they are more difficult to duplicate. If given to another person to gain entry, the card must be returned for use by the authorized cardholder. Different types of card readers can be employed to provide ease of use (proximity readers) and different card identification technology. Adding biometrics to the process would provide added control along with increased cost and inconvenience that might be justified to protect the contents within.

The most effective card systems use a central control computer that can be programmed to provide different access levels depending on need, time zone controls that limit access to certain hours of the day, and an audit trail of when the card was used and where it was entered. Some systems even provide positive in and out controls that require a card to be used for both entry and exit. If a corresponding entry/exit transaction is not in the system, future entry will be denied until management investigation actions are taken.

Smart card technology is being developed to provide added security and functionality. Smart cards can have multiple uses that expand beyond mere physical access. Additional uses for this type of card include computer access authentication, encryption using digital certificates, and debit cards for employee purchases in the cafeteria or employee store. There is some controversy about multiple-use cards because a single device can be used to gain access to many different resources. If the employee smart card provides multiple access functions as well as purchasing functions, the cardholder will be less likely to loan the badge to an unauthorized person for use and will be more likely to report its loss.

Mantraps and Turnstiles

Additional controls can be provided through the use of mantraps and turnstiles. These devices prevent unauthorized tailgating and can be used to require inspection of parcels when combined with guard stations. These devices also force the use of a badge to enter through a control point and overcome the tendency for guards to allow entry because the person looks familiar to them. Mantraps and turnstiles can control this weakness if the badge is confiscated upon termination of access privileges. The use of positive entry/exit controls can be added to prevent card users from passing their card back through the control point to let a friend enter.

Fire Controls

Different fire control mechanisms must be employed to match the risks that are present in protected areas. Fire control systems may be as simple as a hand-held fire extinguisher or be combined with various detection mechanisms to provide automated activation. Expert advice should be used to match the proper system to the existing threats. In some cases, multiple systems may be used to ensure that fires do not reignite and cause serious damage.

Detectors and Alarms

Smoke and water detectors can provide early warning and alarm the guards that something dangerous may be happening. Alarms may also trigger fire prevention systems to activate. To be effective, they must be carefully placed and tested by experts in fire prevention.

Water-Based Systems

Water-based systems control fires by reducing temperatures below the combustion point. They are usually activated through overhead sprinklers to extinguish fires before they can spread. The problem with water-based systems is that they cause a certain amount of damage to the contents of areas they are designed to protect. In addition, they may cause flooding in adjacent areas if they are not detected and shut off quickly following an event.

Water-based systems may be either dry pipe or wet pipe systems. Wet pipe systems are always ready to go and are activated when heat or accidental means open the sprinkler heads. There is no delay or shut-off mechanism that can be activated prior to the start of water flow. Water in the pipes that connect to the sprinkler heads may become corroded, causing failure of the sprinkler heads to activate in an emergency.

Dry pipe systems are designed to allow some preventive action before they activate. These types of systems employ a valve to prevent the flow of water into the overhead pipes until a fire alarm event triggers water release. Dry pipe systems will not activate and cause damage if a sprinkler head is accidentally broken off. They also allow human intervention to override water flow if the system is accidentally activated.

Gas-Based Fire Extinguishing Systems

Halon-type systems are different from water-based systems in that they control fires by interrupting the chemical reactions needed to continue combustion. They replaced older gas systems such as carbon dioxide that controlled fires by replacing the oxygen with a gas (CO_2) that did not support the combustion process. Oxygen replacement systems were effective, but they were toxic to humans who might be in the CO_2-activated room due to the need for oxygen to survive.

Throughout the 1970s and 1980s, halon systems were the preferred method to protect computer and telecommunication rooms from fire damage because they extinguished the fire without damaging sensitive electronic equipment. Those systems could extinguish fires and yet allow humans to breathe and survive in the flooded room. The problem with halon is that it proved unfriendly to the ozone layer and was banned from new implementations by an international agreement (Montreal Protocol). There are numerous Clean Air Act and EPA regulations now in effect to govern the use of existing halon systems and supplies. Current regulations and information can be obtained by logging onto www.epa.gov/docs/ozone/ title6/snap/hal.html. This site also lists manufacturers of halon substitute systems.

Today, halon replacement systems are available that continue to extinguish fires, do not harm the ozone layer, and, most important, do not harm humans who may be in the gas-flooded room. Although these systems will not kill human inhabitants, most system manufacturers warn that people should leave the gas-flooded area within one minute of system activation. Current regulations do not dictate the removal of halon systems that are in place; however, any new or replacement halon systems must employ the newer ozone-friendly gas (e.g., FM 200).

Utility and Telecommunications Backup Requirements

Emergency Lighting

As stated before, modern computer rooms are usually lacking in windows or other sources of natural light. Therefore, when a power outage occurs, these rooms become very dark and exits become difficult to find. Even in normal offices, power outages may occur in areas that are staffed at night. In all of these cases, emergency lighting with exit signs must be installed to allow people to evacuate in an orderly and safe manner. Emergency lighting is usually provided by battery-equipped lamps that are constantly charged until activated.

UPS Systems

Uninterruptible power supply (UPS) systems ensure that a computing system can continue to run, or at least shut down in an orderly manner, if normal power is lost. Lower cost systems rely on battery backup to provide an orderly shutdown; motor generator backup systems used in conjunction with battery backup can provide continuous power as long as the engines receive fuel (usually diesel). As usual, cost is the driver for choosing the proper UPS system. More enlightened management will insist on a business impact analysis prior to making that decision to ensure that critical business needs are met.

Regardless of the type of system employed, periodic testing is required to ensure that the system will work when needed. Diesel systems should be tested weekly to ensure they work and to keep the engines properly lubricated.

Redundant Connections

Redundancy should be considered for facility electrical power, air conditioning, telecommunications connections, and water supplies. Certain systems such as UPS can be employed to mitigate the need for electrical redundancy. Telecommunications connectivity should be ensured with redundant connections. In this E-commerce world, telecommunications redundancy should also include connections to the Internet. Water is important to the staff, but environmental systems (cooling towers) may also depend on a reliable supply. In most cases, this redundancy can be provided with separate connections to the water main that is provided by the supporting community.

Summary

Physical security must be considered to provide a safe working environment for the people who visit and work in a facility. Although physical access controls must be employed for safety reasons, they also should prevent unauthorized access to critical computing resources.

Many tools are available to provide physical security that continues to be enhanced with current technology. Backbone networks and central control computers can support the protection of geographically separated facilities and operations. IP-supported systems can support the collection of large amounts of data from various sensors and control mechanisms and provide enhanced physical security while keeping manpower at a minimum.

The information security practitioner must become aware of existing physical security issues and be involved. If a separate department provides physical security, coordination with them becomes important to a total security approach. If information security organizations are assigned to provide physical security, they must become aware of the tools that are available and determine where to employ them.

Closed-Circuit Television and Video Surveillance

David Litzau, CISSP

In June 1925, Charles Francis Jenkins successfully transmitted a series of motion pictures of a small windmill to a receiving facility over five miles away. The image included 48 lines of resolution and lasted ten minutes. This demonstration would move the television from an engineer's lark to reality. By 1935, *Broadcast* magazine listed 27 different television broadcast facilities across the nation, some with as many as 45 hours of broadcast a week. Although the television set was still a toy for the prosperous, the number of broadcast facilities began to multiply rapidly.

On August 10, 1948, the American Broadcasting Company (ABC) debuted the television show *Candid Camera*. The basis of the show was to observe the behavior of people in awkward circumstances — much to the amusement of the viewing audience — by a hidden camera. This human behavior by surreptitious observation did not go unnoticed by psychologists and security experts of the time. Psychologists recognized the hidden camera as a way to study human behavior, and for security experts it became a tool of observation. Of particular note to both was the profound effect on behavior that the presence of a camera had on people once they became aware that they were being observed.

Security experts would have to wait for advances in technology before the emerging technology could be used. Television was based on vacuum tube technology and the use of extensive broadcast facilities. It would be the space race of the late 1950s and 1960s that would bring the television and its cameras into the realm of security. Two such advances that contributed were the mass production of transistors and the addition of another new technology known as videotape. The transistor replaced bulky, failure-prone vacuum tubes and resulted in television cameras becoming smaller and more affordable. The videotape machine meant that the images no longer had to be broadcast; the images could be collected through one or more video cameras and the data transmitted via a closed circuit of wiring to be viewed on a video monitor or recorded on tape. This technology became known as closed-circuit television, or CCTV.

In the early 1960s, CCTV would be embraced by the Department of Defense as an aid for perimeter security. In the private sector, security experts for merchants were quick to see the value of such technology as an aid in the prevention of theft by customers and employees. Today, unimagined advances in the technology in cameras and recording devices have brought CCTV into the home and workplace in miniature form.

Why CCTV?

Information security is a multifaceted process, and the goal is to maintain security of the data processing facility and the assets within. Typically, those assets can be categorized as hardware, software, data, and people, which also involves the policies and procedures that govern the behavior of those people. With the possible exception of software, CCTV has the ability to provide defense of these assets on several fronts.

To Deter

The presence of cameras both internally and externally has a controlling effect on those who step into the field of view. In much the same way that a small padlock on a storage shed will keep neighbors from helping themselves to garden tools when the owner is not at home, the camera's lens tends to keep personnel from behaving outside of right and proper conduct. In the case of the storage shed, the lock sends the message that the contents are for the use of those with the key to access it, but it would offer little resistance to a determined thief. Likewise, the CCTV camera sends a similar message and will deter an otherwise honest employee from stepping out of line, but it will not stop someone determined to steal valuable assets. It becomes a conscious act to violate policies and procedures because the act itself will likely be observed and recorded.

With the cameras at the perimeter, those looking for easy targets will likely move on, just as employees within the facility will tend to conduct themselves in a manner that complies with corporate policies and procedures. With cameras trained on data storage devices, it becomes difficult to physically access the device unobserved, thereby deterring the theft of the data contained within. The unauthorized installation or removal of hardware can be greatly deterred by placing cameras in a manner that permits the observation of portals such as windows or doors. Overall, the statistics of crimes in the presence of CCTV cameras is dramatically reduced.

To Detect

Of particular value to the security professional is the ability of a CCTV system to provide detection. The eyes of a security guard can only observe a single location at a time, but CCTV systems can be configured in such a manner that a single pair of eyes can observe a bank of monitors. Further, each monitor can display the output of multiple cameras. The net effect is that the guard in turn can observe dozens of locations from a single observation point. During periods of little or no traffic, a person walking into the view of a camera is easily detected. Placing the camera input from high-security and high-traffic locations in the center of the displays can further enhance the coverage, because an intruder entering the field of view on a surrounding monitor would be easily detected even though the focus of attention is at the center of the monitors. Technology is in use that will evaluate the image field; and if the content of the image changes, an alarm can be sounded or the mode of recording changed to capture more detail of the image. Further, with the aid of recording equipment, videotape recordings can be reviewed in fast-forward or rewind to quickly identify the presence of intruders or other suspicious activities.

To Enforce

The human eyewitness has been challenged in the court of law more often in recent history. The lack of sleep, age of the witness, emotional state, etc., can all come to bear on the validity of an eyewitness statement. On the other hand, the camera does not get tired; video recording equipment is not susceptible to such human frailties. A video surveillance recording can vastly alter the outcome of legal proceedings and has an excellent track record in swaying juries as to the guilt or innocence of the accused. Often, disciplinary action is not even required once the alleged act is viewed on video by the accused, thereby circumventing the expense of a trial or arbitration. If an act is caught on tape that requires legal or disciplinary action, the tape ensures that there is additional evidence to support the allegations.

With the combined abilities of deterrence, detection, and enforcement of policies and procedures over several categories of assets, the CCTV becomes a very effective aid in the process of information security, clearly an aid that should be carefully considered when selecting countermeasures and defenses.

CCTV Components

One of the many appealing aspects of CCTV is the relative simplicity of its component parts. As in any system, the configuration can only be as good as the weakest link. Inexpensive speakers on the highest quality sound system will result in inexpensive quality sound. Likewise, a poor quality component in a CCTV system produces poor results. There are basically four groups of components:

1. Cameras
2. Transmission media

3. Monitors
4. Peripherals

The Camera

The job of the camera is to collect images of the desired viewing area and is by far the component that requires the most consideration when configuring a CCTV system. In a typical installation, the camera relies on visible light to illuminate the target; the reflected light is then collected through the camera lens and converted into an electronic signal that is transmitted back through the system to be processed.

The camera body contains the components to convert visible light to electronic signals. There are still good-quality, vacuum-tube cameras that produce an analog signal, but most cameras in use today are solid-state devices producing digital signal output. Primary considerations when selecting a camera are the security objectives. The sensitivity of a camera refers to the number of receptors on the imaging surface and will determine the resolution of the output; the greater the number of receptors, the greater the resolution. If there is a need to identify humans with a high level of certainty, one should consider a color camera with a high level of sensitivity. On the other hand, if the purpose of the system is primarily to observe traffic, a simple black-and-white camera with a lower sensitivity will suffice.

The size of cameras can range from the outwardly overt size of a large shoebox to the very covert size of a matchbox. Although the miniaturized cameras are capable of producing a respectable enough image to detect the presence of a human, most do not collect enough reflective light to produce an image quality that could be used for positive identification. This is an area of the technology that is seeing rapid improvement.

There are so many considerations in the placement of cameras that an expert should be consulted for the task. Some of those considerations include whether the targeted coverage is internal or external to the facility. External cameras need to be positioned so that all approaches to the facility can be observed, thereby eliminating blind spots. The camera should be placed high enough off the ground so that it cannot be easily disabled, but not so high that the images from the scene only produce the tops of people's heads and the camera is difficult to service. The camera mount can have motor drives that will permit aiming left and right (panning) or up and down (tilting), commonly referred to as a *pan/tilt drive*. Additionally, if the camera is on the exterior of the facility, it may require the use of a sunshade to prevent the internal temperature from reaching damaging levels. A mount that can provide heating to permit de-icing should be considered in regions of extreme cold so that snow and ice will not damage the pan/tilt drive. Internal cameras require an equal amount of consideration; and, again, the area to be covered and ambient light will play a large part in the placement. Cameras may be overt or covert and will need to be positioned such that people coming or going from highly valued assets or portals can be observed.

Because the quality of the image relies in large part on the reflective light, the lens on the camera must be carefully selected to make good use of available light. The cameras should be placed in a manner that will allow the evening lighting to work with the camera to provide front lighting (lights that shine in the same direction that the camera is aimed) to prevent shadowing of approaching people or objects. Constant adjustments must be made to lenses to accommodate the effects of a constantly changing angle of sunlight, changing atmospheric conditions, highly reflective rain or snowfall, and the transition to artificial lighting in the evening; all affect ambient light. This is best accomplished with the use of an automatic iris. The iris in a camera, just as in the human eye, opens and closes to adjust the amount of light that reaches the imaging surface. Direct exposure to an intense light source will result in blossoming of the image — where the image becomes all white and washes out the picture to the point where nothing is seen — and can also result in serious damage to the imaging surface within the camera.

The single most-important element of the camera is the lens. There are basically four types of lenses: standard, wide-angle, telephoto, and zoom. When compared to human eyesight, the standard lens is the rough equivalent; the wide-angle takes in a scene wider than what humans can see; and the telephoto is magnified and roughly equivalent to looking through a telescope. All are fixed focal length lenses. The characteristics of these three combined are a zoom lens.

The Transmission Media

Transmission media refer to how the video signal from the cameras will be transported to the multiplexer or monitor. This is typically some type of wiring.

Coaxial Cable

By far the most commonly used media are coaxial cables. There are varying grades of coaxial cable, and the quality of the cable will have a profound effect on the quality of the video. Coaxial cable consists of a single center conductor with a piezoelectric insulator surrounding it. The insulation is then encased in a foil wrap and further surrounded by a wire mesh. A final coating of weather-resistant insulation is placed around the entire bundle to produce a durable wire that provides strong protection for the signal as it transits through the center conductor. The center conductor can be a single solid wire or a single conductor made up of multiple strands of wire. Engineers agree that the best conductor for a video signal is pure copper. The amount of shielding will determine the level of protection for the center conductor. The shielding is grounded at both ends of the connection and thereby shunts extraneous noise from electromagnetic radiation to ground.

Although 100 percent pure copper is an excellent conductor of the electronic signal, there is still a level of internal resistance that will eventually degrade the signal's strength. To overcome the loss of signal strength, the diameter of the center conductor and the amount of shielding can be increased to obtain greater transmission lengths before an in-line repeater/amplifier will be required. This aspect of the cable is expressed in an industry rating. The farther the distance the signal must traverse, the higher the rating of the coaxial cable that should be used or noticeable signal degradation will occur.

Some examples are:

- RG59/U rated to carry the signal up to distances of 1000 feet
- RG6/U rated to carry a signal up to 1500 feet
- RG11/U rated to carry a signal up to 3000 feet

One of the benefits of coaxial cable is that it is easy to troubleshoot the media should there be a failure. A device that sends a square-wave signal down the wire (time domain reflectometer) can pinpoint the location of excessive resistance or a broken wire. Avoid using a solid center conductor wire on cameras mounted on a pan/tilt drive because the motion of the camera can fatigue the wire and cause a failure; thus, multi-strand wire should be used.

Fiber-Optic Cable

Fiber-optic cable is designed to transmit data in the form of light pulses. It typically consists of a single strand of highly purified silica (glass), smaller than a human hair, surrounded by another jacket of lower grade glass. This bundle is then clad in a protective layer to prevent physical damage to the core. The properties of the fiber-optic core are such that the outer surface of the center fiber has a mirror effect, thereby reflecting the light back into itself. This means that the cable can be curved, and it has almost no effect on the light pulses within. This effect, along with the fact that the frequency spectrum that spans the range of light is quite broad, produces an outstanding medium for the transfer of a signal. There is very little resistance or degradation of the signal as it traverses the cable, and the end result is much greater transmission lengths and available communication channels when compared to a metallic medium.

The reason that fiber-optics has not entirely replaced its coaxial counterpart is that the cost is substantially higher. Because the fiber does not conduct any electrical energy, the output signal must be converted to light pulses. This conversion is known as modulation and is accomplished using a laser. Once converted to light pulses, the signal is transferred into the fiber-optic cable. Because the fiber of the cable is so small, establishing good connections and splices is critical. Any misalignment or damage to the fiber will result in reflective energy or complete termination of the signal. Therefore, a skilled technician with precision splicing and connection tools is required. This cost, along with modulators/demodulators and the price of the medium, adds substantial cost to the typical CCTV installation.

For the additional cost, some of the benefits include generous gains in bandwidth. This means that more signals carrying a greater amount of data can be realized. Adding audio from microphones, adjustment signals to control zoom lenses and automatic irises, and additional cameras can be accommodated. The medium is smaller and lighter and can carry a signal measured in miles instead of feet. Because there is no electromagnetic energy to create compromising emanations, and a splice to tap the connection usually creates an easily detected interruption of the signal, there is the additional benefit of a high level of assurance of data integrity and security. In an environment of remote locations or a site containing highly valued assets, these benefits easily offset the additional cost of fiber-optic transmission.

Wireless Transmission

The option of not using wiring at all is available for CCTV. The output signals from cameras can be converted to radio frequency, light waves, or microwave signals for transmission. This may be the only viable option for some remote sites and can range from neighboring buildings using infrared transceivers to a satellite link for centralized monitoring of remote sites throughout the globe. Infrared technology must be configured in a line-of-sight manner and has a limited range of distance. Radio frequency and microwaves can get substantial improvements in distance but will require the use of repeaters and substations to traverse distances measured in miles. The more obstacles that must be negotiated (i.e., buildings, mountains, etc.), the greater the degradation of the signal that takes place.

Two of the biggest drawbacks of utilizing wireless are that the signal is vulnerable to atmospheric conditions and, as in any wireless transmission, easily intercepted and inherently insecure. Everything from the local weather to solar activity can affect the quality of the signal. From a security standpoint, the transmission is vulnerable to interception, which could reveal to the viewer the activity within a facility and compromise other internal defenses. Further, the signal could be jammed or modified to render the system useless or to provide false images. If wireless transmission is to be utilized, some type of signal scrambling or channel-hopping technology should be utilized to enhance the signal confidentiality and integrity.

Some of the more recent trends in transmission media have been the use of existing telephone lines and computer networking media. The dial-up modem has been implemented in some installations with success, but the limited amount of data that can be transmitted results in slow image refreshing; and control commands to the camera (focus, pan, tilt, etc.) are slow to respond. The response times and refresh rates can be substantially increased through the use of ISDN phone line technology. Some recent advances in data compression, and protocols that allow video over IP, have moved the transmission possibilities into existing computer network cabling.

The Monitor

The monitor is used to convert the signal from cameras into a visible image. The monitor can be used for real-time observation or the playback of previously recorded data.

Color or black-and-white video monitors are available but differ somewhat from a standard television set. A television set will come with the electronics to convert signals broadcast on the UHF and VHF frequency spectrums and demodulate those signals into a visible display of the images. The CCTV monitor does not come with such electronics and is designed to process the signals of a standard 75-ohm impedance video signal into visible images. This does not mean that a television set cannot be used as a video monitor, but proper attenuation equipment will be needed to convert the video into a signal that the television can process.

The lines of resolution determine detail and the overall sharpness of the image. The key to reproducing a quality image is matching as closely as possible the resolution of the monitor to the camera; but it is generally accepted that, if a close match is not made, then it is better to have a monitor with a greater resolution. The reason for this is that a 900-line monitor displaying an image of 300 lines of resolution will provide three available lines for each line of image. The image will be large and appear less crisp; but if at a later date the monitor is used in a split-screen fashion to display the output from several cameras on the screen at the same time, there will be enough resolution for each image. On the other hand, if the resolution of the monitor is lower than that of the camera, detail will be lost because the entire image cannot be displayed.

The size of the monitor to be used is based on several factors. The more images to be viewed, the greater the number of monitors. A single monitor is capable of displaying the output from several cameras on the same screen (see multiplexers), but this still requires a comfortable distance between the viewer and monitor. Although not exactly scientific, a general rule of thumb is that the viewer's fist at the end of an extended arm should just cover the image. This would place the viewer farther away from the monitor for a single image and closer if several images were displayed.

The Peripherals

A multiplexer is a hardware device that is capable of receiving the output signal from multiple cameras and processing those signals in several ways. The most common use is to combine the inputs from selected cameras into a single output such that the group of inputs is displayed on a single monitor. A multiplexer is capable

of accepting from four to 32 separate signals and provides video enhancement, data compression, and storing or output to a storage device. Some of the additional features available from a multiplexer include alarm modes that will detect a change to an image scene to alert motion and the ability to convert analog video signals into digital format. Some multiplexers have video storage capabilities, but most provide output that is sent to a separate storage device.

A CCTV system can be as simple as a camera, transmission medium, and a monitor. This may be fine if observation is the goal of the system; but if the intent is part of a security system, storage of captured images should be a serious consideration. The output from cameras can be stored and retrieved to provide nearly irrefutable evidence for legal proceedings.

There are several considerations in making a video storage decision. Foremost is the desired quality of the retrieved video. The quality of the data always equates to quantity of storage space required.

The primary difference in storage devices is whether the data will be stored in analog or digital format. The options for analog primarily consist of standard three-quarter-inch VHS tape or higher quality one-inch tape. The measure of quantity for analog is time, where the speed of recording and tape length will determine the amount of time that can be recorded. To increase the amount of time that a recording spans, one of the best features available in tape is time-lapse recording. Time-lapse videocassette recorders (VCRs) reduce the number of frames per second (fps) that are recorded. This equates to greater spans of time on less tape, but the images will appear as a series of sequential still images when played back. There is the potential of a critical event taking place between pictures and thereby losing its evidentiary value. This risk can be offset if the VCR is working in conjunction with a multiplexer that incorporates motion detection. Then the FPS can be increased to record more data from the channel with the activity. Another consideration of analog storage medium is that the shelf life is limited. Usually if there is no event of significance, then tapes can be recorded over existing data; but if there is a need for long-term storage, the quality of the video will degrade with time.

Another option for the storage of data is digital format. There are many advantages to utilizing digital storage media. The beauty of digital is that the signal is converted to binary 1s and 0s, and once converted the data is ageless. The data can then be stored on any data processing hardware, including hard disk drives, tapes, DVDs, magneto-optical disks, etc. By far the best-suited hardware is the digital video recorder (DVR). Some of the capabilities of DVRs may include triplex functions (simultaneous video observation, playback, and recording), multiple camera inputs, multi-screen display outputs, unlimited recording time by adding multiple hard disk drives, hot-swappable RAID, multiple trigger events for alarms, and tape archiving of trigger events. Because the data can be indexed on events such as time, dates, and alarms, the video can be retrieved for playback almost instantly.

Whether analog or digital, the sensitivity of the cameras used, frames recorded each second, whether the signal is in black and white or color, and the length of time to store will impact the amount of storage space required.

Putting It All Together

By understanding the stages of implementation and how hardware components are integrated, the security professional will have a much higher likelihood of successfully integrating a CCTV system. There is no typical installation, and every site will have its unique characteristics to accommodate; but there is a typical progression of events from design to completion.

- *Define the purpose.* If observation of an entrance is the only goal, there will be little planning to consider. Will the quality of images be sufficient to positively identify an individual? Will there be a requirement to store image data, and what will be the retention period? Should the presence of a CCTV system be obvious with the presence of cameras, or will they be hidden? Ultimately, the question becomes: What is the purpose of implementing and what is to be gained?
- *Define the surveyed area.* Complete coverage for the exterior and interior of a large facility or multiple facilities will require a substantial budget. If there are financial restraints, then decisions will have to be made concerning what areas will be observed. Some of the factors that will influence that decision may be the value of the assets under scrutiny and the security requirements in a particular location.

- *Select appropriate cameras.* At this point in the planning, a professional consultation should be considered. Internal surveillance is comparatively simpler than external because the light levels are consistent; but external surveillance requires an in-depth understanding of how light, lenses, weather, and other considerations will affect the quality of the images. Placement of cameras can make a substantial difference in the efficiency of coverage and the effectiveness of the images that will be captured.
- *Selection and placement of monitors.* Considerations that need to be addressed when planning the purchase of monitors include the question of how many camera inputs will have to be observed at the same time. How many people will be doing the observation simultaneously? How much room space is available in the monitoring room? Is there sufficient air conditioning to accommodate the heat generated by large banks of monitors?
- *Installation of transmission media.* Once the camera locations and the monitoring location have been determined, the installation of the transmission media can then begin. A decision should have already been made on the type of media that will be utilized and sufficient quantities ordered. Technicians skilled in installation, splicing, and testing will be required.
- *Peripherals.* If the security requirements are such that image data must be recorded and retained, then storage equipment will have to be installed. Placement of multiplexers, switches, universal power supplies, and other supporting equipment will have to be planned in advance. Personnel access controls are critical to areas containing such equipment.

Summary

CCTV systems are by no means a guarantee of security, but the controlling effect they have on human behavior cannot be dismissed easily. The mere presence of a camera, regardless of whether it works, has proven to be invaluable in the security industry as a deterrent.

Defense-in-depth is the mantra of the information security industry. It is the convergence of many layers of protection that will ultimately provide the highest level of assurance, and the physical security of a data processing facility is often the weakest layer. There is little else that can compare to a properly implemented CCTV system to provide security of the facility, data, and people, as well as enforcement of policies and procedures.

Types of Information Security Controls

Harold F. Tipton, CISSP

Security is generally defined as the freedom from danger or as the condition of safety. Computer security, specifically, is the protection of data in a system against unauthorized disclosure, modification, or destruction and protection of the computer system itself against unauthorized use, modification, or denial of service. Because certain computer security controls inhibit productivity, security is typically a compromise toward which security practitioners, system users, and system operations and administrative personnel work to achieve a satisfactory balance between security and productivity.

Controls for providing information security can be physical, technical, or administrative. These three categories of controls can be further classified as either preventive or detective. Preventive controls attempt to avoid the occurrence of unwanted events, whereas detective controls attempt to identify unwanted events after they have occurred. Preventive controls inhibit the free use of computing resources and therefore can be applied only to the degree that the users are willing to accept. Effective security awareness programs can help increase users' level of tolerance for preventive controls by helping them understand how such controls enable them to trust their computing systems. Common detective controls include audit trails, intrusion detection methods, and checksums.

Three other types of controls supplement preventive and detective controls. They are usually described as deterrent, corrective, and recovery. Deterrent controls are intended to discourage individuals from intentionally violating information security policies or procedures. These usually take the form of constraints that make it difficult or undesirable to perform unauthorized activities or threats of consequences that influence a potential intruder to not violate security (e.g., threats ranging from embarrassment to severe punishment).

Corrective controls either remedy the circumstances that allowed the unauthorized activity or return conditions to what they were before the violation. Execution of corrective controls could result in changes to existing physical, technical, and administrative controls. Recovery controls restore lost computing resources or capabilities and help the organization recover monetary losses caused by a security violation.

Deterrent, corrective, and recovery controls are considered to be special cases within the major categories of physical, technical, and administrative controls; they do not clearly belong in either preventive or detective categories. For example, it could be argued that deterrence is a form of prevention because it can cause an intruder to turn away; however, deterrence also involves detecting violations, which may be what the intruder fears most. Corrective controls, on the other hand, are not preventive or detective, but they are clearly linked with technical controls when anti-viral software eradicates a virus or with administrative controls when backup procedures enable restoring a damaged database. Finally, recovery controls are neither preventive nor detective but are included in administrative controls as disaster recovery or contingency plans.

Because of these overlaps with physical, technical, and administrative controls, the deterrent, corrective, and recovery controls are not discussed further in this chapter. Instead, the preventive and detective controls within the three major categories are examined.

Physical Controls

Physical security is the use of locks, security guards, badges, alarms, and similar measures to control access to computers, related equipment (including utilities), and the processing facility itself. In addition, measures are required for protecting computers, related equipment, and their contents from espionage, theft, and destruction or damage by accident, fire, or natural disaster (e.g., floods and earthquakes).

Preventive Physical Controls

Preventive physical controls are employed to prevent unauthorized personnel from entering computing facilities (i.e., locations housing computing resources, supporting utilities, computer hard copy, and input data media) and to help protect against natural disasters. Examples of these controls include:

- Backup files and documentation
- Fences
- Security guards
- Badge systems
- Double door systems
- Locks and keys
- Backup power
- Biometric access controls
- Site selection
- Fire extinguishers

Backup Files and Documentation

Should an accident or intruder destroy active data files or documentation, it is essential that backup copies be readily available. Backup files should be stored far enough away from the active data or documentation to avoid destruction by the same incident that destroyed the original. Backup material should be stored in a secure location constructed of noncombustible materials, including two-hour-rated fire walls. Backups of sensitive information should have the same level of protection as the active files of this information; it is senseless to provide tight security for data on the system but lax security for the same data in a backup location.

Fences

Although fences around the perimeter of the building do not provide much protection against a determined intruder, they do establish a formal no-trespassing line and can dissuade the simply curious person. Fences should have alarms or should be under continuous surveillance by guards, dogs, or TV monitors.

Security Guards

Security guards are often stationed at the entrances of facilities to intercept intruders and ensure that only authorized persons are allowed to enter. Guards are effective in inspecting packages or other hand-carried items to ensure that only authorized, properly described articles are taken into or out of the facility. The effectiveness of stationary guards can be greatly enhanced if the building is wired with appropriate electronic detectors with alarms or other warning indicators terminating at the guard station. In addition, guards are often used to patrol unattended spaces inside buildings after normal working hours to deter intruders from obtaining or profiting from unauthorized access.

Badge Systems

Physical access to computing areas can be effectively controlled using a badge system. With this method of control, employees and visitors must wear appropriate badges whenever they are in access-controlled areas. Badge-reading systems programmed to allow entrance only to authorized persons can then easily identify intruders.

Double Door Systems

Double door systems can be used at entrances to restricted areas (e.g., computing facilities) to force people to identify themselves to the guard before they can be released into the secured area. Double doors are an excellent way to prevent intruders from following closely behind authorized persons and slipping into restricted areas.

Locks and Keys

Locks and keys are commonly used for controlling access to restricted areas. Because it is difficult to control copying of keys, many installations use cipher locks (i.e., combination locks containing buttons that open the lock when pushed in the proper sequence). With cipher locks, care must be taken to conceal which buttons are being pushed to avoid a compromise of the combination.

Backup Power

Backup power is necessary to ensure that computer services are in a constant state of readiness and to help avoid damage to equipment if normal power is lost. For short periods of power loss, backup power is usually provided by batteries. In areas susceptible to outages of more than 15 to 30 minutes, diesel generators are usually recommended.

Biometric Access Controls

Biometric identification is a more-sophisticated method of controlling access to computing facilities than badge readers, but the two methods operate in much the same way. Biometrics used for identification include fingerprints, handprints, voice patterns, signature samples, and retinal scans. Because biometrics cannot be lost, stolen, or shared, they provide a higher level of security than badges. Biometric identification is recommended for high-security, low-traffic entrance control.

Site Selection

The site for the building that houses the computing facilities should be carefully chosen to avoid obvious risks. For example, wooded areas can pose a fire hazard, areas on or adjacent to an earthquake fault can be dangerous and sites located in a flood plain are susceptible to water damage. In addition, locations under an aircraft approach or departure route are risky, and locations adjacent to railroad tracks can be susceptible to vibrations that can precipitate equipment problems.

Fire Extinguishers

The control of fire is important to prevent an emergency from turning into a disaster that seriously interrupts data processing. Computing facilities should be located far from potential fire sources (e.g., kitchens or cafeterias) and should be constructed of noncombustible materials. Furnishings should also be noncombustible. It is important that appropriate types of fire extinguishers be conveniently located for easy access. Employees must be trained in the proper use of fire extinguishers and in the procedures to follow should a fire break out.

Automatic sprinklers are essential in computer rooms and surrounding spaces and when expensive equipment is located on raised floors. Sprinklers are usually specified by insurance companies for the protection of any computer room that contains combustible materials. However, the risk of water damage to computing equipment is often greater than the risk of fire damage. Therefore, carbon dioxide extinguishing systems were developed; these systems flood an area threatened by fire with carbon dioxide, which suppresses fire by removing oxygen from the air. Although carbon dioxide does not cause water damage, it is potentially lethal to people in the area and is now used only in unattended areas.

Current extinguishing systems flood the area with halon, which is usually harmless to equipment and less dangerous to personnel than carbon dioxide. At a concentration of about 10percent, halon extinguishes fire and can be safely breathed by humans. However, higher concentrations can eventually be a health hazard. In addition, the blast from releasing halon under pressure can blow loose objects around and can be a danger to equipment and personnel. For these reasons and because of the high cost of halon, it is typically used only under raised floors in computer rooms. Because it contains chlorofluorocarbons, it will soon be phased out in favor of a gas that is less hazardous to the environment.

Detective Physical Controls

Detective physical controls warn protective services personnel that physical security measures are being violated. Examples of these controls include:

- Motion detectors
- Smoke and fire detectors
- Closed-circuit television monitors
- Sensors and alarms

Motion Detectors

In computing facilities that usually do not have people in them, motion detectors are useful for calling attention to potential intrusions. Motion detectors must be constantly monitored by guards.

Fire and Smoke Detectors

Fire and smoke detectors should be strategically located to provide early warning of a fire. All fire detection equipment should be tested periodically to ensure that it is in working condition.

Closed-Circuit Television Monitors

Closed-circuit televisions can be used to monitor the activities in computing areas where users or operators are frequently absent. This method helps detect individuals behaving suspiciously.

Sensors and Alarms

Sensors and alarms monitor the environment surrounding the equipment to ensure that air and cooling water temperatures remain within the levels specified by equipment design. If proper conditions are not maintained, the alarms summon operations and maintenance personnel to correct the situation before a business interruption occurs.

Technical Controls

Technical security involves the use of safeguards incorporated in computer hardware, operations or applications software, communications hardware and software, and related devices. Technical controls are sometimes referred to as logical controls.

Preventive Technical Controls

Preventive technical controls are used to prevent unauthorized personnel or programs from gaining remote access to computing resources. Examples of these controls include:

- Access control software
- Antivirus software
- Library control systems
- Passwords
- Smart cards
- Encryption
- Dial-up access control and callback systems

Access Control Software

The purpose of access control software is to control sharing of data and programs between users. In many computer systems, access to data and programs is implemented by access control lists that designate which users are allowed access. Access control software provides the ability to control access to the system by establishing that only registered users with an authorized log-on ID and password can gain access to the computer system.

After access to the system has been granted, the next step is to control access to the data and programs residing in the system. The data or program owner can establish rules that designate who is authorized to use the data or program.

Anti-Virus Software

Viruses have reached epidemic proportions throughout the microcomputing world and can cause processing disruptions and loss of data as well as significant loss of productivity while cleanup is conducted. In addition, new viruses are emerging at an ever-increasing rate — currently about one every 48 hours. It is recommended that anti-virus software be installed on all microcomputers to detect, identify, isolate, and eradicate viruses. This software must be updated frequently to help fight new viruses. In addition, to help ensure that viruses are intercepted as early as possible, anti-virus software should be kept active on a system, not used intermittently at the discretion of users.

Library Control Systems

These systems require that all changes to production programs be implemented by library control personnel instead of the programmers who created the changes. This practice ensures separation of duties, which helps prevent unauthorized changes to production programs.

Passwords

Passwords are used to verify that the user of an ID is the owner of the ID. The ID–password combination is unique to each user and therefore provides a means of holding users accountable for their activity on the system.

Fixed passwords that are used for a defined period of time are often easy for hackers to compromise; therefore, great care must be exercised to ensure that these passwords do not appear in any dictionary. Fixed passwords are often used to control access to specific databases. In this use, however, all persons who have authorized access to the database use the same password; therefore, no accountability can be achieved.

Currently, dynamic or one-time passwords, which are different for each log-on, are preferred over fixed passwords. Dynamic passwords are created by a token that is programmed to generate passwords randomly.

Smart Cards

Smart cards are usually about the size of a credit card and contain a chip with logic functions and information that can be read at a remote terminal to identify a specific user's privileges. Smart cards now carry prerecorded, usually encrypted access control information that is compared with data that the user provides (e.g., a personal ID number or biometric data) to verify authorization to access the computer or network.

Encryption

Encryption is defined as the transformation of plaintext (i.e., readable data) into ciphertext (i.e., unreadable data) by cryptographic techniques. Encryption is currently considered to be the only sure way of protecting data from disclosure during network transmissions.

Encryption can be implemented with either hardware or software. Software-based encryption is the least expensive method and is suitable for applications involving low-volume transmissions; the use of software for large volumes of data results in an unacceptable increase in processing costs. Because there is no overhead associated with hardware encryption, this method is preferred when large volumes of data are involved.

Dial-Up Access Control and Callback Systems

Dial-up access to a computer system increases the risk of intrusion by hackers. In networks that contain personal computers or are connected to other networks, it is difficult to determine whether dial-up access is available or not because of the ease with which a modem can be added to a personal computer to turn it into a dial-up access point. Known dial-up access points should be controlled so that only authorized dial-up users can get through.

Currently, the best dial-up access controls use a microcomputer to intercept calls, verify the identity of the caller (using a dynamic password mechanism), and switch the user to authorized computing resources as requested. Previously, call-back systems intercepted dial-up callers, verified their authorization and called them back at their registered number, which at first proved effective; however, sophisticated hackers have learned how to defeat this control using call-forwarding techniques.

Detective Technical Controls

Detective technical controls warn personnel of violations or attempted violations of preventive technical controls. Examples of these include audit trails and intrusion detection expert systems, which are discussed in the following sections.

Audit Trails

An audit trail is a record of system activities that enables the reconstruction and examination of the sequence of events of a transaction, from its inception to output of final results. Violation reports present significant, security-oriented events that may indicate either actual or attempted policy transgressions reflected in the audit trail. Violation reports should be frequently and regularly reviewed by security officers and database owners to identify and investigate successful or unsuccessful unauthorized accesses.

Intrusion Detection Systems

These expert systems track users (on the basis of their personal profiles) while they are using the system to determine whether their current activities are consistent with an established norm. If not, the user's session can be terminated or a security officer can be called to investigate. Intrusion detection can be especially effective in cases in which intruders are pretending to be authorized users or when authorized users are involved in unauthorized activities.

Administrative Controls

Administrative, or personnel, security consists of management constraints, operational procedures, accountability procedures, and supplemental administrative controls established to provide an acceptable level of protection for computing resources. In addition, administrative controls include procedures established to ensure that all personnel who have access to computing resources have the required authorizations and appropriate security clearances.

Preventive Administrative Controls

Preventive administrative controls are personnel-oriented techniques for controlling people's behavior to ensure the confidentiality, integrity, and availability of computing data and programs. Examples of preventive administrative controls include:

- Security awareness and technical training
- Separation of duties
- Procedures for recruiting and terminating employees
- Security policies and procedures
- Supervision
- Disaster recovery, contingency, and emergency plans
- User registration for computer access

Security Awareness and Technical Training

Security awareness training is a preventive measure that helps users to understand the benefits of security practices. If employees do not understand the need for the controls being imposed, they may eventually circumvent them and thereby weaken the security program or render it ineffective.

Technical training can help users prevent the most common security problem — errors and omissions — as well as ensure that they understand how to make appropriate backup files and detect and control viruses. Technical training in the form of emergency and fire drills for operations personnel can ensure that proper action will be taken to prevent such events from escalating into disasters.

Separation of Duties

This administrative control separates a process into component parts, with different users responsible for different parts of the process. Judicious separation of duties prevents one individual from obtaining control of an entire process and forces collusion with others in order to manipulate the process for personal gain.

Recruitment and Termination Procedures

Appropriate recruitment procedures can prevent the hiring of people who are likely to violate security policies. A thorough background investigation should be conducted, including checking on the applicant's criminal

history and references. Although this does not necessarily screen individuals for honesty and integrity, it can help identify areas that should be investigated further.

Three types of references should be obtained: (1) employment, (2) character, and (3) credit. Employment references can help estimate an individual's competence to perform, or be trained to perform, the tasks required on the job. Character references can help determine such qualities as trustworthiness, reliability, and ability to get along with others. Credit references can indicate a person's financial habits, which in turn can be an indication of maturity and willingness to assume responsibility for one's own actions.

In addition, certain procedures should be followed when any employee leaves the company, regardless of the conditions of termination. Any employee being involuntarily terminated should be asked to leave the premises immediately upon notification, to prevent further access to computing resources. Voluntary terminations may be handled differently, depending on the judgment of the employee's supervisors, to enable the employee to complete work in process or train a replacement.

All authorizations that have been granted to an employee should be revoked upon departure. If the departing employee has the authority to grant authorizations to others, these other authorizations should also be reviewed. All keys, badges, and other devices used to gain access to premises, information, or equipment should be retrieved from the departing employee. The combinations of all locks known to a departing employee should be changed immediately. In addition, the employee's log-on IDs and passwords should be canceled, and the related active and backup files should be either deleted or reassigned to a replacement employee.

Any special conditions to the termination (e.g., denial of the right to use certain information) should be reviewed with the departing employee; in addition, a document stating these conditions should be signed by the employee. All terminations should be routed through the computer security representative for the facility where the terminated employee works to ensure that all information system access authority has been revoked.

Security Policies and Procedures

Appropriate policies and procedures are key to the establishment of an effective information security program. Policies and procedures should reflect the general policies of the organization as regards the protection of information and computing resources. Policies should cover the use of computing resources, marking of sensitive information, movement of computing resources outside the facility, introduction of personal computing equipment and media into the facility, disposal of sensitive waste, and computer and data security incident reporting. Enforcement of these policies is essential to their effectiveness.

Supervision

Often, an alert supervisor is the first person to notice a change in an employee's attitude. Early signs of job dissatisfaction or personal distress should prompt supervisors to consider subtly moving the employee out of a critical or sensitive position.

Supervisors must be thoroughly familiar with the policies and procedures related to the responsibilities of their department. Supervisors should require that their staff members comply with pertinent policies and procedures and should observe the effectiveness of these guidelines. If the objectives of the policies and procedures can be accomplished more effectively, the supervisor should recommend appropriate improvements. Job assignments should be reviewed regularly to ensure that an appropriate separation of duties is maintained, that employees in sensitive positions are occasionally removed from a complete processing cycle without prior announcement, and that critical or sensitive jobs are rotated periodically among qualified personnel.

Disaster Recovery, Contingency, and Emergency Plans

The disaster recovery plan is a document containing procedures for emergency response, extended backup operations, and recovery should a computer installation experience a partial or total loss of computing resources or physical facilities (or of access to such facilities). The primary objective of this plan, used in conjunction with the contingency plans, is to provide reasonable assurance that a computing installation can recover from disasters, continue to process critical applications in a degraded mode, and return to a normal mode of operation within a reasonable time. A key part of disaster recovery planning is to provide for processing at an alternative site during the time that the original facility is unavailable.

Contingency and emergency plans establish recovery procedures that address specific threats. These plans help prevent minor incidents from escalating into disasters. For example, a contingency plan might

provide a set of procedures that defines the condition and response required to return a computing capability to nominal operation; an emergency plan might be a specific procedure for shutting down equipment in the event of a fire or for evacuating a facility in the event of an earthquake.

User Registration for Computer Access

Formal user registration ensures that all users are properly authorized for system and service access. In addition, it provides the opportunity to acquaint users with their responsibilities for the security of computing resources and to obtain their agreement to comply with related policies and procedures.

Detective Administrative Controls

Detective administrative controls are used to determine how well security policies and procedures are complied with, to detect fraud, and to avoid employing persons that represent an unacceptable security risk. This type of control includes:

- Security reviews and audits
- Performance evaluations
- Required vacations
- Background investigations
- Rotation of duties

Security Reviews and Audits

Reviews and audits can identify instances in which policies and procedures are not being followed satisfactorily. Management involvement in correcting deficiencies can be a significant factor in obtaining user support for the computer security program.

Performance Evaluations

Regularly conducted performance evaluations are an important element in encouraging quality performance. In addition, they can be an effective forum for reinforcing management's support of information security principles.

Required Vacations

Tense employees are more likely to have accidents or make errors and omissions while performing their duties. Vacations contribute to the health of employees by relieving the tensions and anxieties that typically develop from long periods of work. In addition, if all employees in critical or sensitive positions are forced to take vacations, there will be less opportunity for an employee to set up a fraudulent scheme that depends on the employee's presence (e.g., to maintain the fraud's continuity or secrecy). Even if the employee's presence is not necessary to the scheme, required vacations can be a deterrent to embezzlement because the employee may fear discovery during his or her absence.

Background Investigations

Background investigations may disclose past performances that might indicate the potential risks of future performance. Background investigations should be conducted on all employees being considered for promotion or transfer into a position of trust; such investigations should be completed before the employee is actually placed in a sensitive position. Job applicants being considered for sensitive positions should also be investigated for potential problems. Companies involved in government-classified projects should conduct these investigations while obtaining the required security clearance for the employee.

Rotation of Duties

Like required vacations, rotation of duties (i.e., moving employees from one job to another at random intervals) helps deter fraud. An additional benefit is that as a result of rotating duties, employees are cross-trained to perform each other's functions in case of illness, vacation, or termination.

PHYSICAL CONTROLS

Preventive

- Backup files and documentation
- Fences
- Security guards
- Badge systems
- Locks and keys
- Backup power
- Biometric access controls
- Site selection
- Fire extinguishers

Detective

- Motion detectors
- Smoke and fire detectors
- Closed-circuit television monitoring
- Sensors and alarms

TECHNICAL CONTROLS

Preventive

- Access control software
- Anti-virus software
- Library control systems
- Passwords
- Smart cards
- Encryption
- Dial-up access control and callback systems

Detective

- Audit trails
- Intrusion-detection expert systems

ADMINISTRATIVE CONTROLS

Preventive

- Security awareness and technical training
- Separation of duties
- Procedures for recruiting and terminating employees
- Security policies and procedures
- Supervision
- Disaster recovery and contingency plans
- User registration for computer access

Detective

- Security reviews and audits
- Performance evaluations
- Required vacations
- Background investigations
- Rotation of duties

EXHIBIT 162.1 Information security controls.

Summary

Information security controls can be classified as physical, technical, or administrative. These are further divided into preventive and detective controls. Exhibit 162.1 lists the controls discussed in this chapter.

The organization's security policy should be reviewed to determine the confidentiality, integrity, and availability needs of the organization. The appropriate physical, technical, and administrative controls can then be selected to provide the required level of information protection, as stated in the security policy.

A careful balance between preventive and detective control measures is needed to ensure that users consider the security controls reasonable and to ensure that the controls do not overly inhibit productivity. The combination of physical, technical, and administrative controls best suited for a specific computing environment can be identified by completing a quantitative risk analysis. Because this is usually an expensive, tedious, and subjective process, however, an alternative approach — referred to as meeting the standard of due care — is often used. Controls that meet a standard of due care are those that would be considered prudent by most organizations in similar circumstances or environments. Controls that meet the standard of due care generally are readily available for a reasonable cost and support the security policy of the organization; they include, at the least, controls that provide individual accountability, auditability, and separation of duties.

Physical Security

Tom Peltier

Before any controls can be implemented into the workplace, it is necessary to assess the current level of security. This can be accomplished in a number of ways. The easiest one is a "walk-about." After hours, walk through the facility and check for five key controls:

1. Office doors are locked.
2. Desks and cabinets are locked.
3. Workstations are secured.
4. Diskettes are secured.
5. Company information is secured.

Checking for these five key control elements will give you a basic understanding of the level of controls already in place and a benchmark for measuring improvements once a security control system is implemented. Typically, this review will nearly show a 90% control deficiency rate. A second review is recommended six to nine months after the new security controls are in place.

This chapter examines two key elements of basic computer security: physical security and biometrics. Physical security protects your organization's physical computer facilities. It includes access to the building, to the computer room(s), to the computers (mainframe, mini, and micros), to the magnetic media, and to other media. Biometrics devices record physical traits (i.e., fingerprint, palm print, facial features, etc.) or behavioral traits (signature, typing habits, etc.).

A BRIEF HISTORY

In the beginning of the computer age, it was easy to protect the systems; they were locked away in a lab and only a select few "wizards" were granted access. Today, computers are cheaper, smaller, and more accessible to almost everyone.

During the mid-twentieth century, the worldwide market for mainframe computer systems exploded. As the third-generation systems became available in the 1960s, companies began to understand their dependence on these systems. By the mid to late 1970s, the security industry began to

catch up: with Halon fire suppression systems, card access, and RACF and ACF2. In the final quarter of the century, mainframe-centered computing was at its zenith.

By 1983, the affordable portable computer began to change the working landscape for information security professionals. An exodus from the mainframe to the desktop began. The controls that had been so hard won in the previous two decades were now considered the cause of much bureaucracy. Physical security is now needed in desktops. For years, conventional thinking was that a computer is a computer is a computer is a computer. Controls are even more important in the desktop or workstation environment than in the mainframe environment.

The computing environment is now moving from the desktop to the user. With the acceptance of telecommuting, the next challenge will be to apply physical security solutions to the user-centered computing environment.

With computers on every desk connected via networks to other local and remote systems, physical security needs must be reviewed and upgraded wherever necessary. Advances in computer and communications security are not enough; physical security remains a vitally important component of an overall information security plan.

WHERE TO FOCUS ATTENTION

Before implementing any form of physical security, it may be helpful to conduct a limited business impact analysis (BIA) to focus on existing threats to the computer systems and determine where resources can best be spent. It is very important to consider all potential threats, even unlikely ones. Ignore those with a zero likelihood, such as a tsunami in Phoenix or a sandstorm in Maui. A very simple BIA could be diagrammed as shown in Exhibit 1.

An unlimited number of threats can be of concern to your organization. Any number of high-likelihood threats can be identified. First consider those threats that might actually affect your organization (e.g., fire, flood, or fraud). Three elements are generally associated with each threat:

- The agent: the destructive agent can be a human, a machine, or nature.
- The motive: the only agent that can threaten accidentally and intentionally is the human.
- The results: for the information systems community, this would be a loss of access or unauthorized access, modification, or disclosure or destruction of data or information.

TYPE OF THREAT	Probability	Human Impact	Property Impact	Business Impact	Internal Resource	External Resource	TOTAL
	4 ←				→	1	
Fire	3	3	4	4	2	2	16

Exhibit 1. Business Impact Analysis Example.

Note: Rank each impact based on 4 = high to 1 = low. Rank each resource based on 4 = weak resources available to 1 = strong resources available.

The focus of physical security has often been on human-made disasters, such as sabotage, hacking, and human error. Don't forget that the same kinds of threats can also occur from natural disasters.

NATURAL DISASTERS AND CONTROLS

Fire — A conflagration affects information systems through heat, smoke, or suppression agent (e.g., fire extinguishers and water) damage. This threat category can be minor, major, or catastrophic. *Controls:* install smoke detectors near equipment; keep fire extinguishers near equipment and train employees in their proper use; conduct regular fire evacuation exercises.

Environmental failure — This type of disaster includes any interruption in the supply of controlled environmental support provided to the operations center. Environmental controls include clean air, air conditioning, humidity, and water. *Controls:* since humans and computers don't coexist well, try to keep them separate. Many companies are establishing command centers for employees and a "lights-out" environment for the machines. Keep all rooms containing computers at reasonable temperatures (60 to 75°F or 10 to 25°C). Keep humidity levels at 20 to 70% and monitor environmental settings.

Earthquake — A violent ground motion results from stresses and movements of the earth's surface. *Controls:* keep computer systems away from

glass and elevated surfaces; in high-risk areas secure the computers with antivibration devices.

Liquid Leakage — A liquid inundation includes burst or leaking pipes and accidental discharge of sprinklers. *Controls:* keep liquid-proof covers near the equipment and install water detectors on the structural floor near the computer systems.

Lightning — An electrical charge of air can cause either direct lightning strikes to the facility or surges due to strikes to electrical power transmission lines, transformers, and substations. *Controls:* install surge suppressors, store backups in grounded storage media, install and test Uninterruptible Power Supply (UPS) and diesel generators.

Electrical Interruption — A disruption in the electrical power supply, usually lasting longer than one-half hour, can have serious business impact. *Controls:* install and test UPS, install line filters to control voltage spikes, and install antistatic carpeting.

THE HUMAN FACTOR

Recent FBI statistics indicate that 72% of all thefts, fraud, sabotage, and accidents are caused by a company's own employees. Another 15 to 20% comes from contractors and consultants who are given access to buildings, systems, and information. Only about 5 to 8% is done by external people, yet the press and management focus mostly on them. The typical computer criminal is a nontechnical authorized user of the system who has been around long enough to locate the control deficiencies.

When implementing control devices, make certain that the controls meet the organization's needs. Include a review of internal access, and be certain that employees meet the standards of due care imposed on external sources. "Intruders" can include anybody who is not authorized to enter a building, system, or data.

The first defense against instruders is to keep them out of the building or computer room. However, because of cost-cutting measures in the past two decades, very few computer facilities are guarded anymore. With computers everywhere, determining where to install locks is a significant problem.

To gain access to any business environment, everybody should have to pass an authentication and/or authorization test. The three ways of authenticating users involve something:

- That the user knows (a password).
- That the user has (a badge, key, card, or token).
- Of their physiognomy (fingerprint, retinal image, voice).

LOCKS

In addition to securing the campus, it may be necessary to secure the computers, networks, disk drives, and electronic media. One method of securing a workstation is with an anchor pad, a metal pad with locking rods secured to the surface of the workstation. The mechanism is installed to the shell of the computer. These are available from many vendors.

Many organizations use cables and locks. Security cables are multi-strand, aircraft-type steel cables affixed to the workstation with a permanently attached plate that anchors the security cable to the desk or other fixture.

Disk locks are another way to secure the workstation. These small devices are quickly inserted into the diskette slot and lock out any other diskette from the unit. They can prevent unauthorized booting from diskettes and infection from viruses.

Cryptographic locks also prevent unauthorized access by rendering information unreadable to unauthorized personnel. Encryption software does not impact day-to-day operations while ensuring the confidentiality of sensitive business information. Crypographic locks are cost-effective and easily available.

TOKENS

As human security forces shrink, there is more need to ensure that only authorized personnel can get into the computer room. A token is an object the user carries to authenticate his or her identity. These devices can be token cards, card readers, or biometric devices. They have the same purpose: to validate the user to the system. The most prevalent form is the card, an electric device that normally contains encoded information about the individual who is authorized to carry it. Tokens are typically used with another type of authentication. Many cipher locks have been replaced with token card access systems.

Challenge-Response Tokens

Challenge-response tokens supply passcodes that are generated using a challenge from the process requesting authentication (such as the Security Dynamics' SecurID). Users enter their assigned user IDs and passwords plus a password supplied by the token card. This process requires that the user supply something they possess (the token) and something that they know (the challenge/response process). This process makes passcode sniffing and brute force attacks futile.

Challenge-response is an asynchronous process. An alternative to challenge-response is the synchronous token that generates the password without the input of a challenge from the system. It is synchronized with

the authenticating computer when the user and token combination is registered on the system.

Dumb Cards

For many years, photo identification badges have sufficed as a credential for most people. With drivers' licenses, passports, and employee ID badges, the picture — along with the individual's statistics — supplies enough information for the authentication process to be completed. Most people flash the badge to the security guard or give a license to a bank teller. Someone visually matches the ID holder's face to the information on the card.

Smart Cards

The automatic teller machine (ATM) card is an improvement on the "dumb card"; these "smart" cards require the user to enter a personal ID number (PIN) along with the card to gain access. The ATM compares the information encoded on the magnetic stripe with the information entered at the ATM machine.

The smart card contains microchips that consist of a processor, memory used to store programs and data, and some kind of user interface. Sensitive information is kept in a secret read-only area in its memory, which is encoded during manufacturing and is inaccessible to the card's owner. Typically, these cards use some form of cryptography that protects the information. Not all smart cards work with card readers. A user inserts the card into the reader, the system displays a message, and if there is a match, then the user is granted access.

Types of Access Cards

Access cards employ different types of technology to ensure authenticity:

- Photo ID cards contain a photograph of the user's face and are checked visually.
- Optical-coded cards contain tiny, photographically etched or laser-burned dots representing binary zeros and ones that contain the individual's encoded ID number. The card's protective lamination cannot be removed without destroying the data and invalidating the card.
- Electric circuit cards contain a printed circuit pattern. When inserted into a reader, the card closes certain electrical circuits.
- Magnetic cards, the most common form of access control card, contain magnetic particles that contain, in encoded form, the user's permanent ID number. Data can be encoded on the card, but the tape itself cannot be altered or copied.
- Metallic stripe cards contain rows of copper strips. The presence or absence of strips determines the code.

BIOMETRIC DEVICES

Every person has unique physiological, behavioral, and morphological characteristics that can be examined and quantified. Biometrics is the use of these characteristics to provide positive personal identification. Fingerprints and signatures have been used for years to prove an individual's identity, but individuals can be identified in many other ways. Computerized biometrics identification systems examine a particular trait and use that information to decide whether the user may enter a building, unlock a computer, or access system information.

Biometric devices use some type of data input device, such as a video camera, retinal scanner, or microphone, to collect information that is unique to the individual. A digitized representation of a user's biometric characteristic (fingerprint, voice, etc.) is used in the authentication process. This type of authentication is virtually spoof-proof and is never misplaced. The data are relatively static but not necessarily secret. The advantage of this authentication process is that it provides the correct data to the input devices.

Fingerprint Scan

The individual places a finger in or on a reader that scans the finger, digitizes the fingerprint, and compares it against a stored fingerprint image in the file. This method can be used to verify the identity of individuals or compare information against a data base covering many individuals for recognition. Performance:

- False rejection rate = 9.4%
- False acceptance rate = 0
- Average processing time = 7 seconds

Retinal Scan

This device requires that the user look into an eyepiece that laser-scans the pattern of the blood vessels. The patterns are compared to provide positive identification. It costs about $2,650. Performance:

- False rejection rate = 1.5%
- False acceptance rate = 1.5%
- Average processing time = 7 seconds

Palm Scan

The system scans 10,000 points of information from a 2-inch-square area of the human palm. With the information, the system identifies the person as an impostor or authentic. The typical price is $2,500. Performance:

- False rejection rate = 0
- False acceptance rate = 0.00025%
- Average processing time = 2-3 seconds

Hand Geometry

This device uses three-dimensional hand geometry measurements to provide identification. The typical price is $2,150. Performance:

- False rejection rate = 0.1%
- False acceptance rate = 0.1%
- Average processing time = 2 to 3 seconds

Facial Recognition

Using a camera mounted at the authentication place (gate, monitor, etc.) the device compares the image of the person seeking entry with the stored image of the authorized user indexed to the system. The typical price is $2,500. Performance:

- Average processing time = 2 seconds

Voice Verification

When a person speaks a specified phrase into a microphone, this device analyzes the voice pattern and compares it against a stored data base. The price can run as high as $12,000 for 3,000 users. Performance:

- False rejection rate = 8.2%
- False acceptance rate = 0.4%
- Average processing time = 2 to 3 seconds (response time is calculated after the password or phrase is actually spoken into the voice verification system).

TESTING

Security systems, passwords, locks, token cards, biometrics, and other authentication devices are expected to function accurately from the moment they are installed, but it is the management and testing that makes them work. There is little point in installing an elaborate access control system for the computer room if the employees routinely use the emergency fire exits. Employees must be trained in the proper use of physical security systems. Access logs must be monitored and reconciled in a timely manner.

Training and awareness demands time, money, and personnel, but it is essential for organizations to meet the challenges brought about by increased competition and reduced resources. There must be a partnership between the technology and the employees. Exhibit on spending at

least as much time and resources on training employees on how to use the technology as on procuring and installing it. Employees must understand why the control mechanisms were selected and what their roles are in the security process.

SUMMARY

Companies where employees hold open the door for others to walk through may need to review their level of security awareness. The first step in implementing a physical security program is determining the level of need and the current level of awareness. To implement a cost-effective security program (1) analyze the problems, (2) design or procure controls, (3) implement those controls, (4) test and exercise those controls, and (5) monitor the controls. Implement only controls needed to meet the current needs, but make sure that additional control can be added later if required. Physical security is an organization's first line of defense against theft, sabotage, and natural disasters.

Physical Security: The Threat after September 11, 2001

Jaymes Williams, CISSP

The day that changed everything began for me at 5:50 a.m. I woke up and turned on the television to watch some news. This was early Tuesday morning, September 11, 2001. My local news station had just interrupted its regular broadcast and switched over to CNN, so right away I knew something important had happened. I learned an airliner had crashed into one of the towers of the World Trade Center in New York.

In disbelief, I made my way to the kitchen and poured myself a cup of coffee. I returned to the television and listened to journalists and airline experts debate the likely cause of this event. I thought to myself, "there isn't a cloud in the sky; how could an aircraft accidentally hit such a large structure?" Knowing, but not wanting to accept the answer, I listened while hoping the television would give me a better one.

While waiting for the answer that never came, I noticed an aircraft come from the right side of the screen. It appeared to be going behind the towers of the Trade Center, or perhaps I was only hoping it would. This was one of those instances where time appeared to dramatically slow down. In the split second it took to realize the plane should have already come out from behind the towers, the fireball burst out the side of the tower instead. It was now undeniable. This was no accident.

Later, after getting another cup of coffee, I returned to the television to see only smoke; the kind of smoke you only see when a building is imploded to make way for new construction. To my horror, I knew a tower had collapsed. Then, while the journalists were recovering from the shock and trying to maintain their on-air composure, they showed the top of the remaining tower. For some reason, it appeared that the camera had started to pan up. I started to feel a bit of vertigo. Then, once again, a horrible realization struck. The camera was not going up; the building was going down. Within the span of minutes, the World Trade Center was no more; and Manhattan was totally obscured by smoke. I was in total disbelief. This had to be a movie; but it was not. The mind's self-defenses take over when things occur that it cannot fathom, and I felt completely numb. I had witnessed the deaths of untold thousands of people on live TV. Although I live 3000 miles away, it might as well have happened down the street. The impact was the same. Then the news of the crash at the Pentagon came, followed by the crash of the aircraft in Pennsylvania.

I tried to compose myself to go to work, although work seemed quite unimportant at the moment. Somehow, I put myself together and made my way out the door. On the way to work, I thought to myself that this must be the Pearl Harbor of my generation. And, I realized, my country was probably at war — but with whom?

The preceding is my recollection of the morning of September 11. This day has since become one of those days in history where we all remember where we were and what we were doing. Although we all have our own individual experiences from that horrible day, some people more affected than others, these individual experiences all form a collective experience that surprised and shocked us all.

Security practitioners around the world, and especially in the United States, have to ask themselves some questions. Can this happen here? Is my organization a potential target? Now that a War on Terrorism has begun as a result of the September 11 attacks, the answer to both of these questions, unfortunately, is "yes." However, there are some things that can be done to lessen the risk. This chapter examines why the risk of terrorism has increased, what types of organizations or facilities are at higher risk, and what can be done to lessen that risk.

Why Is America a Target?

> Just because you're not paranoid doesn't mean they're not out to get you!
>
> **— From the U.S. Air Force Special Operations Creed**

There are many reasons terrorist groups target America. One reason is ideological differences. There are nations or cultures that do not appreciate the freedom and tolerance espoused by Americans. America is inarguably the world's leading industrial power and capitalist state. There are people in the world who may view America as a robber baron nation and hate Americans because of our perceived wealth. Another reason is religious differences. There are religiously motivated groups that may despise America and the West because of perceived nonconformance with their religious values and faith. A further reason is the perception that the U.S. government has too much influence over the actions of other governments. Terrorists may think that, through acts of terror, the U.S. government will negotiate and ultimately comply with their demands. However, our government has repeatedly stated it will not negotiate with terrorists.

A final reason is that Americans are perceived as easy targets. The "open society" in America and many Western countries makes for easy movement and activities by terrorists. Whether performing in charitable organizations, businesses, in governmental capacities, or as tourists, Americans are all over the world. This makes targeting Americans quite easy for even relatively poorly trained terrorist groups. U.S. military forces stationed around the world are seen as visible symbols of U.S. power and, as such, are also appealing targets to terrorists.

Why be Concerned?

Terrorism can be defined as the calculated use of violence, or threat of violence, to inculcate fear; intended to coerce or intimidate governments or societies in the pursuit of goals that are generally political, religious, or ideological. Some examples of terrorist objectives and tactics can be seen in Exhibit 163.1.

The increased threat of terrorism and cyber-terrorism is a new and important consideration for information security practitioners. Previously, physical security threats included such things as unauthorized access, crime, environmental conditions, inclement weather, earthquakes, etc. The events of September 11 have shown us exactly how vulnerable we are. One of the most important lessons we security practitioners can take from that day is to recognize the need to reevaluate our physical security practices to include terrorism. Adding terrorism to the mix necessitates some fundamental changes in the way we view traditional physical security. These changes need to include protective measures from terrorism.

Depending on the type of organization, it is quite possible that terrorists may target it. Whether they target facilities or offices for physical destruction or they select an organization for a cyber-strike, prudent information security practitioners will assume they have been targeted and plan accordingly.

Is Your Organization a Potential Target?

Many organizations may be potential targets of terrorists and have no idea they are even vulnerable. Government agencies, including federal, state, and local, and infrastructure companies may be primary targets. Other vulnerable organizations may be large multinational companies that market American products around the world and organizations located in well-known skyscrapers. Specific examples of these types of potential targets

EXHIBIT 163.1 Terrorist Objectives and Tactics

Examples of Terrorist Objectives
Attract publicity for the group's cause
Demonstrate the group's power
Show the existing government's lack of power
Extract revenge
Obtain logistic support
Cause a government to overreact
Common Terrorist Tactics
Assassination
Arson
Bombing
Hostage taking
Kidnapping
Hijacking or skyjacking
Seizure
Raids or attacks on facilities
Sabotage
Hoaxes
Use of special weapons
Environmental destruction
Use of technology

will not be named to avoid the possibility of placing them at higher risk. See Exhibit 163.2 for different types of potential targets.

Government Agencies

There are many terrorists who hate the U.S. government and those of many Western countries. In the minds of terrorists and their sympathizers, governments create the policies and represent the values with which they vehemently disagree. It does not take a rocket scientist, or an information security practitioner for that matter, to realize that agencies of the U.S. government are prime targets for terrorists. This, of course, also includes the U.S. military. Other Western countries, especially those supporting the United States in the War on Terrorism, may also find themselves targets of terrorists. State and local governments may also be at risk.

- *Infrastructure companies.* Companies that comprise the infrastructure also face an increased risk of terrorism. Not only may terrorists want to hurt the U.S. and Western governments, but they may also want to disrupt normal life and the economies of the Western world. Disrupting the flow of energy, travel, finance, and information is one such way to accomplish this. The medical sector is also included here. One has to now consider the previously unthinkable, look beyond our usual mindsets, and recognize that, because medical facilities have not previously been targeted, it is conceivable they could be targeted in the future.
- *Location-based targets.* There are also those targets that by their location or function are at risk. Just as the towers of the World Trade Center represented the power of the American economy to the September 11 terrorists, other landmarks can be interpreted as representing things uniquely American to those with hostile intent. Such landmarks can include skyscrapers in major cities or any of the various landmarks that represent American or Western interests. Popular tourist destinations or events with large numbers of people in attendance can also be at risk because they are either uniquely American/Western or simply because they are heavily populated.
- *Things that mean America.* There is another category to consider. This category has some overlap with the above categories but still deserves mention. Large corporations that represent America or the West to the rest of the world can also be targeted. This also includes companies whose products are sold around the world and represent America to the people of the world.

EXHIBIT 163.2 Potential Terrorist Targets

Government Agencies
U.S. federal agencies
U.S. military facilities
State governments
County governments
Local governments
Infrastructure
Energy
Transportation
Financial
Water
Internet
Medical
Location Based
Tall office buildings
National landmarks
Popular tourist destinations
Large events
Associated with America
Large corporations synonymous with the Western world
American or *U.S.* in the name
Companies that produce famous American brand products

If an organization falls into one of the above categories, it may face a greater risk from terrorism than previously thought. If an organization does not fit one of the above categories, information security practitioners are still well-advised to take as many antiterrorism precautions as feasible.

Paradigm Shift: Deterrence to Prevention

> Business more than any other occupation is a continual dealing with the future; it is a continual calculation, an instinctive exercise in foresight.
>
> **— Henry R. Luce**

The operating paradigm of physical security has been deterrence. The idea of a perpetrator not wanting to be caught, arrested, or even killed has become so ingrained in the way we think that we take it for granted. As we probably all know by now, there are people motivated by fervent religious beliefs or political causes that do not share this perspective; they may be willing or even desiring to die to commit an act they believe will further their cause.

Most security protections considered industry standard today are based on the deterrence paradigm. Security devices such as cameras, alarms, x-ray, or infrared detection are all used with the intent to deter a perpetrator who does not want to be caught. Although deterrence-based measures will provide adequate security for the overwhelming majority of physical security threats, these measures may be largely ineffective against someone who plans to die committing an act of terrorism.

On the morning of September 11, 2001, we learned a painful lesson: that deterrence does not deter those who are willing to die to perpetrate whatever act they have in mind. Unfortunately, this makes physical security much more difficult and expensive. Information security practitioners need to realize that commonly accepted standards such as having security cameras, cipher-lock doors, and ID badges may only slow down a potential terrorist. Instead of working to deter intruders, we now have to also consider the previously unconsidered — the suicidal terrorist. This means considering what measures it will take to prevent someone who is willing to die to commit a terrorist act.

The airline industry appears to have learned that much more stringent security measures are required to prevent a recurrence of what happened on September 11. Previously, an airline's worst nightmare was either a bombing of an aircraft or a hijacking followed by tense negotiations to release hostage passengers. No one had considered the threat of using an airliner as a weapon of mass destruction. Anyone who has flown since then is familiar with the additional delays, searches, and ID checks. They are inconvenient and slow down the traveler; however, this is a small price to pay for having better security.

Although there is still much more to be done, this serves as an example of using the prevention paradigm. The airlines have taken many security measures to prevent another such occurrence. Unfortunately, as with information security, there is no such thing as absolute physical security. There is always the possibility that something not previously considered will occur. Information security practitioners will also likely have to work within corporate/governmental budget constraints, risk assessments, etc. that may limit their ability to implement the needed physical security changes.

Reducing The Risk of Terrorism

> The determination of these terrorists will not deter the determination of the American people. We are survivors and freedom is a survivor.
>
> **— Attorney General John Ashcroft**
>
> **Press conference on September 11, 2001**

Now that we have a better understanding of why we face a greater risk of terrorism and who may be a target, the issue becomes how to better protect our organizations and our fellow employees. There are many methods to reduce the risk of terrorism. These methods include reviewing and increasing the physical security of an organization using the previously discussed prevention paradigm; controlling sensitive information through operational security; developing terrorism incident handling procedures; and building security procedures and antiterrorism procedures for employees. Several of these methods rely on employee training and periodic drills to be successful.

Physical Security Assessments

The first step in reducing risk is to control the physical environment. In this section we use the term *standard* to imply industry-standard practices for physical security. The term *enhanced* will refer to enhanced procedures that incorporate the prevention paradigm.

Verify Standard Physical Security Practices Are in Place

Conduct a standard physical security assessment and implement changes as required. It is important to have physical security practices at least at current standards. Doing this will also minimize the risk from most standard physical security threats. As the trend toward holding organizations liable continues to emerge in information security, it is also likely to occur with physical security in the foreseeable future.

Conduct an Enhanced Physical Security Assessment

Once the standard physical security is in place, conduct another assessment that is much more stringent. This assessment should include enhanced physical security methods. Unfortunately, there is not yet a set of industry standards to protect against the enhanced threat. Many excellent resources are available from the U.S. government. Although they are designed for protecting military or other government facilities, many of these standards can also be successfully implemented in the private sector. At this point, information security practitioners are essentially left to their own initiative to implement standards. Perhaps, in the near future, a set of standards will be developed that include the enhanced threat.

Currently, there are many excellent resources available on the Internet from the U.S. government. However, at the time of this writing, the U.S. government is becoming more selective about what information is available to the public via the Internet for security reasons. It is quite possible that these resources may disappear from the Internet at some point in the near future. Information security practitioners may wish to locate these valuable resources before they disappear. A listing of Internet resources can be found in Exhibit 163.3.

Implement Recommended Changes

Again, because there is no uniform set of standards for enhanced physical security for the private sector, we are left to our own devices for enhancing our physical security. Because we are not likely to have unlimited budgets for improving physical security, information security practitioners will have to assess the risk for their organizations, including the potential threat of terrorism, and make recommended changes based on the assessed risk. Ideally, these changes should be implemented in the most expeditious manner possible.

Controlling Sensitive Information through Operational Security (OPSec)

We have now successfully "circled the wagons" and improved physical access controls to our facilities. The next step is to better control our sensitive information. As illustrated by the famous World War II security poster depicted in Exhibit 163.4, the successful control of information can win or lose wars. The Allied capture of the Enigma encryption device proved a critical blow to the Germans during World War II. The Allies were then able to decipher critical codes, which gave them an insurmountable advantage. Again, during the Gulf War, the vast technical advantage enjoyed by the Allied Coalition gave them information supremacy that translated into air supremacy.

These lessons of history illustrate the importance of keeping sensitive information out of the hands of those who wish to do harm. In the days since September 11, this means keeping sensitive information from all who do not need access. First, we need to define exactly what information is sensitive. Then we need to determine how to best control the sensitive information.

- *Defining sensitive information.* Sensitive information can easily be defined as information that, if available to an unauthorized party, can disclose vulnerabilities or can be combined with other information to be used against an organization. For example, seemingly innocuous information on a public Web site can provide a hostile party with enough information to target that organization. Information such as addresses of facilities, maps to facilities, officer and employee names, and names and addresses of customers or clients can all be combined to build a roadmap. This roadmap can tell the potential terrorist not only where the organization is and what it does, but also who is part of the organization and where it is vulnerable.

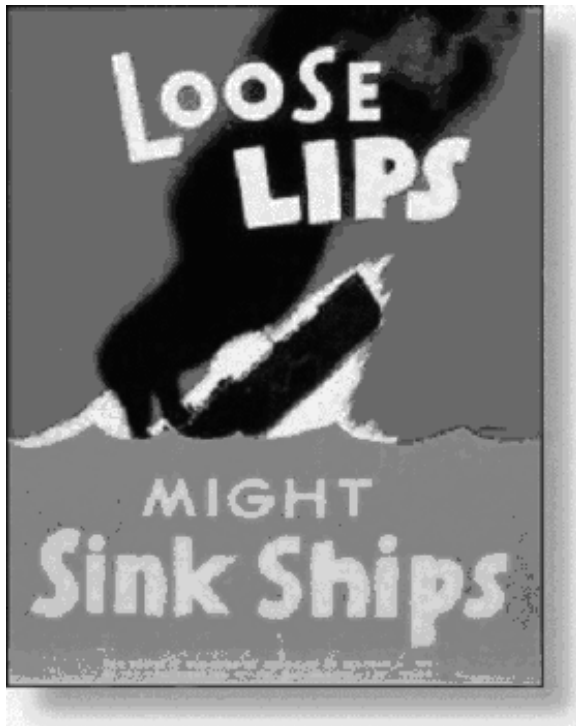

EXHIBIT 163.4 Famous World War II security poster.

- *Controlling sensitive information.* Prudent information security practitioners will first want to control the information source that leaves them the most vulnerable. There are several methods security practitioners can use to maintain control of their sensitive information: removing sensitive information from Web sites and corporate communications; destroying trash with sensitive information; having a clean desk policy; and limiting contractor/vendor access to sensitive information.
  - *Remove sensitive information from publicly available Web sites.* Removing physical addresses, maps, officer/employee names, etc. from these Web sites is highly advisable. They can either be removed entirely from the site or moved into a secured section of the site where access to this information is verified and logged.
  - On January 17, 2002, the National Infrastructure Protection Center released NIPC Advisory 02-001: Internet Content Advisory: Considering the Unintended Audience. See Exhibit 163.5 for a reprint of the advisory. This advisory can function as a set of standards for deciding what and what not to place on publicly available Internet sites. When bringing up the issue with management of removing information from Web sites, the information security practitioner may receive a response that echoes item number seven in the advisory: "Because the information is publicly available in many places, it is not worth an effort to remove it from our site." Although the information does exist elsewhere, the most likely and easiest place for terrorists to find it is on the target organization's Web site. This is also probably the first place they will look. Responsible information security practitioners, or corporate officers for that matter, should make it as difficult as possible for those with hostile intent to gain useful information from their Internet site.
  - *Remove sensitive information from all corporate communications.* No corporate communications should contain any sensitive information. If an organization already has an information clas-

EXHIBIT 163.5 NIPC Advisory 02-001

Internet Content Advisory: Considering the Unintended Audience

January 17, 2002

As worldwide usage of the Internet has increased, so too have the vast resources available to anyone online. Among the information available to Internet users are details on critical infrastructures, emergency response plans and other data of potential use to persons with criminal intent. Search engines and similar technologies have made arcane and seemingly isolated information quickly and easily retrievable by anyone with access to the Internet. The National Infrastructure Protection Center (NIPC) has received reporting that infrastructure related information, available on the Internet, is being accessed from sites around the world. Although in and of itself this information is not significant, it highlights a potential vulnerability.

The NIPC is issuing this advisory to heighten community awareness of this potential problem and to encourage Internet content providers to review the data they make available online. A related information piece on "Terrorists and the Internet: Publicly Available Data should be Carefully Reviewed" was published in the NIPC's *Highlights* 11-01 on December 07, 2001, and is available at the NIPC web site http://www.nipc.gov/. Of course, the NIPC remains mindful that, when viewing information access from a security point of view, the advantages of posting certain information could outweigh the risks of doing so. For safety and security information that requires wide dissemination and for which the Internet remains the preferred means, security officers are encouraged to include in corporate security plans mechanisms for risk management and crisis response that pertain to malicious use of open source information.

When evaluating Internet content from a security perspective, some points to consider include:

1. Has the information been cleared and authorized for public release?
2. Does the information provide details concerning enterprise safety and security? Are there alternative means of delivering sensitive security information to the intended audience?
3. Is any personal data posted (such as biographical data, addresses, etc.)?
4. How could someone intent on causing harm misuse this information?
5. Could this information be dangerous if it were used in conjunction with other publicly available data?
6. Could someone use the information to target your personnel or resources?
7. Many archival sites exist on the Internet, and that information removed from an official site might nevertheless remain publicly available elsewhere.

The NIPC encourages the Internet community to apply common sense in deciding what to publish on the Internet. This advisory serves as a reminder to the community of how the events of September 11, 2001, have shed new light on our security considerations.

The NIPC encourages recipients of this advisory to report computer intrusions to their local FBI office http://www.fbi.gov/contact/fo/fo.htm or the NIPC, and to other appropriate authorities. Recipients may report incidents online at http://www.nipc.gov/ incident/cirr.htm, and can reach the NIPC Watch and Warning Unit at (202) 323-3205, 1-888-585-9078, or nipc.watch@fbi.gov

sification structure in place, this vulnerability should already be resolved. However, if there is no information classification structure in place, this is excellent justification for implementing such a program. And, with such a program, the need for marking documents also exists.

- *Shred/destroy trash with sensitive information.* Do you really know who goes through your trash? Do you know your janitorial staff? Dumpster diving is a widely practiced social engineering method. Shredding is an excellent way to avoid this vulnerability and is already widely practiced. Many organizations have either on-site shredders or bins to collect sensitive documents, which are later shredded by contracted shredding companies.
- *Create a clean desk policy.* Information left unattended on a desktop is a favorite of social engineers. It is easier than dumpster diving (cleaner, too!) and will likely yield better results. Although the definition of clean desk may vary, the intent of such a policy is to keep sensitive information from being left unattended on desktops.
- *Limit contractor/vendor access to sensitive information.* This is a standard physical security practice, but it deserves special mention within the OPSec category because it is fairly easy to implement controls on contractor/vendor access. Restricting access to proprietary information is also a good practice.

EXHIBIT 163.6 Safe Mail-Handling Checklist

Suspicious Packages or Mail
Suspicious characteristics to look for include:
- An unusual or unknown place of origin
- No return address
- An excessive amount of postage
- Abnormal or unusual size
- Oily stains on the package
- Wires or strings protruding from or attached to an item
- Incorrect spelling on the package label
- Differing return address and postmark
- Appearance of foreign style handwriting
- Peculiar odor (many explosives used by terrorists smell like shoe polish or almonds)
- Unusual heaviness or lightness
- Uneven balance or shape
- Springiness in the top, bottom, or sides

Never cut tape, strings, or other wrappings on a suspect package or immerse a suspected letter or package in water; either action could cause an explosive device to detonate
Never touch or move a suspicious package or letter
Report any suspicious packages or mail to security officials immediately

- *Verify identity of all building/office visitors.* Many large organizations and office buildings are verifying the identity of all visitors. Some organizations and buildings are checking identification for everyone who enters. This is an excellent practice because it greatly reduces the risk of unauthorized access.
- *Report unusual visitors or activity to law enforcement agencies (LEA).* Visitors behaving in a suspicious or unusual manner should be reported to building security, if possible, and then to law enforcement authorities. Quick reporting may prevent undesired activities.
- *Exercise safe mail handling procedures.* Mail-handling procedures became of greater importance during the anthrax scare in the autumn of 2001. See Exhibit 163.6 for a list of safe mail handling procedures.

Develop Terrorism Incident Handling Procedures

Security Working Group

Many organizations have established security working groups. These groups may be composed of management, information security practitioners, other security specialists, and safety and facilities management people. Members of the group can also serve as focal points for networking with local, state, and federal authorities and professional organizations to receive intelligence/threat information. The group may meet regularly to review the organization's security posture and act as a body for implementing upgraded security procedures. It may also conduct security evaluations.

Establish Terrorism Incident Procedures

Just as it is important to have incident response plans and procedures for computer security incidents, it is also highly advisable to have incident response plans and procedures for terrorist threats or incidents.

An integral part of any terrorism incident response is checklists for bomb threats and other terrorist threats. These checklists should contain numerous questions to ask the individual making the threatening call: where is the bomb, when is it going to go explode, what does it look like, etc. The checklists should also contain blanks to fill in descriptions of the caller's voice — foreign accent, male or female, tone of voice, background noise, etc. Checklists should be located near all phones or, at a minimum, in company telephone directories. Many federal and state agencies have such checklists available for the general public. The Bureau of Alcohol, Tobacco & Firearms has an excellent checklist that is used by many agencies and is shown in Exhibit 163.7.

Again, as with computer incident response teams, training is quite important. Employees need to know how to respond in these types of high-stress situations. Recurring training on how to respond to threatening phone calls and to complete the checklist all contribute to reduced risk.

EXHIBIT 163.7 BATF Bomb Threat Checklist

ATF BOMB THREAT CHECKLIST
Exact time of call:

_____

Exact words of caller:

_____

QUESTIONS TO ASK

1. When is bomb going to explode?
2. Where is the bomb?
3. What does it look like?
4. What kind of bomb is it?
5. What will cause it to explode?
6. Did you place the bomb?
7. Why?
8. Where are you calling from?
9. What is your address?
10. What is your name?

CALLER'S VOICE (circle)

Calm	Slow	Crying	Slurred
Stutter	Deep	Loud	Broken
Giggling	Accent	Angry	Rapid
Stressed	Nasal	Lisp	Excited
Disguised	Sincere	Squeaky	Normal

If voice is familiar, whom did it sound like?
Were there any background noises?
Remarks:
Person receiving call:
Telephone number call received at:
Date:
Report call immediately to:
(Refer to bomb incident plan)

Safety Practices

Here is an excellent opportunity to involve organizational safety personnel or committees. Some practices to involve them with are:

- *Review building evacuation procedures.* This will provide the current and best method for evacuating buildings should the need arise. Also plan for secondary evacuation routes in the event the primary route is unusable.
- *Conduct building evacuation drills.* Periodic building evacuation drills, such as fire drills, provide training and familiarity with escape routes. In an emergency, it is far better to respond with training. These should be conducted without prior notification on all shifts. Drills should not be the same every time. Periodically, vary the drill by blocking an escape route, forcing evacuees to alter their route.
- *Conduct terrorism event drills.* Other drills, such as responding to various terrorism scenarios, may be beneficial in providing the necessary training to respond quickly and safely in such a situation.
- *Issue protective equipment.* Many of the individuals who survived the World Trade Center disaster suffered smoke inhalation, eye injuries, etc. These types of injuries might be avoided if emergency equipment is issued to employees, such as hardhats, dust masks, goggles, flashlights, gloves, etc.

Building Security Procedures

A determined terrorist can penetrate most office buildings. However, the presence and use of guards and physical security devices (e.g., exterior lights, locks, mirrors, visual devices) create a significant psychological

deterrent. Terrorists are likely to shun risky targets for less protected ones. If terrorists decide to accept the risk, security measures can decrease their chance of success. Of course, if the terrorists are willing to die in the effort, their chance of success increases and the efforts to thwart them are much more complex and expensive. Corporate and government executives should develop comprehensive building security programs and frequently conduct security surveys that provide the basis for an effective building security program. These surveys generate essential information for the proper evaluation of security conditions and problems, available resources, and potential security policy. Only one of the many facets in a complex structure, security policies must be integrated with other important areas such as fire safety, normal police procedures, work environment, and work transactions. The building security checklist found in Exhibit 163.8 provides guidance when developing building security procedures.

Antiterrorism Procedures for Employees

Antiterrorism procedures can be defined as defensive measures used to reduce vulnerability to terrorist attacks. These defensive measures, or procedures, although originated by the U.S. government, are certainly applicable to those living in a high terrorist threat condition. To some security practitioners, many of these procedures may seem on the verge of paranoia; however, they are presented with two intentions: (1) to illustrate the varying dangers that exist and methods to avoid them, and (2) to allow readers to determine for themselves which procedures to use.

Many of the procedures are simply common sense. Others are procedures that are generally only known to those who live and work in high terrorist threat environments. See Exhibit 163.9 for the personnel antiterrorism checklist.

Lessons Learned from September 11

> Our plan worked and did what it was supposed to do. Our employees were evacuated safely.
>
> **— Paul Honey**
>
> **Director of Global Contingency Planning for Merrill Lynch**

Many well-prepared organizations weathered the disaster of September 11. However, there were also many businesses caught unprepared; of those, many no longer exist. Organizations from around the United States and the world are benefiting from the lessons learned on that fateful day. One large and quite well-known organization that was well prepared and survived the event was Merrill Lynch.

When Paul Honey, director of global contingency planning for Merrill Lynch, arrived for work on the morning of September 11, he was met by the disaster of the collapsed World Trade Center. Honey then went to one of the company's emergency command centers, where his contingency planning staff was hard at work. Within an hour of the disaster, the crisis management team had already established communication with key representatives, and emergency procedures were well underway.

Honey's team was able to facilitate the resumption of critical operations within one day and, within a week, the relocation of 8000 employees. This effort required the activation of a well-documented and robust business continuity program, an enormous communications effort, and a lot of teamwork.

Business Continuity Plans

Honey has business continuity planning responsibility for all of Merrill Lynch's businesses. He runs a team of 19 planners who verify that the business
follows the business continuity plan, or BCP. His team is not responsible for the technology recovery planning, and they do not write the plans. They are the subject matter experts in program management and set the standards through a complete BCP program life cycle. Planning involves many different departments within the company because of the comprehensive nature of the program. Each business and support group (i.e., the trading floor, operations, finance, etc.) assigns a planning manager who is responsible for that area.

EXHIBIT 163.8 Building Security Checklist

Office Accessibility

- Buildings most likely to be terrorist targets should not be directly accessible to the public.
- Executive offices should not be located on the ground floor.
- Place ingress door within view of the person responsible for screening personnel and objects passing through the door.
- Doors may be remotely controlled by installing an electromagnetic door lock.
- The most effective physical security configuration is to have doors locked from within and have only one visitor access door into the executive office area. Locked doors should also have panic bars.
- Depending on the nature of the organization's activities, deception measures such as a large waiting area controlling access to several offices can be taken to draw attention away from the location and function of a particular office.

Physical Security Measures

- Consider installing the following security devices: burglar alarm systems (preferably connected to a central security facility), sonic warning devices or other intrusion systems, exterior floodlights, deadbolt locks on doors, locks on windows, and iron grills or heavy screens for windows.
- Depending on the nature of the facility, consider installing a 15 to 20-foot fence or wall and a comprehensive external lighting system. External lighting is one of the cheapest and most effective deterrents to unlawful entry.
- Position light fixtures to make tampering difficult and noticeable.
- Check grounds to ensure that there are no covered or concealed avenues of approach for terrorists and other intruders, especially near entrances.
- Deny exterior access to fire escapes, stairway, and roofs.
- Manhole covers near the building should be secured or locked.
- Cover, lock, or screen outdoor openings (e.g., coal bins, air vents, utility access points).
- Screen windows (particularly near the ground or accessible from adjacent buildings.
- Consider adding a thin, clear plastic sheet to windows to degrade the effects of flying glass in case of explosion.
- Periodically inspect the interior of the entire building, including the basement and other infrequently used areas.
- Locate outdoor trash containers, storage bins, and bicycle racks away from the building.
- Book depositories or mail slots should not be adjacent to or in the building.
- Mailboxes should not be close to the building.
- Seal the top of voids and open spaces above cabinets, bookcases, and display cases.
- Keep janitorial closets, service openings, telephone closets, and electrical closets locked at all times. Protect communications closets and utility areas with an alarm system.
- Remove names from reserved parking spaces.
- Empty trash receptacles daily (preferably twice daily).
- Periodically check all fire extinguishers to ensure that they are in working order and readily available. Periodically check all smoke alarms to ensure that they are in working order.

Personnel Procedures

- Stress heightened awareness of personnel working in the building, because effective building security depends largely on the actions and awareness of people.
- Develop and disseminate clear instructions on personnel security procedures.
- Hold regular security briefings for building occupants.
- Personnel should understand security measures, appropriate responses, and should know whom to contact in an emergency.
- Conduct drills if appropriate.
- Senior personnel should not work late on a routine basis. No one should ever work alone.
- Give all personnel, particularly secretaries, special training in handling bomb threats and extortion telephone calls. Ensure a bomb threat checklist and a pen or pencil is located at each telephone.
- Ensure the existence of secure communications systems between senior personnel, secretaries, and security personnel with intercoms, telephones, and duress alarm systems.
- Develop an alternate means of communications (e.g., two-way radio) in case the primary communications systems fail.
- Do not open packages or large envelopes in buildings unless the sender or source is positively known. Notify security personnel of a suspicious package.
- Have mail room personnel trained in bomb detection handling and inspection.

EXHIBIT 163.8 Building Security Checklist (continued)

- Lock all doors at night, on weekends, and when the building is unattended.
- Maintain tight control of keys. Lock cabinets and closets when not in use.
- When feasible, lock all building rest rooms when not in use.
- Escort visitors in the building and maintain complete control of strangers who seek entrance.
- Check janitors and their equipment before admitting them and observe while they are performing their functions.
- Secure official papers from unauthorized viewing.
- Do not reveal the location of building personnel to callers unless they are positively identified and have a need for this information.
- Use extreme care when providing information over the telephone.
- Do not give the names, positions, and especially the home addresses or phone numbers of office personnel to strangers or telephone callers.
- Do not list the addresses and telephone numbers of potential terrorist targets in books and rosters.
- Avoid discussing travel plans or timetables in the presence of visitors.
- Be alert to people disguised as public utility crews who might station themselves near the building to observe activities and gather information.
- Note parked or abandoned vehicles, especially trucks, near the entrance to the building or near the walls.
- Note the license plate number, make, model, year, and color of suspicious vehicles and the occupant's description, and report that information to your supervisor, security officer, or law enforcement agency.

Controlling Entry

- Consider installing a peephole, intercom, interview grill, or small aperture in entry doorways to screen visitors before the door is opened.
- Use a reception room to handle visitors, thereby restricting their access to interior offices.
- Consider installing metal detection devices at controlled entrances. Prohibit non-organization members from bringing boxes and parcels into the building.
- Arrange building space so that unescorted visitors are under the receptionist's visual observation and to ensure that the visitors follow stringent access control procedures.
- Do not make exceptions to the building's access control system.
- Upgrade access control systems to provide better security through the use of intercoms, access control badges or cards, and closed-circuit television.

Public Areas

- Remove all potted plants and ornamental objects from public areas.
- Empty trash receptacles frequently.
- Lock doors to service areas.
- Lock trapdoors in the ceiling or floor, including skylights.
- Ensure that construction or placement of furniture and other items would not conceal explosive devices or weapons.
- Keep furniture away from walls or corners.
- Modify curtains, drapes, or cloth covers so that concealed items can be seen easily.
- Box in the tops of high cabinets, shelves, or other fixtures.
- Exercise particular precautions in public rest rooms.
- Install springs on stall doors in rest rooms so they stand open when not locked. Equip stalls with an inside latch to prevent someone from hiding a device in a locked stall.
- Install a fixed covering over the tops on commode water tanks.
- Use open mesh baskets for soiled towels. Empty frequently.
- Guards in public areas should have a way to silently alert the office of danger and to summon assistance (e.g., foot-activated buzzer).

Discovery of a Suspected Explosive Device

- Do not touch or move a suspicious object. If it is possible for someone to account for the presence of the object, then ask the person to identify it with a verbal description. This should not be done if it entails bringing evacuated personnel back into the area. Take the following actions if an object's presence remains inexplicable:
- Evacuate buildings and surrounding areas, including the search team.
- Evacuated areas must be at least 100 meters from the suspicious object.
- Establish a cordon and incident control point, or ICP.

EXHIBIT 163.8 Building Security Checklist (continued)

- Inform the ICP that an object has been found.
- Keep person who located the object at the ICP until questioned.
- Cordon suspicious objects to a distance of at least 100 meters and cordon suspicious vehicles to a distance of at least 200 meters. Ensure that no one enters the cordoned area. Establish an ICP on the cordon to control access and relinquish ICP responsibility to law enforcement authorities upon their arrival. Maintain the cordon until law enforcement authorities have completed their examination or state that the cordon may stand down. The decision to allow reoccupation of an evacuated facility rests with the individual in charge of the facility.

Honey's team responds to nearly 70 emergencies, on average, during the course of a year. Facilities and retail branch offices around the globe experience a variety of incidents such as earthquakes, storms, power outages, floods, or bomb threats.

When Honey's team plans for business interruption, the team instructs the business groups to plan for a worst-case scenario of six weeks without access to their facility and, naturally, at the worst possible time for an outage.

The planning also includes having absolutely no access to anything from any building — computers, files, papers, etc. "That's how we force people to think about alternate sites, vital records, physical relocation of staff, and so on, as well as obviously making sure the technology is available at another site," says Honey.

Upgraded Plans and Procedures after Y2K

Merrill Lynch must comply with standards mandated by regulatory agencies such as the Federal Reserve and the Federal Financial Institutions Examination Council. Honey says, "There's a market expectation that companies such as Merrill Lynch would have very robust contingency plans, so we probably attack it over and above any regulatory requirements that are out there." The BCP team's recent efforts to exceed regulatory standards placed Merrill Lynch in a good position to recover successfully from the September 11 attacks.

Extensive Testing of Contingency Plans

All plans are tested twice annually, and once a year the large-scale, corporatewide plans are tested. Honey's team overhauled the headquarters evacuation plan earlier in the year. They distributed nearly 8000 placards with the new procedures. These placards proved quite useful on the day of the attacks. Furthermore, the company's human resources database is downloaded monthly into the team's business continuity planning software program. This ensures that the BCP team has a frequently updated list of all current employees within each building. All this preparation resulted in effective execution of the business continuity plans on September 11.

Recent Test Using Scenario Similar to Terrorist Attacks

In May 2001, Honey's team conducted a two-day planning scenario for the headquarters' key staff. The scenario, although different from September 11, covered an event of devastating impact — a major hurricane in New York City. "While the hurricane scenario doesn't compare to the tragedies of 9/11 in terms of loss of life, we actually put our company through a fairly extensive two-day scenario, which had more impact to the firm in terms of difficulties in transportation and actual damage in the region," says Honey. "So, we were really very well prepared; we had a lot of people who already thought through a lot of the logistical, technology, and HR-type issues."

The Evacuation

The corporate response team was activated at about 8:55 a.m., while Honey was en route to Canal Street. The team, comprised of representatives from all business support groups, is instrumental in assessing the situation, such as building management, physical security personnel, media relations, key technology resources, and key business units. Despite a multitude of telecommunications troubles in the area, the team was finally able to

EXHIBIT 163.9 Personnel antiterrorism checklist

General Security Procedures

- Instruct your family and associates not to provide strangers with information about you or your family.
- Avoid giving unnecessary personal details to information collectors.
- Report all suspicious persons loitering near your residence or office; attempt to provide a complete description of the person and/or vehicle to police or security.
- Vary daily routines to avoid habitual patterns.
- If possible, fluctuate travel times and routes to and from work.
- Refuse to meet with strangers outside your workplace.
- Always advise associates or family members of your destination when leaving the office or home and the anticipated time of arrival.
- Do not open doors to strangers.
- Memorize key phone numbers — office, home, police, etc. Be cautious about giving out information regarding family travel plans or security measures and procedures.
- If you travel overseas, learn and practice a few key phrases in the native language, such as "I need a policeman, doctor," etc.

Business Travel

- Airport Procedures
  - — Arrive early; watch for suspicious activity.
  - — Notice nervous passengers who maintain eye contact with others from a distance. Observe what people are carrying. Note behavior not consistent with that of others in the area.
  - — No matter where you are in the terminal, identify objects suitable for cover in the event of attack; pillars, trash cans, luggage, large planters, counters, and furniture can provide protection.
  - — Do not linger near open public areas. Quickly transit waiting rooms, commercial shops, and restaurants.
  - — Proceed through security checkpoints as soon as possible.
  - — Avoid secluded areas that provide concealment for attackers.
  - — Be aware of unattended baggage anywhere in the terminal.
  - — Be extremely observant of personal carry-on luggage. Thefts of briefcases designed for laptop computers are increasing at airports worldwide; likewise, luggage not properly guarded provides an opportunity for a terrorist to place an unwanted object or device in your carry-on bag. As much as possible, do not pack anything you cannot afford to lose; if the documents are important, make a copy and carry the copy.
  - — Observe the baggage claim area from a distance. Do not retrieve your bags until the crowd clears. Proceed to the customs lines at the edge of the crowd.
  - — Report suspicious activity to the airport security personnel.
- On-Board Procedures
  - — Select window seats; they offer more protection because aisle seats are closer to the hijackers' movements up and down the aisle.
  - — Rear seats also offer more protection because they are farther from the center of hostile action, which is often near the cockpit.
  - — Seats at an emergency exit may provide an opportunity to escape.
- Hotel Procedures
  - — Keep your room key on your person at all times.
  - — Be observant for suspicious persons loitering in the area.
  - — Do not give your room number to strangers.
  - — Keep your room and personal effects neat and orderly so you will recognize tampering or strange out-of-place objects.
  - — Know the locations of emergency exits and fire extinguishers.
  - — Do not admit strangers to your room.
  - — Know how to locate hotel security guards.

Keep a Low Profile

- Your dress, conduct, and mannerisms should not attract attention.
- Make an effort to blend into the local environment.

EXHIBIT 163.9 Personnel Antiterrorism Checklist (continued)

- Avoid publicity and do not go out in large groups.
- Stay away from civil disturbances and demonstrations.

Tips for the Family at Home

- Restrict the possession of house keys.
- Change locks if keys are lost or stolen and when moving into a previously occupied residence.
- Lock all entrances at night, including the garage.
- Keep the house locked, even if you are at home.
- Develop friendly relations with your neighbors.
- Do not draw attention to yourself; be considerate of neighbors.
- Avoid frequent exposure on balconies and near windows.

Be Suspicious

- Be alert to public works crews requesting access to residence; check their identities through a peephole before allowing entry.
- Be alert to peddlers and strangers.
- Write down license numbers of suspicious vehicles; note descriptions of occupants.
- Treat with suspicion any inquiries about the whereabouts or activities of other family members.
- Report all suspicious activity to police or local law enforcement.

Security Precautions when You Are Away

- Leave the house with a lived-in look.
- Stop deliveries or forward mail to a neighbor's home.
- Do not leave notes on doors.
- Do not hide keys outside house.
- Use a timer (appropriate to local electricity) to turn lights on and off at varying times and locations.
- Leave radio on (best with a timer).
- Hide valuables.
- Notify the police or a trusted neighbor of your absence.

Residential Security

- Exterior grounds:
  - — Do not put your name on the outside of your residence or mailbox.
  - — Have good lighting.
  - — Control vegetation to eliminate hiding places.
- Entrances and exits should have:
  - — Solid doors with deadbolt locks
  - — One-way peepholes in door
  - — Bars and locks on skylights
  - — Metal grating on glass doors, and ground-floor windows, with interior release mechanisms that are not reachable from outside
- Interior features:
  - — Alarm and intercom systems
  - — Fire extinguishers
  - — Medical and first-aid equipment
- Other desirable features:
  - — A clear view of approaches
  - — More than one access road
  - — Off-street parking
  - — High (six to eight feet) perimeter wall or fence

EXHIBIT 163.9 Personnel Antiterrorism Checklist (continued)

Parking

- Always lock your car.
- Do not leave it on the street overnight, if possible.
- Never get out without checking for suspicious persons. If in doubt, drive away.
- Leave only the ignition key with parking attendant.
- Do not allow entry to the trunk unless you are there to watch.
- Never leave garage doors open or unlocked.
- Use a remote garage door opener if available. Enter and exit your car in the security of the closed garage.

On the Road

- Before leaving buildings to get into your vehicle, check the surrounding area to determine if anything of a suspicious nature exists. Display the same wariness before exiting your vehicle.
- Prior to getting into a vehicle, check beneath it. Look for wires, tape, or anything unusual.
- If possible, vary routes to work and home.
- Avoid late-night travel.
- Travel with companions.
- Avoid isolated roads or dark alleys when possible.
- Habitually ride with seatbelts buckled, doors locked, and windows closed.
- Do not allow your vehicle to be boxed in; maintain a minimum eight-foot interval between you and the vehicle in front; avoid the inner lanes. Be alert while driving or riding.

Know How to React if You Are Being Followed

- Circle the block for confirmation of surveillance.
- Do not stop or take other actions that could lead to confrontation.
- Do not drive home.
- Get description of car and its occupants.
- Go to the nearest safe haven.
- Report incident to police.

Recognize Events that can Signal the Start of an Attack:

- Cyclist falling in front of your car.
- Flagman or workman stopping your car.
- Fake police or government checkpoint.
- Disabled vehicle/accident victims on the road.
- Unusual detours.
- An accident in which your car is struck.
- Cars or pedestrian traffic that box you in.
- Sudden activity or gunfire.

Know What to Do if under Attack in a Vehicle:

- Without subjecting yourself, passengers, or pedestrians to harm, try to draw attention to your car by sounding the horn
- Put another vehicle between you and your pursuer
- Execute immediate turn and escape; jump the curb at 30–45 degree angle, 35 mph maximum
- Ram blocking vehicle if necessary
- Go to closest safe haven
- Report incident to police

Commercial Buses, Trains, and Taxis

- Vary mode of commercial transportation.
- Select busy stops.

EXHIBIT 163.9 Personnel Antiterrorism Checklist (continued)

- Do not always use the same taxi company.
- Do not let someone you do not know direct you to a specific cab.
- Ensure taxi is licensed and has safety equipment (seatbelts at a minimum).
- Ensure face of driver and picture on license are the same.
- Try to travel with a companion.
- If possible, specify the route you want the taxi to follow.

Clothing

- Travel in conservative clothing when using commercial transportation overseas or if you are to connect with a flight at a commercial terminal in a high-risk area.
- Do not wear U.S.-identified items such as cowboy hats or boots, baseball caps, American logo T-shirts, jackets, or sweatshirts.
- Wear a long-sleeved shirt if you have a visible U.S.-affiliated tattoo.

Actions if Attacked

- Dive for cover. Do not run. Running increases the probability of shrapnel hitting vital organs or the head.
- If you must move, belly crawl or roll. Stay low to the ground, using available cover.
- If you see grenades, lay flat on the floor, with feet and knees tightly together with soles toward the grenade. In this position, your shoes, feet, and legs protect the rest of your body. Shrapnel will rise in a cone from the point of detonation, passing over your body.
- Place arms and elbows next to your ribcage to protect your lungs, heart, and chest. Cover your ears and head with your hands to protect neck, arteries, ears, and skull.
- Responding security personnel will not be able to distinguish you from attackers. Do not attempt to assist them in any way. Lay still until told to get up.

Actions if Hijacked

- Remain calm, be polite, and cooperate with your captors.
- Be aware that all hijackers may not reveal themselves at the same time. A lone hijacker may be used to draw out security personnel for neutralization by other hijackers.
- Surrender your tourist passport in response to a general demand for identification.
- Do not offer any information.
- Do not draw attention to yourself with sudden body movements, verbal remarks, or hostile looks.
- Prepare yourself for possible verbal and physical abuse, lack of food and drink, and unsanitary conditions.
- If permitted, read, sleep, or write to occupy your time.
- Discretely observe your captors and memorize their physical descriptions. Include voice patterns and language distinctions as well as clothing and unique physical characteristics.
- Cooperate with any rescue attempt. Lie on the floor until told to rise.

establish a conference call at 9:30 a.m. to communicate with its other command center in Jersey City, New Jersey, to figure out what was happening.

"In hindsight it seems odd, but we really didn't know, apart from the planes hitting the buildings, whether this was an accident or a terrorist attack," says Honey. "So really, the challenge at that time was to account for our employees, and then to try and understand what had happened. The damage to our buildings also was a concern. How were our buildings. Were they still standing? What was the state of the infrastructure in them?"

Call trees were used to contact employees, and employees also knew how to contact their managers to let them know they got out of the area safely. "In a typical evacuation of a building, employees go about 100 yards from the building and wait to get their names ticked off a list," says Honey. "The issue we faced here is that the whole of lower Manhattan was evacuated. So employees were going home or trying to get to other offices — so that was a challenge for us." Honey says the wallet cards key employees carried were extremely beneficial. "Everyone knew who to call and when," he says. "That was a real valuable planning aid to have."

Once the team had the call trees and other communications processes under way, they began to implement the predefined continuity plans and assess what critical business items they wanted to focus on and when.

The Recovery

Critical Management Functions Resumed within Minutes

Many of the company's recovery procedures were based on backup data centers at Merrill Lynch facilities outside the area. The data recovery procedures were followed through without incident. The company has a hot site provider, but they did not have to use that service.

The company's preparedness efforts for Y2K resulted in near-routine recovery of critical data. "We had a very large IT disaster recovery program in place," says Honey, "and we've been working for a couple years now with the businesses to really strengthen the business procedures to use it. So backup data centers, mirroring over fiber channels, etc. — that all worked pretty well." Likewise for the recovery personnel at the command centers: "A lot of people already knew what a command center was, why they had to be there, and what they needed to do because we had gone through that during Y2K, and I'm very grateful that we did."

8000 Employees Back at Work within a Week

A major challenge for the BCP team was getting the displaced employees back to work. First, the company was able to utilize two campus facilities in New Jersey. The company also had its real estate department itemize every available space in the tri-state area and put it onto a roster. Honey's team collected requirements and coordinated the assignment of available space to each business unit. The company operates a fairly comprehensive alternate work arrangement program, so some employees were permitted to work from home. Finally, the team was able to transfer some work abroad or to other Merrill Lynch offices, which relieved some of the workload from the affected employees.

Resuming Normal Operations

By the end of the week, the BCP team's priority shifted to making sure they could communicate with all employees. Workers needed to be assured that the company was handling the crisis and that space was allocated for displaced workers. Messages were sent instructing them on where to go for more information and what human resource hotlines were available for them to call.

Merrill Lynch's chairman, CEO, and senior business and technology managers made prerecorded messages that were sent out automatically to all employees impacted by the incident by use of a special emergency communication system. This accounted for approximately 74,000 phone calls during the first week after the disaster. "That was a very key part," says Honey. "Getting accurate information to our employee base was a real challenge because of a lot of misinformation in the press, which makes the job very challenging. Plus, key business folks made a huge effort to call all our key customers and reassure them with the accurate information that Merrill Lynch was open for business."

A key logistical challenge was getting the thousands of displaced workers to their new work locations. The company ran a series of ferryboats and buses from various points within the city to other points. The company Web site was also used to communicate transportation information to the affected employees.

Lessons Learned

Honey and his team will be reevaluating certain aspects of their plans in the coming months, even after their success in recovering from such a devastating event, "One of the things I think we'll concentrate on a lot more in the future is region-wide disasters. For example, not so much, 'Your building is knocked out and you can't get in,' but maybe, 'The city you're in is impacted in significant ways.' So, we'll be looking to see how we can make the firm a lot more robust in terms of instances where a city is impacted, rather than just the building."

Honey also believes that many companies will reevaluate their real estate strategies. "Do you really want to have all your operations in one building?" he asks. "Fortunately, for a company like Merrill Lynch, we have a number of real estate options we can utilize."

The Work Ahead

The BCP team was busy working on backup plans for the backup facilities by the end of the second week, while primary sites were either cleaned up or acquired. "Many of our operations are in backup mode," says Honey, "so we did a lot of work to try and develop backup plans for the backup plans. That was a big challenge."

Now the team is in the planning stages for reoccupying the primary sites, which presents its own set of challenges. Switching back to primary facilities will have to be undertaken only when it is perfectly safe for employees to reoccupy the damaged facilities.

One of the most important things for Honey and his team was that, by the Monday morning following the attack, everything was back to nearly 95 percent of normal operations. Their efforts over the past few years preparing for a disruption of this magnitude appear to have paid off. "Certainly from my perspective, I was very glad that we put the company through the training exercise in May," says Honey. "It enlightened an awful lot of the key managers on what they would have to do, so we were very prepared for that. Most folks knew what to do, which was very reassuring to me."

Conclusion

Reducing vulnerability to physical security threats became immensely more complex after September 11, 2001. Terrorism now needs to be included in all physical security planning. The events of September 11 showed us that procedures designed to deter those with hostile intent might be ineffective against suicidal terrorists. Physical security now needs to change its operating paradigm from that of deterrence to prevention to reduce the risk from terrorism. Taking the additional precautions to prevent hostile acts rather than deter them is much more difficult and costly, but necessary. Protecting one's organization, co-workers, and family from terrorism is possible with training. Maintaining control of access to sensitive information that could be used by terrorists is paramount. Many government Web sites are awash with information that could be useful in combating terrorism. Unfortunately, many of these Web sites can also provide this information to potential terrorists who could use that information to discover vulnerabilities.

Dedication

This chapter is respectfully dedicated to those whose lives were lost or affected by the events of September 11, 2001. It is the author's deepest hope that information presented in this chapter will aid in reducing the likelihood of another such event.

Appendix A
Glossary

Abend: The abnormal termination of a computer application or job because of a non-system condition or failure that causes a program to halt.

Abstraction: The process of identifying the characteristics that distinguish a collection of similar objects; the result of the process of abstraction is a type.

Acceptable Use Policy (AUP): A definition of what is acceptable online behavior, and what is not.

Acceptance Testing: The formal testing conducted to determine whether a software system satisfies its acceptance criteria, enabling the customer to determine whether to accept the system.

Access: The ability of a subject to view, change, or communicate with an object. Typically, access involves a flow of information between the subject and the object.

Access Control: The process of allowing only authorized users, programs, or other computer system (i.e., networks) to access the resources of a computer system.

Access Control List (ACL): Most network security systems operate by allowing selective use of service. An Access Control List is the usual means by which access to, and denial of, service is controlled. It is simply a list of the services available, each with a list of the hosts permitted to use the services.

Access Control Mechanisms: Hardware, software, or firmware features and operating and management procedures in various combinations designed to detect and prevent unauthorized access and to permit authorized access to a computer system.

Access Period: A segment of time, generally expressed on a daily or weekly basis, during which access rights prevail.

Access Type: The nature of access granted to a particular device, program, or file (e.g., read, write, execute, append, modify, delete, or create).

Accountability: A security principle stating that individuals must be able to be identified. With accountability, violations or attempted violations can be traced to individuals who can be held responsible for their actions.

Accreditation: A program whereby a laboratory demonstrates that something is operating under accepted standards to ensure quality assurance.

Acknowledgment (ACK): A type of message sent to indicate that a block of data arrived at its destination without error. A negative acknowledgment is called a "NAK."

Active Object: An object that has its own process; the process must be ongoing while the active object exists.

Active Wiretapping: The attachment of an unauthorized device (e.g., a computer terminal) to a communications circuit to gain access to data by generating false messages or control signals or by altering the communications of legitimate users.

ActiveX: Microsoft's Windows-specific non-Java technique for writing applets. ActiveX applets take considerably longer to download than the equivalent Java applets; however, they more fully exploit the features of Windows. ActiveX is sometimes said to be a "superset of Java."

Ada: A programming language that allows use of structured techniques for program design; concise but powerful language designed to fill government requirements for real-time applications.

Add-On Security: The retrofitting of protection mechanisms, implemented by hardware, firmware, or software, on a computer system that has become operational.

Address: (1) A sequence of bits or characters that identifies the destination and sometimes the source of a transmission. (2) An identification (e.g., number, name, or label) for a location in which data is stored.

Address Mapping: The process by which an alphabetic Internet address is converted into a numeric IP address, and vice versa.

Address Mask: A bit mask used to identify which bits in an IP address correspond to the network address and subnet portions of the address. This mask is often referred to as the subnet mask because the network portion of the address can be determined by the class inherent in an IP address. The address mask has ones in positions corresponding to the network and subnet numbers and zeros in the host number positions.

Address Resolution: A means for mapping network layer addresses onto media-specific addresses.

Address Resolution Protocol (ARP): The Internet protocol used to dynamically map Internet addresses to physical (hardware) addresses on the local area network. Limited to networks that support hardware broadcast.

Administrative Security: The management constraints, operational procedures, accountability procedures, and supplemental controls established to provide an acceptable level of protection for sensitive data.

Agent: In the client/server model, the part of the system that performs information preparation and exchange on behalf of a client or server application.

Aggregation: A relation, such as CONSISTS OF or CONTAINS between types that defines the composition of a type from other types.

Aging: The identification, by date, of unprocessed or retained items in a file. This is usually done by date of transaction, classifying items according to ranges of data.

Algorithm: A computing procedure designed to perform a task such as encryption, compressing, or hashing.

Aliases: Used to reroute browser requests from one URL to another.

American National Standards Institute (ANSI): The agency that recommends standards for computer hardware, software, and firmware design and use.

American Registry for Internet Numbers (ARIN): A nonprofit organization established for the purpose of administration and registration of Internet Protocol (IP) numbers to the geographical areas currently managed by Network Solutions (InterNIC). Those areas include, but are not limited to North America, South America, South Africa, and the Caribbean.

American Standard Code for Information Interchange (ASCII): A byte-oriented coding system based on an 8-bit code and used primarily to format information for transfer in a data communications environment.

Amplitude Modulation (AM): The technique of varying the amplitude or wavelength of a carrier wave in direct proportion to the strength of the input signal while maintaining a constant frequency and phase.

Analog: A voice transmission mode that is not digital in which information is transmitted in its original form by converting it to a continuously variable electrical signal.

Analysis and Design Phase: The phase of the systems development life cycle in which an existing system is studied in detail and its functional specifications are generated.

Annual Loss Expectancy (ALE): In risk assessment, the average monetary value of losses per year.

Anonymous FTP: A type of FTP that allows a user to log on to a remote host, which the user would otherwise not have access to, to download files.

ANSI: *See* American National Standards Institute.

Applet: A small Java program embedded in an HTML document.

Application: Computer software used to perform a distinct function. Also used to describe the function itself.

Application Layer: The top-most layer in the OSI Reference Model providing such communication service is invoked through a software package.

Application Objects: Applications and their components that are managed within an object-oriented system. Example operations on such objects are OPEN, INSTALL, MOVE, and REMOVE.

Application Program Interface (API): A set of calling conventions defining how a service is invoked through a software package.

Architecture: The structure or ordering of components in a computational or other system. The classes and the interrelation of the classes define the architecture of a particular application. At another level, the architecture of a system is determined by the arrangement of the hardware and software components. The terms "logical architecture" and "physical architecture" are often used to emphasize this distinction.

Array: Consecutive storage areas in memory that are identified by the same name. The elements (or groups) within these storage areas are accessed through subscripts.

Artificial Intelligence (AI): A field of study involving techniques and methods under which computers can simulate such human intellectual activities as learning.

Assembler Language: A computer programming language in which alphanumeric symbols represent computer operations and memory addresses. Each assembler instruction translates into a single machine language instruction.

Assembler Program: A program language translator that converts assembler language into machine code.

Asynchronous: A variable or random time interval between successive characters, blocks, operations, or events. Asynchronous data transmission provides variable intercharacter time but fixed interbit time within characters.

Asynchronous Transfer Mode (ATM): A transfer mode in which data is transmitted in the form of 53-byte units called cells. Each cell consists of a 5-byte header and a 48-byte payload. The term "asynchronous" in this context refers to the fact that cells from any one particular source need not be periodically spaced within the overall cell stream. That is, users are not assigned a set position in a recurring frame as is common in circuit switching.

Atomicity: The assurance that an operation either changes the state of all participating objects consistent with the semantics of the operation or changes none at all.

Attribute: A characteristic defined for a class. Attributes are used to maintain the state of the object of a class. Values can be connected to objects via the attributes of the class. Typically, the connected value is determined by an operation with a single parameter identifying the object. Attributes implement the properties of a type.

Audit: An independent review and examination of system records and activities that test for the adequacy of system controls, ensure

compliance with established policy and operational procedures, and recommend any indicated changes in controls, policy, and procedures.

Audit trail: A chronological record of system activities that is sufficient to enable the reconstruction, review, and examination of each event in a transaction from inception to output of final results.

Authentication: The act of identifying or verifying the eligibility of a station, originator, or individual to access specific categories of information. Typically, a measure designed to protect against fraudulent transmissions by establishing the validity of a transmission, message, station, or originator.

Authorization: The granting of right of access to a user, program, or process.

Backbone: The primary connectivity mechanism of a hierarchical distributed system. All systems that have connectivity to an intermediate system on the backbone are assured of connectivity to each other.

Backoff: The (usually random) retransmission delay enforced by contentious MAC protocols after a network node with data to transmit determines that the physical medium is already in use.

Backup and Recovery: The ability to recreate current master files using appropriate prior master records and transactions.

Backup Procedures: Provisions make for the recovery of data files and program libraries and for the restart or replacement of computer equipment after the occurrence of a system failure or disaster.

Bandwidth: Difference between the highest and lowest frequencies available for network signals. The term is also used to describe the rated throughput capacity of a given network medium or protocol.

Baseband: Characteristic of any network technology that uses a single carrier frequency and requires all stations attached to the network to participate in every transmission. *See* broadband.

BCP: The newest subseries of RFCs that are written to describe Best Current Practices in the Internet. Rather than specify the best ways to use the protocols and the best ways to configure options to ensure interoperability between various vendors' products, BCPs carry the endorsement of the IESG.

Between-the-Lines Entry: Access obtained through the use of active wiretapping by an unauthorized user to a momentarily inactive terminal of a legitimate user assigned to a communications channel.

BIOS: The BIOS is built-in software that determines what a computer can do without accessing programs from a disk. On PCs, the BIOS contains all the code required to control the keyboard, display screen, disk drives, serial communications, and a number of miscellaneous functions.

Bit: A binary value represented by an electronic component that has a value of 0 or 1.

Bit Error Rate (BER): The probability that a particular bit will have the wrong value.

Bit Map: A specialized form of an index indicating the existence or non-existence of a condition for a group of blocks or records. Although they are expensive to build and maintain, they provide very fast comparison and access facilities.

Bit Mask: A pattern of binary values that is combined with some value using bitwise AND with the result that bits in the value in positions where the mask is zero are also set to zero.

Bit Rate: This is the speed at which bits are transmitted on a circuit, usually expressed in bits per second.

Block Cipher: A method of encrypting text to produce ciphertext in which a cryptographic key and algorithm are applied to a block of data as a group instead of one bit at a time.

Body: One of four possible components of a message. Other components are the headings, attachment, and the envelope.

Bounds Checking: The testing of computer program results for access to storage outside of its authorized limits.

Bridge: A device that connects two or more physical networks and forwards packets between them. Bridges can usually be made to filter packets, that is, to forward only certain traffic.

Broadband: Characteristic of any network that multiplexes multiple, independent network carriers onto a single cable. Broadband technology allows several networks to coexist on one single cable; traffic from one network does not interfere with traffic from another because the conversations happen on different frequencies in the "ether," rather like the commercial radio system.

Broadcast: A packet delivery system where a copy of a given packet is given to all hosts attached to the network. Example: Ethernet.

Broadcast Storm: A condition that can occur on broadcast type networks such as Ethernet. This can happen for a number of reasons, ranging from hardware malfunction to configuration error and bandwidth saturation.

Brouter: A concatenation of "bridge" and "router." Used to refer to devices that perform both bridging and routing.

Browser: Short for *Web browser,* a software application used to locate and display Web pages. The two most popular browsers are Netscape Navigator and Microsoft Internet Explorer. Both of these are *graphical browsers,* which means that they can display graphics as well as text. In addition, most modern browsers can present multimedia information, including sound and video, although they require plug-ins for some formats.

Browsing: The searching of computer storage to locate or acquire information, without necessarily knowing whether it exists or in what format.

Buffer *(n):* A temporary storage area, usually in RAM. The purpose of most buffers is to act as a holding area, enabling the CPU to manipulate data before transferring it to a device. Because the processes of reading and writing data to a disk are relatively slow, many programs keep track of data changes in a buffer and then copy the buffer to a disk. For example, word processors employ a buffer to keep track of changes to files. Then when you *save* the file, the word processor updates the disk file with the contents of the buffer. This is much more efficient than accessing the file on the disk each time you make a change to the file. Note that because your changes are initially stored in a buffer, not on the disk, all of them will be lost if the computer fails during an editing session. For this reason, it is a good idea to save your file periodically. Most word processors automatically save files at regular intervals. Another common use of buffers is for printing documents. When you enter a PRINT command, the operating system copies your document to a print buffer (a free area in memory or on a disk) from which the printer can draw characters at its own pace. This frees the computer to perform other tasks while the printer is running in the background. Print buffering is called *spooling*. Most keyboard drivers also contain a buffer so that you can edit typing mistakes before sending your command to a program. Many operating systems, including DOS, also use a *disk buffer* to temporarily hold data that they have read from a disk. The disk buffer is really a cache.

Bug: A coded program statement containing a logical or syntactical error.

Bulletin Board Service (BBS): A computer that allows you to log on and post messages to other subscribers to the service.

Burn Box: A device used to destroy computer data. Usually a box with magnets or electrical current that will degauss disks and tapes.

Bus: A data path that connects the CPU, input, output, and storage devices.

Business Continuity Plan (BCP): A documented and tested plan for responding to an emergency.

Byte: The basic unit of storage for many computers; typically, one configuration consists of 8 bits used to represent data plus a parity bit for checking the accuracy of representation.

C: A third-generation computer language used for programming on microcomputers. Most microcomputer software products such as spreadsheets and DBMS programs are written in C.

Cable: Transmission medium of copper wire or optical fiber wrapped in a protective cover.

Cache: Pronounced *cash*, a special high-speed storage mechanism. It can be either a reserved section of main memory or an independent high-speed storage device. Two types of caching are commonly used in personal computers: *memory caching* and *disk caching*. A memory

cache, sometimes called a *cache store* or *RAM cache*, is a portion of memory made of high-speed static RAM (SRAM) instead of the slower and cheaper dynamic RAM (DRAM) used for main memory. Memory caching is effective because most programs access the same data or instructions over and over. Disk caching works under the same principle as memory caching, but instead of using high-speed SRAM, a disk cache uses conventional main memory. When data is found in the cache, it is called a *cache hit,* and the effectiveness of a cache is judged by its *hit rate.*

Callback: A procedure that identifies a terminal dialing into a computer system or network by disconnecting the calling terminal, verifying the authorized terminal against the automated control table, and then, if authorized, reestablishing the connection by having the computer system dial the telephone number of the calling terminal.

Carrier Sense, Multiple Access (CSMA): A multiple-station access scheme for avoiding contention in packet networks in which each station can sense the presence of carrier signals from other stations and thus avoid transmitting a packet that would result in a collision. *See also* collision detection.

Central Processing Unit (CPU): The part of the computer system containing the control and arithmetic logic units.

CERN: European Laboratory for Particle Physics. Birthplace of the World Wide Web.

Certification: The acceptance of software by an authorized agent, usually after the software has been validated by the agent or its validity has been demonstrated to the agent.

Chain of Custody: The identity of persons who handle evidence between the time of commission of the alleged offense and the ultimate disposition of the case. It is the responsibility of each transferee to ensure that the items are accounted for during the time that it is in their possession, that it is properly protected, and that there is a record of the names of the persons from whom they received it and to whom they delivered it, together with the time and date of such receipt and delivery.

Chain of Evidence: The "sequencing" of the chain of evidence follows this order:

Collection and identification
Analysis
Storage
Preservation
Presentation in court
Return to owner

Chain of evidence shows:

Who obtained the evidence
Where and when the evidence was obtained

Who secured the evidence
Who had control or possession of the evidence

CHAP (Challenge Handshake Authentication Protocol): Applies a three-way handshaking procedure. After the link is established, the server sends a "challenge" message to the originator. The originator responds with a value calculated using a one-way hash function. The server checks the response against its own calculation of the expected hash value. If the values match, the authentication is acknowledged; otherwise, the connection is usually terminated.

Chat Room: An area of a Web chat service that people can "enter" with their Web browsers where the conversations are devoted to a specific topic; equivalent to a channel in IRC.

Check Digit: One digit, usually the last, of an identifying field is a mathematical function of all of the other digits in the field. This value can be calculated from the other digits in the field and compared with the check digit to verify validity of the whole field.

Checksum: A computed value that depends on the contents of a packet. This value is sent along with the packet when it is transmitted. The receiving system computes a new checksum based on receiving data and compares this value with the one sent with the packet. If the two values are the same, the receiver has a high degree of confidence that the data was received correctly.

Ciphertext: Information that has been encrypted, making it unreadable without knowledge of the key.

Circuit Switching: A communications paradigm in which a dedicated communication path is established between two hosts and on which all packets travel. The telephone system is an example of a circuit-switched network.

Class: An implementation of an abstract data type. A definition of the data structures, methods, and interface of software objects. A template for the instantiation (creation) of software objects.

Client: A workstation in a network that is set up to use the resources of a server.

Client/Server: In networking, a network in which several PC-type systems (clients) are connected to one or more powerful, central computers (servers). In databases, refers to a model in which a client system runs a database application (front end) that accesses information in a database management system situated on a server (back end).

Client/Server Architecture: A local area network in which microcomputers, called servers, provide specialized service on behalf of the user's computers, which are called clients.

Cloning: The term given to the operation of creating an exact duplicate of one medium on another like medium. This is also referred to as a Mirror Image or Physical Sector Copy.

Coaxial Cable: A medium used for telecommunications. It is similar to the type of cable used for carrying television signals.

Code Division Multiple Access (CDMA): A technique permitting the use of a single frequency band by a number of users. Users are allocated a sequence that uniquely identifies them.

Collision: This is a condition that is present when two or more terminals are in contention during simultaneous network access attempts.

Collision Detection: An avoidance method for communications channel contention that depends on two stations detecting the simultaneous start of each other's transmission, stopping, and waiting a random period of time before beginning again. *See also* carrier sense, multiple access.

Commit: A condition implemented by the programmer signaling to the DBMS that all update activity that the program conducts be executed against a database. Before the commit, all update activity can be rolled back or canceled without negative impact on the database contents.

Commit Protocol: An algorithm to ensure that a transaction is successfully completed.

Common Business Oriented Language (COBOL): A high-level programming language for business computer applications.

Common Carrier: An organization or company that provides data or other electronic communication services for a fee.

Common Object Request Broker Architecture (CORBA): CORBA is the Object Management Group's (OMG) answer to the need for interoperability among the rapidly proliferating number of hardware and software products available today. Simply stated, CORBA allows applications to communicate with one another no matter where they are located or who has designed them.

Communications Security: The protection that ensures the authenticity of telecommunications and that results from the application of measures taken to deny unauthorized persons access to valuable information that might be derived from the acquisition of telecommunications.

Compartmentalization: The isolation of the operating system, user programs, and data files from one another in main storage to protect them against unauthorized or concurrent access by other users or programs. Also, the division of sensitive data into small, isolated blocks to reduce risk to the data.

Compiler: A program that translates high-level computer language instructions into machine code.

Compromise: Unauthorized disclosure or loss of sensitive information.

Compromising Emanations: Electromagnetic emanations that convey data and that, if intercepted and analyzed, could compromise sensitive information being processed by a computer system.

Computer Emergency Response Team (CERT): The CERT is chartered to work with the Internet community to facilitate its response to computer security events involving Internet hosts, to take proactive steps to raise the community's awareness of computer security issues, and to conduct research targeted at improving the security of existing systems. The U.S. CERT is based at Carnegie Mellon University in Pittsburgh; regional CERTs are like NICs, springing up in different parts of the world.

Computer Evidence: Computer evidence is a copy of a document stored in a computer file that is identical to the original. The legal "best evidence" rules change when it comes to the processing of computer evidence. Another unique aspect of computer evidence is the potential for unauthorized copies to be made of important computer files without leaving behind a trace that the copy was made. This situation creates problems concerning the investigation of the theft of trade secrets (e.g., client lists, research materials, computer-aided design files, formulas, and proprietary software).

Computer Forensics: The term "computer forensics" was coined in 1991 in the first training session held by the International Association of Computer Specialists (IACIS) in Portland, Oregon. Since then, computer forensics has become a popular topic in computer security circles and in the legal community. Like any other forensic science, computer forensics deals with the application of law to a science. In this case, the science involved is computer science and some refer to it as Forensic Computer Science. Computer forensics has also been described as the autopsy of a computer hard disk drive because specialized software tools and techniques are required to analyze the various levels at which computer data is stored after the fact. Computer forensics deals with the preservation, identification, extraction, and documentation of computer evidence. The field is relatively new to the private sector, but it has been the mainstay of technology-related investigations and intelligence gathering in law enforcement and military agencies since the mid-1980s. Like any other forensic science, computer forensics involves the use of sophisticated technology tools and procedures that must be followed to guarantee the accuracy of the preservation of evidence and the accuracy of results concerning computer evidence processing. Typically, computer forensic tools exist in the form of computer software.

Computer Fraud and Abuse Act PL 99-474: Computer Fraud and Abuse Act of 1986. Strengthens and expands the 1984 Federal Computer Crime Legislation. Law extended to computer crimes in private enterprise and anyone who willfully disseminates information for the purpose of committing a computer crime (i.e., distribute phone numbers to hackers from a BBS).

Computer Matching Act Public Law (PL) 100-53: Computer Matching and Privacy Act of 1988. Ensures privacy, integrity, and verification of data disclosed for computer matching; establishes Data Integrity Boards within federal agencies.

Computer Security: The practice of protecting a computer system against internal failures, human error, attacks, and natural catastrophes that might cause improper disclosure, modification, destruction, or denial-of-service.

Computer Security Act PL 100-235: Computer Security Act of 1987 directs the National Bureau of Standards (now the National Institute of Standards and Technology [NIST]) to establish a computer security standards program for federal computer systems.

Computer System: An interacting assembly of elements, including at least computer hardware and usually software, data procedures, and people.

Computer System Security: All of the technological safeguards and managerial procedures established and applied to computers and their networks (including related hardware, firmware, software, and data) to protect organizational assets and individual privacy.

Computer-Aided Software Engineering (CASE): Tools that automate the design, development, operation, and maintenance of software.

Concealment Systems: A method of keeping sensitive information confidential by embedding it in irrelevant data.

Concurrent Processing: The capability of a computer to share memory with several programs and simultaneously execute the instructions provided by each.

Condensation: The process of reducing the volume of data managed without reducing the logical consistency of data. It is essentially different than compaction in that condensation is done at the record level whereas compaction is done at the system level.

Confidentiality: A concept that applies to data that must be held in confidence and describes that status or degree of protection that must be provided for such data about individuals as well as organizations.

Configuration Management: The use of procedures appropriate for controlling changes to a system's hardware, software, or firmware structure to ensure that such changes will not lead to a weakness or fault in the system.

Connection-Oriented: The model of interconnection in which communication proceeds through three well-defined phases: connection establishment, data transfer, and connection release. Examples: X.25, Internet TCP and OSI TP4, ordinary telephone calls.

Connectionless: The model of interconnection in which communication takes place without first establishing a connection. Sometimes (imprecisely) called datagram. Examples: Internet IP and OSI CLNP, UDP, ordinary postcards.

Console Operator: Someone who works at a computer console to monitor operations and initiate instructions for efficient use of computer resources.

Construct: An object; especially a concept that is constructed or synthesized from simple elements.

Contention: Occurs during multiple access to a network in which the network capacity is allocated on a "first come, first served" basis.

Contingency Plans: Plans for emergency response, backup operations, and post-disaster recovery maintained by a computer information processing facility as a part of its security program.

Control: Any protective action, device, procedure, technique, or other measure that reduces exposures.

Control Break: A point during program processing at which some special processing event takes place. A change in the value of a control field within a data record is characteristic of a control break.

Control Totals: Accumulations of numeric data fields that are used to check the accuracy of the input, processing, or output data.

Control Zone: The space surrounding equipment that is used to process sensitive information and that is under sufficient physical and technical control to preclude an unauthorized entry or compromise.

Cookie: A small file stored on your computer by a Web browser that tracks your surfing activity.

Cooperative Processing: The ability to distribute resources (i.e., programs, files, and databases) across the network.

Copy: An accurate reproduction of information contained on an original physical item, independent of the original physical item.

Copyright: The author or artist's right to control the copying of his or her work.

CORBA: Common Object Request Broker Architecture, introduced in 1991 by the OMG, defined the Interface Definition Language (IDL) and the Application Programming Interfaces (APIs) that enable client/server object interaction within a specific implementation of an Object Request Broker (ORB).

Corrective Action: The practice and procedure for reporting, tracking, and resolving identified problems, in both the software product and the development process. Their resolution provides a final solution to the identified problem.

Corrective Maintenance: The identification and removal of code defects.

Cost/Benefit Analysis: Determination of the economic feasibility of developing a system on the basis of a comparison of the projected costs of a proposed system and the expected benefits from its operation.

Cost-Risk Analysis: The assessment of the cost of potential risk of loss or compromise of data in a computer system without data protection versus the cost of providing data protection.

CPU: The central processing unit; the brains of the computer.

Critical Path: A tool used in project management techniques and is the duration based on the sum of the individual tasks and their dependencies. The critical path is the shortest period in which a project can be accomplished.

Crossover Error Rate (CER): A comparison metric for different biometric devices and technologies; the error rate at which FAR equals FRR. The lower the CER, the more accurate and reliable the biometric device.

Cryptanalysis: The study of techniques for attempting to defeat cryptographic techniques and, more generally, information security services.

Cryptanalyst: Someone who engages in cryptanalysis.

Cryptography: The study of mathematical techniques related to aspects of information security such as confidentiality, data integrity, entity authentication, and data origin authentication. Cryptography is not the only means of providing information security services, but rather one set of techniques. The word itself comes from the Greek word *kryptos,* which means "hidden" or "covered." Cryptography is a way to hide writing ("-graphy") but yet retain a way to uncover it again.

Cryptology: The field of study that encompasses both cryptography and cryptanalysis.

Cryptosystem: A general term referring to a set of cryptographic primitives used to provide information security services.

Cyberspace: A term coined to denote the online world of the Internet.

Cyclic Redundancy Check (CRC): A number derived from a set of data that will be transmitted.

Data: Raw facts and figures that are meaningless by themselves. Data can be expressed in characters, digits, and symbols, which can represent people, things, and events.

Data Communications: The transmission of data between more than one site through the use of public and private communications channels or lines.

Data Contamination: A deliberate or accidental process or act that compromises the integrity of the original data.

Data Definition Language (DDL): A set of instructions or commands used to define data for the data dictionary. A data definition language (DDL) is used to describe the structure of a database.

Data Dictionary: A document or listing defining all items or processes represented in a data flow diagram or used in a system.

Data Element: The smallest unit of data accessible to a database management system or a field of data within a file processing system.

Data Encryption Standard (DES): A data encryption standard developed by the U.S. National Bureau of Standards (NBS). DES is a symmetric block cipher with a block length of 64 bits and an effective key length of 56 bits.

Data Integrity: The state that exists when automated information or data is the same as that in the source documents and has not been exposed to accidental or malicious modification, alteration, or destruction.

Data Item: A discrete representation having the properties that define the data element to which it belongs. *See also* data element.

Data Link: A serial communications path between nodes or devices without any intermediate switching nodes. Also, the physical two-way connection between such devices.

Data Manipulation Language (DML): A data manipulation language (DML) provides the necessary commands for all database operations, including storing, retrieving, updating, and deleting database records.

Data Objects: Objects or information of potential probative value that are associated with physical items. Data objects may occur in different formats without altering the original information.

Data Record: An identifiable set of data values treated as a unit, an occurrence of a schema in a database, or collection of atomic data items describing a specific object, event, or tuple (e.g., row of a table).

Data Security: The protection of data from accidental or malicious modification, destruction, or disclosure.

Data Set: A named collection of logically related data items, arranged in a prescribed manner and described by control information to which the programming system has access.

Data Warehouse: A collection of integrated subject-oriented databases designed to support the Decision Support function, where each unit of data is relevant to some moment in time. The data warehouse contains atomic data and summarized data.

Database: An integrated aggregation of data usually organized to reflect logical or functional relationships among data elements.

Database Administrator (DBA): (1) A person who is in charge of defining and managing the contents of a database. (2) The individual in an organization who is responsible for the daily monitoring and maintenance of the databases. The database administrator's function is more closely associated with physical database design than the data administrator's function is.

Database Management System (DBMS): The software that directs and controls data resources.

Datagram: Logical grouping of information sent as a network layer unit over a transmission medium without prior establishment of a virtual circuit. IP datagrams are the primary information units in the Internet. The terms "cell," "frame," "message," "packet," and "segment" are also used to describe logical information groupings at various layers of the OSI Reference Model and in various technology circles.

Data-Link Control Layer: Layer 2 in the SNA architectural model. Responsible for the transmission of data over a particular physical link. Corresponds roughly to the data-link layer of the OSI model.

Data-Link Layer: Layer 2 of the OSI reference model. Provides reliable transit of data across a physical link. The data-link layer is concerned with physical addressing, network topology, line discipline, error notification, ordered delivery of frames, and flow control. The IEEE divided this layer into two sublayers: the MAC sublayer and the LLC sublayer. Sometimes simply called the link layer. Roughly corresponds to the data-link control layer of the SNA model.

Deadlock: A condition that occurs when two users invoke conflicting locks in trying to gain access to a specific record or records.

Decipher: The ability to convert, by use of the appropriate key, enciphered text into its equivalent plaintext.

Decrypt: Synonymous with decipher.

Decrypt/Decipher/Decode: Decryption is the opposite of encryption. It is the transformation of encrypted information back into a legible form. Essentially, decryption is about removing disguise and reclaiming the meaning of information.

Decryption: The conversion through mechanisms or procedures of encrypted data into its original form.

Dedicated Lines: Private circuits between two or more stations, switches, or subscribers.

Dedicated Mode: The operation of a computer system such that the central computer facility, connected peripheral devices, communications facilities, and all remote terminals are used and controlled exclusively by the users or groups of users for the processing of particular types and categories of information.

Degauss: To erase or demagnetize magnetic recording media (usually tapes) by applying a variable, alternating current (AC) field.

Degree (of a relation): The number of attributes or columns of a relation.

Delegation: The notation that an object can issue a request to another object in response to a request. The first object therefore delegates the responsibility to the second object. Delegation can be used as an alternative to inheritance.

Delphi: A forecasting method where several knowledgeable individuals make forecasts and a forecast is derived by a trained analyst from a weighted average.

Demodulation: The reconstruction of an original signal from the modulated signal received at a destination device.

Denial-of-Service (DoS): Attacks on systems written to deny users legitimate access to system resources. These attacks take many forms, but are primarily applications or malicious applets that take more processes or memory allocation area than they should use, such as filling up a file system or allocating all of a system's memory.

Denial-of-service (DoS) attacks are among the most commonly encountered Java security concerns and, unfortunately, Java has a weak defense against it.

Design: The aspect of the specification process that involves the prior consideration of the implementation. Design is the process that extends and modifies an analysis specification. It accommodates certain qualities including extensibility, reusability, testability, and maintainability. Design also includes the specification of implementation requirements such as user interface and data persistence.

Design and Implementation: A phase of the systems development life cycle in which a set of functional specifications produced during systems analysis is transformed into an operational system for hardware, software, and firmware.

Design Review: The quality assurance process in which all aspects of a system are reviewed publicly.

Dial-Up: Access to switched network, usually through a dial or push-button telephone.

Digital: A mode of transmission where information is coded in binary form for transmission on the network.

Digital Audio Tape (DAT): A magnetic tape technology. DAT uses 4-mm cassettes capable of backing up anywhere between 26 and 126 bytes of information.

Digital Signature: The act of electronically affixing an encrypted message digest to a computer file or message in which the originator is then authenticated to the recipient.

Digital Signature Standard (DSS): The National Security Administration's standard for verifying an electronic message.

Direct Access: The method of reading and writing specific records without having to process all preceding records in a file.

Direct Access Storage Device (DASD): A data storage unit on which data can be accessed directly without having to progress through a serial file such as a magnetic tape file. A disk unit is a direct access storage device.

Directory: A table specifying the relationships between items of data. Sometimes a table (index) giving the addresses of data.

Discrepancy Reports: A listing of items that have violated some detective control and require further investigation.

Disk Duplexing: This refers to the use of two controllers to drive a disk subsystem. Should one of the controllers fail, the other is still available for disk I/O. Software applications can take advantage of both controllers to simultaneously read and write to different drives.

Disk Mirroring: Disk mirroring protects data against hardware failure. In its simplest form, a two-disk subsystem would be attached to a host controller. One disk serves as the mirror image of the other. When data is written to it, it is also written to the other disk. Both disks

will contain exactly the same information. If one fails, the other can supply the user data without problem.

Disk Operating System (DOS): Software that controls the execution of programs and may provide system services as resource allocation.

Diskette: A flexible disk storage medium most often used with microcomputers; also called a floppy disk.

Distributed Component Object Model (DCOM): A protocol that enables software components to communicate directly over a network. Developed by Microsoft and previously called "Network OLE," DCOM is designed for use across multiple network transports including Internet Protocols such as HTTP.

Distributed Computing: The distribution of processes among computing components that are within the same computer or different computers on a shared network.

Distributed Database: A database management system with the ability to effectively manage data that is distributed across multiple computers on a network.

Distributed Environment: A set of related data processing systems in which each system has its own capacity to operate autonomously but has some applications that are executed at multiple sites. Some of the systems may be connected with teleprocessing links into a network with each system serving as a node.

Domain Name: The name used to identify an Internet host.

Domain Name Server: An Internet host that checks the addresses of incoming and outgoing Internet messages.

Domain Name System (DNS): The distributed name and address mechanism used in the Internet.

Dumb Terminal: A device used to interact directly with the end user where all data is processed on a remote computer. A dumb terminal only gathers and displays data; it has no processing capability.

Dump: The contents of a file or memory that are output as listings. These listing can be formatted.

Duplex: Communications systems or equipment that can simultaneously carry information in both directions between two points. Also used to describe redundant equipment configurations (e.g., duplexed processors).

Early Token Release: Technique used in Token Ring networks that allows a station to release a new token onto the ring immediately after transmitting, instead of waiting for the first frame to return. This feature can increase the total bandwidth on the ring. *See also* Token Ring.

Earth Stations: Ground terminals that use antennas and other related electronic equipment designed to transmit, receive, and process satellite communications.

Eavesdropping: The unauthorized interception of information-bearing emanations through methods other than wiretapping.

Echo: The display of characters on a terminal output device as they are entered into the system.

Edit: The process of inspecting a data field or element to verify the correctness of its content.

Electromagnetic Emanations: Signals transmitted as radiation through the air or conductors.

Electromagnetic Interference (EMI): Electromagnetic waves emitted by a device.

Electronic Code Book (ECB): A basic encryption method that provides privacy but not authentication.

Electronic Communications Privacy Act of 1986 PL 99-508 (ECPA): Electronic Communications Privacy Act of 1986; extends the Privacy Act of 1974 to all forms of electronic communication, including email.

Electronic Data Interchange (EDI): A process whereby such specially formatted documents as an invoice can be transmitted from one organization to another.

Electronic Data Vaulting: Electronic vaulting protects information from loss by providing automatic and transparent backup of valuable data over high-speed phone lines to a secure facility.

Electronic Frontier Foundation: A foundation established to address social and legal issues arising from the impact on society of the increasingly pervasive use of computers as the means of communication and information distribution.

Electronic Funds Transfer (EFT): The process of moving money between accounts via computer.

Electronic Journal: A computerized log file summarizing, in chronological sequence, the processing activities and events performed by a system. The log file is usually maintained on magnetic storage media.

Emanation Security: The protection that results from all measures designed to deny unauthorized persons access to valuable information that might be derived from interception and analysis of compromising emanations.

Encrypt/Encipher/Encode: Encryption is the transformation of information into a form that is impossible to read unless you have a specific piece of information, which is usually referred to as the "key." The purpose is to keep information private from those who are not intended to have access to it. To encrypt is essentially about making information confusing and hiding the meaning of it.

Encryption: The use of algorithms to encode data in order to render a message or other file readable only for the intended recipient.

Encryption Algorithm: A set of mathematically expressed rules for encoding information, thereby rendering it unintelligible to those who do not have the algorithm decoding key.

Encryption Key: A special mathematical code that allows encryption hardware/software to encode and then decipher an encrypted message.

End System: An OSI system that contains application processes capable of communication through all seven layers of OSI protocols. Equivalent to Internet host.

End-to-End Encryption: The encryption of information at the point of origin within the communications network and postponing of decryption to the final destination point.

Enrollment: The initial process of collecting biometric data from a user and then storing it in a template for later comparison.

Entrapment: The deliberate planting of apparent flows in a system to invite penetrations.

Error: A discrepancy between actual values or conditions and those expected.

Error Rate: A measure of the quality of circuits or equipment. The ratio of erroneously transmitted information to the total sent (generally computed per million characters sent).

Espionage: The practice or employment of spies; the practice of watching the words and conduct of others, to make discoveries, as spies or secret emissaries; secret watching. This category of computer crime includes international spies and their contractors who steal secrets from defense, academic, and laboratory research facility computer systems. It includes criminals who steal information and intelligence from law enforcement computers, and industrial espionage agents who operate for competitive companies or for foreign governments who are willing to pay for the information. What has generally been known as industrial espionage is now being called competitive intelligence. A lot of information can be gained through "open source" collection and analysis without ever having to break into a competitor's computer. This information gathering is also competitive intelligence, although it is not as ethically questionable as other techniques.

Ethernet: A 10-Mbps standard for LANs, initially developed by Xerox and later refined by Digital, Intel, and Xerox (DIX). All hosts are connected to a coaxial cable where they contend for network access using a Carrier Sense Multiple Access with Collision Detection (CSMA/CD) paradigm.

Exception Report: A manager report that highlights abnormal business conditions. Usually, such reports prompt management action or inquiry.

Expert System: The application of computer-based artificial intelligence in areas of specialized knowledge.

Extensibility: A property of software such that new kinds of object or functionality can be added to it with little or no effect to the existing system.

eXtensible Markup Language (XML): Designed to enable the use of SGML on the World Wide Web, XML is a regular markup language that defines what you can do (or what you have done) in the way of describing information for a fixed class of documents (like HTML). XML goes beyond this and allows you to define your own customized markup language. It can do this because it is an application profile of SGML. XML is a metalanguage, a language for describing languages.

Fail Safe: The automatic termination and protection of programs or other processing operations when a hardware, software, or firmware failure is detected in a computer system.

Fail Soft: The selective termination of nonessential processing affected by a hardware, software, or firmware failure in a computer system.

Fallback Procedures: Predefined operations (manual or automatic) invoked when a fault or failure is detected in a system.

False Acceptance Rate (FAR): The percentage of imposters incorrectly matched to a valid user's biometric. False rejection rate (FRR) is the percentage of incorrectly rejected valid users.

Fast Ethernet: Any of a number of 100-Mbps Ethernet specifications. Fast Ethernet offers a speed increase ten times that of the 10BaseT Ethernet specification, while preserving such qualities as frame format, MAC mechanisms, and MTU. Such similarities allow the use of existing 10BaseT applications and network management tools on Fast Ethernet networks. Based on an extension to the IEEE 802.3 specification. *Compare with* Ethernet.

Fetch Protection: A system-provided restriction to prevent a program from accessing data in another user's segment of storage.

Fiber Distributed Data Interface (FDDI): LAN standard, defined by ANSI X3T9.5, specifying a 100-Mbps token-passing network using fiber-optic cable, with transmission distances of up to 2 km. FDDI uses a dual-ring architecture to provide redundancy.

Field Definition Record (FDR): A record of field definition. A list of the attributes that define the type of information that can be entered into a data field.

File Protection: The aggregate of all processes and procedures established in a computer system and designed to inhibit unauthorized access, contamination, or elimination of a file.

File Transfer: The process of copying a file from one computer to another over a network.

File Transfer Protocol (FTP): The Internet protocol (and program) used to transfer files between hosts.

Filter: A process or device that screens incoming information for definite characteristics and allows a subset of that information to pass through.

Finger: A program (and a protocol) that displays information about a particular user, or all users, logged on a local system or on a remote system. It typically shows full-time name, last login time, idle time, terminal line, and terminal location (where applicable). It may also display plan and project files left by the user.

Firewall: A system designed to prevent unauthorized access to or from a private network. Firewalls can be implemented in both hardware and software, or a combination of both. Firewalls are frequently used to prevent unauthorized Internet users from accessing private networks connected to the Internet, especially *intranets*. All messages entering or leaving the intranet pass through the firewall, which examines each message and blocks those that do not meet the specified security criteria. There are several types of firewall techniques:

- *Packet filter:* Looks at each packet entering or leaving the network and accepts or rejects it based on user-defined rules. Packet filtering is fairly effective and transparent to users, but it is difficult to configure. In addition, it is susceptible to IP spoofing.
- *Application gateway:* Applies security mechanisms to specific applications, such as FTP and Telnet servers. This is very effective, but can impose performance degradation.
- *Circuit-level gateway:* Applies security mechanisms when a TCP or UDP connection is established. Once the connection has been made, packets can flow between the hosts without further checking.
- *Proxy server:* Intercepts all messages entering and leaving the network. The proxy server effectively hides the true network addresses.

Firmware: Software or computer instructions that have been permanently encoded into the circuits of semiconductor chips.

Flame: To express strong opinion or criticism of something, usually as a frank inflammatory statement in an electronic message.

Flat File: A collection of records containing no data aggregates, nested, or repeated data items, or groups of data items.

Foreign Corrupt Practices Act: The act covers an organization's system of internal accounting control and requires public companies to make and keep books, records, and accounts that, in reasonable detail, accurately and fairly reflect the transactions and disposition of company assets and to devise and maintain a system of sufficient internal accounting controls. This act was amended in 1988.

Formal Review: A type of review typically scheduled at the end of each activity or stage of development to review a component of a deliverable or, in some cases, a complete deliverable or the software product and its supporting documentation.

Format: The physical arrangement of data characters, fields, records, and files.

Forum of Incident Response and Security Teams (FIRST): A unit of the Internet Society that coordinates the activities of worldwide Computer Emergency Response Teams, regarding security-related incidents and information sharing on Internet security risks.

Fragment: A piece of a packet. When a router is forwarding an IP packet to a network with a Maximum Transmission Unit smaller than the packet size, it is forced to break up that packet into multiple fragments. These fragments will be reassembled by the IP layer at the destination host.

Fragmentation: The process in which an IP datagram is broken into smaller pieces to fit the requirements of a given physical network. The reverse process is termed "reassembly."

Frame Relay: A switching interface that operates in packet mode. Generally regarded as the replacement for X.25.

Front-End Computer: A computer that offloads input and output activities from the central computer so it can operate primarily in a processing mode; sometimes called a front-end processor.

Front-End Processor (FEP): (1) A communications computer associated with a host computer can perform line control, message handling, code conversion, error control, and application functions. (2) A teleprocessing concentrator and router, as opposed to a back-end processor or a database machine.

Front Porch: The access point to a secure network environment; also known as a firewall.

Full-Duplex (FDX): An asynchronous communications protocol that allows the communications channel to transmit and receive signals simultaneously.

Fully Qualified Domain Name (FQDN): A complete Internet address, including the complete host and domain name.

Function: In computer programming, a processing activity that performs a single identifiable task.

Functional Specification: The main product of systems analysis, which presents a detailed logical description of the new system. It contains sets of input, processing, storage, and output requirements specifying what the new system can do.

Garbage Collection: A language mechanism that automatically deallocates memory for objects that are not accessible or referenced.

Gateway: A product that enables two dissimilar networks to communicate or interface with each other. In the IP community, an older term referring to a routing device. Today, the term "router" is used to describe nodes that perform this function, and "gateway" refers to a special-purpose device that performs an application layer conversion

of information from one protocol stack to another. *Compare with* router.

General-Purpose Computer: A computer that can be programmed to perform a wide variety of processing tests.

Government OSI Profile (GOSIP): A U.S. Government procurement specification for OSI protocols.

Granularity: The level of detail contained in a unit of data. The more there is, the lower the level of granularity; the less detail, the higher the level of granularity.

Graphical User Interface (GUI): An interface in which the user can manipulate icons, windows, pop-down menus, or other related constructs. A graphical user interface uses graphics such as a window, box, and menu to allow the user to communicate with the system. Allows users to move in and out of programs and manipulate their commands using a pointing device (usually a mouse). *Synonymous with* user interface.

Groupware: Software designed to function over a network to allow several people to work together on documents and files.

Hacker: A person who attempts to break into computers that he or she is not authorized to use.

Hacking: A computer crime in which a person breaks into an information system simply for the challenge of doing so.

Half-Duplex: Capability for data transmission in only one direction at a time between a sending station and a receiving station.

Handprint Character Recognition (HCR): One of several pattern recognition technologies used by digital imaging systems to interpret handprinted characters.

Handshake: Sequence of messages exchanged between two or more network devices to ensure transmission synchronization.

Handshaking Procedure: Dialogue between a user and a computer, two computers, or two programs to identify a user and authenticate his or her identity. This is done through a sequence of questions and answers that are based on information either previously stored in the computer or supplied to the computer by the initiator of the dialogue.

Hard Disk: A fixed or removable disk mass storage system permitting rapid direct access to data, programs, or information.

Hash Total: A total of the values on one or more fields, used for the purpose of auditability and control.

HDLC (High-Level Data-Link Control): Bit-oriented synchronous data-link layer protocol developed by ISO. Derived from SDLC, HDLC specifies a data encapsulation method on synchronous serial links using frame characters and checksums.

HDSL: High-data-rate digital subscriber line. One of four DSL technologies. HDSL delivers 1.544 Mbps of bandwidth each way over two copper

twisted pairs. Because HDSL provides T1 speed, telephone companies have been using HDSL to provision local access to T1 services whenever possible. The operating range of HDSL is limited to 12,000 feet (3658.5 meters), so signal repeaters are installed to extend the service. HDSL requires two twisted pairs, so it is deployed primarily for PBX network connections, digital loop carrier systems, interexchange POPs, Internet servers, and private data networks. *Compare with* ADSL, SDSL, and VDSL.

Header: The beginning of a message sent over the Internet; typically contains addressing information to route the message or packet to its destination.

Hertz (Hz): One cycle per second.

Heuristics The mode of analysis in which the next step is determined by the results of the current step of analysis. Used for decision support processing.

Hexadecimal: A number system with a base of 16.

Hierarchical Database: In a hierarchical database, data is organized like a family tree or organization chart with branches of parent records and child records.

High-Level Data-Link Control (HDLC): A protocol used at the data-link layer that provides point-to-point communications over a physical transmission medium by creating and recognizing frame boundaries.

High-Level Language: The class of procedure-oriented language.

Home Page: The initial screen of information displayed to the user when initiating the client or browser software or when connecting to a remote computer. The home page resides at the top of the directory tree.

Hop: A term used in routing. A hop is one data link. A path from source to destination in a network is a series of hops.

Host: A remote computer that provides a variety of services, typically to multiple users concurrently.

Host Address: The IP address of the host computer.

Host Computer: A computer that, in addition to providing a local service, acts as a central processor for a communications network.

Hostname: The name of the user computer on the network.

HTML: *See* HyperText Markup Language.

HTTP: *See* HyperText Transport Protocol.

Hub: A device connected to several other devices. In ARCnet, a hub is used to connect several computers together. In a message-handling service, a hub is used for transfer of messages across the network. An Ethernet hub is basically a "collapsed network-in-a-box" with a number of ports for the connected devices.

Hypertext: Text that is held in frames and authors develop or define the linkage between frames.

HyperText Markup Language (HTML): The specialized language used to insert formatting commands and links in a hypertext document.

HyperText Transfer Protocol (HTTP): The protocol used to transport hypertext files across the Internet.

IAB: Internet Architecture Board. Board of internetwork researchers who discuss issues pertinent to Internet architecture. Responsible for appointing a variety of Internet-related groups such as the IANA, IESG, and IRSG. The IAB is appointed by the trustees of the ISOC.

ICMP: Internet Control Message Protocol. Network layer Internet protocol that reports errors and provides other information relevant to IP packet processing. Documented in RFC 792.

Icon: A pictorial symbol used to represent data, information, or a program on a GUI screen.

Identification: The process, generally employing unique machine-readable names, that enables recognition of users or resources as identical to those previously described to the computer system.

Impersonation: An attempt to gain access to a system by posing as an authorized user.

Implementation: The specific activities within the systems development life cycle through which the software portion of the system is developed, coded, debugged, tested, and integrated with existing or new software.

Incident: An event that has actual or potentially adverse effects on an information system. A computer security incident can result from a computer virus, other malicious code, intruder, terrorist, unauthorized insider act, malfunction, etc.

Incomplete Parameter Checking: A system fault that exists when all parameters have not been fully checked for correctness and consistency by the operating system, thus leaving the system vulnerable to penetration.

Inference Engine: A system of computer programs in an expert systems application that uses expert experience as a basis for conclusions.

Infobots: Software agents that perform specified tasks for a user or application.

Information Security Service: A method to provide some specific aspect of security. For example, integrity of transmitted data is a security objective, and a method that would achieve that is considered an information security service.

Inheritance: The language mechanism that allows the definition of a class to include the attributes and methods for another more general class. Inheritance is an implementation construct for the specialization relation. The general class is the superclass and the specific class is the subclass in the inheritance relation. Inheritance is a relation between classes that enables the reuse of code and the definition of generalized interface to one or more subclasses.

Input Controls: Techniques and methods for verifying, validating, and editing data to ensure that only correct data enters a system.

Instance: A set of values representing a specific entity belonging to a particular entity type. A single value is also the instance of a data item.

Integrated Data Dictionary (IDD): A database technology that facilitates functional communication among system components.

Integrated Services Digital Network (ISDN): An emerging technology that is beginning to be offered by the telephone carriers of the world. ISDN combines voice and digital network services in a single medium, making it possible to offer customers digital data services as well as voice connections through a single wire. The standards that define ISDN are specified by ITU-TSS.

Integrity: *See also* data integrity. A security service that allows verification that an unauthorized modification (including changes, insertions, deletions and duplications) has not occurred either maliciously or accidentally.

Integrity Checking: The testing of programs to verify the soundness of a software product at each phase of development.

Interactive: A mode of processing that combines some aspects of online processing and some aspects of batch processing. In interactive processing, the user can directly interact with data over which he or she has exclusive control. In addition, the user can cause sequential activity to initiate background activity to be run against the data.

Interface: A shared boundary between devices, equipment, or software components defined by common interconnection characteristics.

Interleaving: The alternating execution of programs residing in the memory of a multiprogramming environment.

Internal Control: The method of safeguarding business assets, including verifying the accuracy and reliability of accounting data, promoting operational efficiency, and encouraging adherence to prescribed organizational policies and procedures.

Internet: The Internet consists of large national backbone networks (such as MILNET, NSFNET, and CREN) and a myriad of regional and local campus networks all over the world. The Internet uses the Internet Protocol suite. To be on the Internet, you must have IP connectivity (i.e., be able to Telnet to — or ping — other systems). Networks with only email connectivity are not actually classified as being on the Internet.

Internet Address: A 32-bit address assigned to hosts using TCP/IP.

Internet Architecture Board (IAB): Formally called the Internet Activities Board. The technical body that oversees the development of the Internet suite of protocols (commonly referred to as "TCP/IP"). It has two task forces (the IRTF and the IETF), each charged with investigating a particular area.

Internet Assigned Numbers Authority (IANA): A largely government-funded overseer of IP allocations chartered by the FNC and the ISOC.

Internet Control Message Protocol (ICMP): The protocol used to handle errors and control messages at the IP layer. ICMP is actually part of the IP.

Internet Engineering Task Force (IETF): An open international community of network designers, operators, vendors, and researchers concerned with the evolution of the Internet's architecture; established by the IAB.

Internet Layer: The stack in the TCP/IP protocols that addresses a packet and sends the packets to the network access layer.

Internet Message Access Protocol (IMAP): A method of accessing electronic mail or bulletin board messages that are kept on a (possibly shared) mail server. IMAP permits a "client" email program to access remote message stores as if they were local. For example, email stored on an IMAP server can be manipulated from a desktop computer at home, a workstation at the office, and a notebook computer while traveling, without the need to transfer messages of files back and forth between these computers. IMAP can be regarded as the next-generation POP.

Internet Protocol (IP, IPv4): The Internet Protocol (version 4), defined in RFC 791, is the network layer for the TCP/IP suite. It is a connectionless, best-effort, packet-switching protocol.

Internet Protocol (Ping, IPv6): IPv6 is a new version of the Internet Protocol that is designed to be evolutionary.

Internet Service Provider (ISP): An organization that provides direct access to the Internet, such as the provider that links your college or university to the Net.

Interoperability: The ability to exchange requests between entities. Objects interoperate if the methods that apply to one object can request services of another object.

Investigation: The phase of the systems development life cycle in which the problem or need is identified and a decision is made on whether to proceed with a full-scale study.

IP Address: A unique number assigned to each computer on the Internet, consisting of four numbers, each less than 256, and each separated by a period, such as 129.16.255.0.

IP Datagram: The fundamental unit of information passed across the Internet. Contains source and destination addresses, along with data and a number of fields that define such things as the length of the datagram, the header checksum, and flags to say whether the datagram can be (or has been) fragmented.

ISO 9000: A certification program that demonstrates an organization adheres to steps that ensure quality of goods and services. A quality

series that comprises a set of five documents and was developed in 1987 by the International Standards Organization (ISO).

Isolation: The separation of users and processes in a computer system from one another, as well as from the protection controls of the operating system.

Iterative Development Life Cycle: A strategy for developing systems that allows for the controlled reworking of parts of a system to remove mistakes or to make improvements based on feedback.

Java: Object-oriented programming language developed at Sun Microsystems to solve a number of problems in modern programming practice. The Java language is used extensively on the World Wide Web, particularly for applets.

Join: An operation that takes two relations as operand and produces a new relation by concealing the tuples and matching the corresponding columns when a stated condition holds between the two.

Jukebox: Hardware that houses, reads, and writes to many optical disks using a variety of mechanical methods for operation.

Kerberos: Developing standard for authenticating network users. Kerberos offers two key benefits: it functions in a multi-vendor network, and it does not transmit passwords over the network.

Key: In cryptography, a sequence of symbols that controls encryption and decryption.

Key/Cryptovariable: Encryption and decryption generally require the use of some secret information, referred to as a *key*. For some encryption mechanisms, the same key is used for both encryption and decryption; for other mechanisms, the keys used for encryption and decryption are different.

Key Generation: The origination of a key or set of distinct keys.

Key, Primary: A unique attribute used to identify a class of records in a database.

Knowledge Base: The part of an expert system that contains specific information and facts about the expert area. Rules that the expert system uses to make decisions are derived from this source.

L2F Protocol: Layer 2 Forwarding Protocol. Protocol that supports the creation of secure virtual private dial-up networks over the Internet.

Label: A set of symbols used to identify or describe an item, record, message, or file.

LAN: Local Area Network. High-speed, low-error data network covering a relatively small geographic area (up to a few thousand meters). LANs connect workstations, peripherals, terminals, and other devices in a single building or other geographically limited area. LAN standards specify cabling and signaling at the physical and data-link layers of the OSI model. Ethernet, FDDI, and Token Ring are widely used LAN technologies. *Compare with* MAN and WAN.

LAN Switch: High-speed switch that forwards packets between data-link segments. Most LAN switches forward traffic based on MAC addresses. This variety of LAN switch is sometimes called a frame switch. LAN switches are often categorized according to the method they use to forward traffic: cut-through packet switching or store-and-forward packet switching. Multi-layer switches are an intelligent subset of LAN switches. *Compare with* multi-layer switch. *See also* cut-through packet switching and store-and-forward packet switching.

Language Translator: Systems software that converts programs written in assembler or a higher-level language into machine code.

Laser: Light Amplification by Stimulated Emission of Radiation. Analog transmission device in which a suitable active material is excited by an external stimulus to produce a narrow beam of coherent light that can be modulated into pulses to carry data. Networks based on laser technology are sometimes run over SONET.

Laser Printer: An output unit that uses intensified light beams to form an image on an electrically charged drum and then transfers the image to paper.

Latency: In local networking, the time (measured in bits at the transmission rate) for a signal to propagate around or throughput the network. The time taken by a DASD device to position a storage location to reach the read arm over the physical storage medium. For general purposes, average latency time is used. Delay between the time a device requests access to a network and the time it is granted permission to transmit.

Layer 3 Switching: The emerging layer 3 switching technology integrates routing with switching to yield very high routing throughput rates in the millions-of-packets-per-second range. The movement to layer 3 switching is designed to address the downsides of the current generation of layer 2 switches, which are functionally equivalent to bridges. These downsides for a large, flat network include being subject to broadcast storms, spanning tree loops, and address limitations that drove the injection of routers into bridged networks in the late 1980s. Currently, layer 3 switching is represented by a number of approaches in the industry.

LDAP: Lightweight Directory Access Protocol. Protocol that provides access for management and browser applications that provide read/write interactive access to the X.500 Directory.

Leased Line: An un-switched telecommunications channel leased to an organization for its exclusive use.

Least Recently Used (LRU): A replacement strategy in which new data must replace existing data in an area of storage; the least recently used items are replaced.

Lightweight Directory Access Protocol (LDAP): This protocol provides access for management and browser application that provide read/write interactive access to the X.500 Directory.

Limit Check: An input control text that assesses the value of a data field to determine whether values fall within set limits.

Line Conditioning: A service offered by common carriers to reduce delay, noise, and amplitude distortion to produce transmission of higher data speeds.

Line Printer: An output unit that prints alphanumeric characters one line at a time.

Line Speed: The transmission rate of signals over a circuit, usually expressed in bits per second.

Load Sharing: A multiple-computer system that shares the load during peak hours. During non-peak periods or standard operation, one system can handle the entire load with the others acting as fallback units.

Logging: The automatic recording of data for the purpose of accessing and updating it.

MAC (Media Access Control): Lower of the two sub-layers of the data-link layer defined by the IEEE. The MAC sub-layer handles access to shared media, such as whether token passing or contention will be used.

MAC Address: Standardized data-link layer address that is required for every port or device that connects to a LAN. Other devices in the network use these addresses to locate specific ports in the network and to create and update routing tables and data structures. MAC addresses are 6 bytes long and are controlled by the IEEE. Also known as a hardware address, MAC-layer address, and physical address. *Compare with* network address.

Machine Language: Computer instructions or code representing computer operations and memory addresses in a numeric form that is executable by the computer without translation.

Maintenance: Tasks associated with the modification or enhancement of production software.

Maintenance Programmer: An applications programmer responsible for making authorized changes to one or more computer programs and ensuring that the changes are tested, documented, and verified.

Masquerade: A type of security threat that occurs when an entity successfully pretends to be a different entity.

Media: The various physical forms (e.g., disk, tape, and diskette) on which data is recorded in machine-readable formats.

Media Access Control (MAC): A local network control protocol that governs station access to a shared transmission medium. Examples are token passing and CSMA. *See* carrier sense, multiple access.

Megabyte (Mbyte, MB): The equivalent of 1,048,576 bytes.

Memory: The area in a computer that serves as temporary storage for programs and data during program execution.

Memory Address: The location of a byte or word of storage in computer memory.

Memory Bounds: The limits in the range of storage addresses for a protected region in memory.

Memory Chips: A small integrated circuit chip with a semiconductor matrix used as computer memory.

Menu: A section of the computer program — usually the top-level module — that controls the order of execution of other program modules. Also, online options displayed to a user, prompting the user for specific input.

Message: The data input by the user in the online environment that is used to drive a transaction. The output of transaction.

Message Address: The information contained in the message header that indicates the destination of the message.

Metadata: The description of such things as the structure, content, keys, and indexes of data.

Metalanguage: A language used to specify other languages.

Metropolitan Area Network (MAN): A data network intended to serve an area approximating that of a large city. Such networks are being implemented by innovative techniques, such as running fiber cables through subway tunnels.

Microprocessor: A single small chip containing circuitry and components for arithmetic, logical, and control operations.

Middleware: The distributed software needed to support interactions between client and servers.

Minicomputer: Typically, a word-oriented computer whose memory size and processing speed falls between that of a microcomputer and a medium-sized computer.

Mirror Image Backup: Mirror image backups (also referred to as bitstream backups) involve the backup of all areas of a computer hard disk drive or another type of storage media (e.g., Zip disks, floppy disks, Jazz disks, etc.). Such mirror image backups exactly replicate all sectors on a given storage device. Thus, all files and ambient data storage areas are copied. Such backups are sometimes referred to as "evidence-grade" backups and they differ substantially from standard file backups and network server backups. The making of a mirror image backup is simple in theory, but the accuracy of the backup must meet evidence standards. Accuracy is essential and to guarantee accuracy, mirror image backup programs typically rely on mathematical CRC computations in the validation process. These mathematical validation processes compare the original source data with the restored data. When computer evidence is involved, accuracy is extremely important, and the making of a mirror image backup

is typically described as the preservation of the "electronic crime scene."

Mode of Operation: A classification for systems that execute in a similar fashion and share distinctive operational characteristics (e.g., Production, DSS, online, and Interactive).

Model: A representation of a problem or subject area that uses abstraction to express concepts.

Modem (Modulator/Demodulator): A device that converts the digital language of the PC to a series of high- and low-pitched tones for transmission over analog telephone lines.

Modification: A type of security threat that occurs when its content is modified in an unanticipated manner by a non-authorized entity.

Multiple Inheritance: The language mechanism that allows the definition of a class to include the attributes and methods defined for more than one superclass.

Multiprocessing: A computer operating method in which two or more processors are linked and execute multiple programs simultaneously.

Multiprogramming: A computer operating environment in which several programs can be placed in memory and executed concurrently.

Multi-purpose Internet Mail Extension (MIME): The standard for multimedia mail contents in the Internet suite of protocols.

NAK: Negative acknowledgment. Response sent from a receiving device to a sending device indicating that the information received contained errors. *Compare with* acknowledgment.

NAK Attack: A penetration technique that capitalizes on an operating system's inability to properly handle asynchronous interrupts.

Name Resolution: The process of mapping a name into the corresponding address.

NAT (Network Address Translation): Mechanism for reducing the need for globally unique IP addresses. NAT allows an organization with addresses that are not globally unique to connect to the Internet by translating those addresses into globally routable address space. *Also known as* Network Address Translator.

Need-to-Know: A security principle stating that an individual should have access only to that needed to perform a particular function.

Negative Acknowledgment (NAK): A response sent by the receiver to indicate that the previous block was unacceptable and the receiver is ready to accept a retransmission.

Network: An integrated, communicating aggregation of computers and peripherals linked through communications facilities.

Network Access Layer: The layer of the TCP/IP stack that sends the message out through the physical network onto the Internet.

Network Access Points (NAPs): (1) Nodes providing entry to the high-speed Internet backbone system. (2) Another name for an Internet Exchange Point.

Network Address: The network portion of an IP address. For a class A network, the network address is the first byte of the IP address. For a class B network, the network address is the first two bytes of the IP address. For a class C network, the network address is the first three bytes of the IP address. In the Internet, assigned network addresses are globally unique.

Network Administrator: The person who maintains user accounts, password files, and system software on your campus network.

Network Information Center (NIC): Originally, there was only one, located at SRI International and tasked to serve the ARPANET (and later DDN) community. Today, there are many NICs, operated by local, regional, and national networks all over the world. Such centers provided user assistance, document service, training, and much more.

Network Layer: The OSI layer that is responsible for routing, switching, and subnetwork access across the entire OSI environment.

Neural Network: A type of system developed by artificial intelligence researchers used for processing logic.

Node: A device attached to a network.

Noise: Random electrical signals introduced by circuit components or natural disturbances that tend to degrade the performance of a communications channel.

Object-Oriented: Any method, language, or system that supports object identity, classification, and encapsulation and specialization. C++, Smalltalk, Objective-C, and Eiffel are examples of object-oriented implementation languages.

Object-Oriented Analysis (OOA): The specification of requirements in terms of objects with identity that encapsulate properties and operations, messaging, inheritance, polymorphism, and binding.

Object-Oriented Database Management System (OODBMS): A database that stores, retrieves, and updates objects using transaction control, queries, locking, and versioning.

Object-Oriented Design (OOD): The development activity that specifies the implementation of a system using the conceptual model defined during the analysis phase.

Object-Oriented Language: A language that supports objects, method resolution, specialization, encapsulation, polymorphism, and inheritance.

Object Program: A program that has been translated from a higher-level source code into machine language.

Object Request Broker (ORB): A software mechanism by which objects make and receive requests and responses.

OLE: Microsoft's Object Linking and Embedding technology designed to let applications share functionality through live data exchange and embedded data. Embedded objects are packaged statically within the source application, called the "client;" linked objects launch the

"server" applications when instructed by the client application. Linking is the capability to call a program, embedding places data in a foreign program.

Online System: Applications that allow direct interaction of the user with the computer (CPU) via a CRT, thus enabling the user to receive back an immediate response to data entered (i.e., an airline reservation system). Only one root node can be used at the beginning of the hierarchical structure.

Open System: A system whose architecture permits components developed by independent organizations or vendors to be combined.

Open Systems Interconnection (OSI): An international standardization program to facilitate communications among computers from different manufactures. *See* ISO.

Operating System: The various sets of computer programs and other software that monitor and operate the computer hardware and the firmware to facilitate use of the hardware.

Optical Disk: A disk that is written to or read from by optical means.

Optical Fiber: A form of transmission medium that uses light to encode signals and has the highest transmission rate of any medium.

Optical Storage: A medium requiring lasers to permanently alter the physical media to create a permanent record. The storage also requires lasers to read stored information from this medium.

OSI Reference Model: The seven-layer architecture designed by OSI for open data communications network.

Overwriting: The obliteration of recorded data by recording different data on the same surface.

PABX: Private Automatic Branch Exchange. Telephone switch for use inside a corporation. PABX is the preferred term in Europe, while PBX is used in the United States.

Packet: Logical grouping of information that includes a header containing control information and (usually) user data. Packets are most often used to refer to network layer units of data. The terms "datagram," "frame," "message," and "segment" are also used to describe logical information groupings at various layers of the OSI Reference Model and in various technology circles.

Packet Internet Grouper (PING): A program used to test reachability of destinations by sending them an ICMP echo request and waiting for a reply. The term is used as a verb: "Ping host X to see if it is up."

Packet Switch: WAN device that routes packets along the most efficient path and allows a communications channel to be shared by multiple connections. Formerly called an Interface Message Processor (IMP).

Packet Switching: A switching procedure that breaks up messages into fixed-length units (called packets) at the message source. These units may travel along different routes before reaching their intended destination.

Padding: A technique used to fill a field, record, or block with default information (e.g., blanks or zeros).

Page: A basic unit of storage in main memory.

Page Fault: A program interruption that occurs when a page that is referred to is not in main memory and must be read from external storage.

Paging: A method of dividing a program into parts called pages and introducing a given page into memory as the processing on the page is required for program execution.

PAP (Password Authentication Protocol): Authentication protocol that allows PPP peers to authenticate one another. The remote router attempting to connect to the local router is required to send an authentication request. Unlike CHAP, PAP passes the password and hostname or username in the clear (unencrypted). PAP does not itself prevent unauthorized access, but merely identifies the remote end. The router or access server then determines if that user is allowed access. PAP is supported only on PPP lines. *Compare with* CHAP.

Parallel Port: The computer's printer port, which in a pinch, allows user access to notebooks and computers that cannot be opened.

Parent: A unit of data in a 1:n relationship with another unit of data called a child, where the parent can exist independently but the child cannot.

Parity: A bit or series of bits appended to a character or block of characters to ensure that the information received is the same as the information that was sent. Parity is used for error detection.

Parity Bit: A bit attached to a byte that is used to check the accuracy of data storage.

Partition: A memory area assigned to a computer program during its execution.

Passive Wiretapping: The monitoring or recording of data while it is being transmitted over a communications link.

Password: A word or string of characters that authenticates a user, a specific resource, or an access type.

Patent: Exclusive right granted to an inventor to produce, sell, and distribute the invention for a specified number of years.

Penetration: A successful unauthorized access to a computer system.

Penetration Testing: The use of special programmer or analyst teams to attempt to penetrate a system to identify security weaknesses.

Persistent Object: An object that can survive the process that created it. A persistent object exists until it is explicitly deleted.

Physical Layer: The OSI layer that provides the means to activate and use physical connections for bit transmission. In plain terms, the physical layer provides the procedures for transferring a single bit across a physical medium.

Piggyback Entry: Unauthorized access to a computer system that is gained through another user's legitimate connection.

Plain Old Telephone System (POTS): What we consider to be the "normal" phone system used with modems. Does not include leased lines or digital lines.

Plaintext: Intelligible text or signals that have meaning and can be read or acted on without being decrypted.

Platform: Foundation upon which processes and systems are built and which can include hardware, software, firmware, etc.

Point-of-Presence (POP): A site where there exists a collection of telecommunications equipment, usually digital leased lines and multi-protocol routers.

Point-to-Point: A network configuration interconnecting only two points. The connection can be dedicated or switched.

Point-to-Point Protocol (PPP): The successor to SLIP, PPP provides router-to-router and host-to-network connections over both synchronous and asynchronous circuits.

Pointer: The address of a record (or other data grouping) contained in another record so that a program may access the former record when it has retrieved the latter record. The address can be absolute, relative, or symbolic, and hence the pointer is referred to as absolute, relative, or symbolic.

Polling: A procedure by which a computer controller unit asks terminals and other peripheral devices in a serial fashion if they have any messages to send.

Polymorphism: A request-handling mechanism that selects a method based on the type of target object. This allows the specification of one request that can result in invocation of different methods depending on the type of the target object. Most object-oriented languages support the selection of the appropriate method based on the class of the object (classical polymorphism). A few languages or systems support characteristics of the object, including values and user-defined defaults (generalized polymorphism).

Port: An outlet, usually on the exterior of a computer system, that enables peripheral devices to be connected and interfaced with the computer.

Portability: The ability to implement and execute software in one type of computing space and have it execute in a different computing space with little or no changes.

Presentation Layer: The OSI layer that determines how application information is represented (i.e., encoded) while in transit between two end systems.

Pretty Good Privacy (PGP): PGP provides confidentiality and authentication services for electronic mail and file storage applications. Devel-

oped by Phil Zimmerman and distributed for free on the Internet. Widely used by the Internet technical community.

Primary Key: An attribute that contains values that uniquely identifies the record in which the key exists.

Principle of Least Privilege: A security procedure under which users are granted only the minimum access authorization they need to perform required tasks.

Privacy: The prevention of unauthorized access and manipulation of data.

Privacy Act of 1974: The federal law that allows individuals to know what information about them is on file and how it is used by all government agencies and their contractors. The 1986 Electronic Communication Act is an extension of the Privacy Act.

Privacy Enhanced Mail (PEM): Internet email standard that provides confidentiality, authentication, and message integrity using various encryption methods. Not widely deployed in the Internet.

Privacy Protection: The establishment of appropriate administrative, technical, and physical safeguards to protect the security and confidentiality of data records against anticipated threats or hazards that could result in substantial harm, embarrassment, inconvenience, or unfairness to any individual about whom such information is maintained.

Private Network: A network established and operated by a private organization for the benefit of members of the organization.

Privilege: A right granted to an individual, a program, or a process.

Privileged Instructions: A set of instructions generally executable only when the computer system is operating in the executive state (e.g., while handling interrupts). These special instructions are typically designed to control such protection features as the storage protection features.

Problem: Any deviation from predefined standards.

Problem Reporting: The method of identifying, tracking, and assigning attributes to problems detected within the software product, deliverables, or within the development processes.

Procedure: Required "how-to" instructions that support some part of a policy or standard.

Processor: The hardware unit containing the functions of memory and the central processing unit.

Program Development Process: The activities involved in developing computer programs, including problem analysis, program design, process design, program coding, debugging, and testing.

Program Maintenance: The process of altering program code or instructions to meet new or changing requirements.

Programmable Read-Only Memory (PROM): Computer memory chips that can be programmed permanently to carry out a defined process.

Programmer: The individual who designs and develops computer programs.

Programmer/Analyst: The individual who analyzes processing requirements and then designs and develops computer programs to direct processing.

Programming Language: A language with special syntax and style conventions for coding computer programs.

Programming Specifications: The complete description of input, processing, output, and storage requirements necessary to code a computer program.

Protection Ring: A hierarchy of access modes through which a computer system enforces the access rights granted to each user, program, and process, ensuring that each operates only within its authorized access mode.

Protocol: A set of instructions required to initiate and maintain communication between sender and receiver devices.

Protocol Analyzer: A data communications testing unit set that enables a network engineer to observe bit patterns and simulate network elements.

Prototype: A usable system or subcomponent that is built inexpensively or quickly with the intention of modifying or replacing it.

Public Key Encryption: An encryption scheme where two pairs of algorithmic keys (one private and one public) are used to encrypt and decrypt messages, files, etc.

Purging: The orderly review of storage and removal of inactive or obsolete data files.

Quality: The totality of features and characteristics of a product or service that bear on its ability to meet stated or implied needs.

Quality Assurance: An overview process that entails planning and systematic actions to ensure that a project is following good quality management practices.

Quality Control: Process by which product quality is compared with standards.

Quality of Service (QoS): The service level defined by a service agreement between a network user and a network provider, which guarantees a certain level of bandwidth and data flow rates.

Query Language: A language that enables a user to interact indirectly with a DBMS to retrieve and possibly modify data held under the DBMS.

RADIUS (Remote Dial-In User Service): Database for authenticating modem and ISDN connections and for tracking connection time.

RAID (Redundant Arrays of Inexpensive Disks): Instead of using one large disk to store data, you use many smaller disks (because they are cheaper). *See* disk mirroring and duplexing. An approach to using many low-cost drives as a group to improve performance, yet also

provides a degree of redundancy that makes the chance of data loss remote.

RAM: A type of computer memory that can be accessed randomly; that is, any byte of memory can be accessed without touching the preceding bytes. RAM is the most common type of memory found in computers and other devices, such as printers. There are two basic types of RAM: dynamic RAM (DRAM) and static RAM (SRAM).

RARP (Reverse Address Resolution Protocol): Protocol in the TCP/IP stack that provides a method for finding IP addresses based on MAC addresses. *Compare with* Address Resolution Protocol (ARP).

Read-Only Memory (ROM): Computer memory chips with preprogrammed circuits for storing such software as word processors and spreadsheets.

Reassembly: The process by which an IP datagram is "put back together" at the receiving hosts after having been fragmented in transit.

Recovery: The restoration of the information processing facility or other related assets following physical destruction or damage.

Recovery Procedures: The action necessary to restore a system's computational capability and data files after system failure or penetration.

Recursion: The definition of something in terms of itself. For example, a bill of material is usually defined in terms of itself.

Referential Integrity: The assurance that an object handle identifies a single object. The facility of a DBMS that ensures the validity of predefined relationships.

Regression Testing: The rerunning of test cases that a program has previously executed correctly to detect errors created during software correction or modification. Tests used to verify a previously tested system whenever it is modified.

Relational Database: In a relational database, data is organized in two-dimensional tables or relations.

Remanence: The residual magnetism that remains on magnetic storage media after degaussing.

Remote Access: The ability to dial into a computer over a local telephone number using a number of digital access techniques.

Remote Authentication Dial-In User Service (RADIUS): A security and authentication mechanism for remote access.

Remote Procedure Call (RPC): An easy and popular paradigm for implementing the client/server model of distributed computing. A request is sent to a remote system to execute a designated procedure, using arguments supplied, and the result returned to the caller.

Replay: A type of security threat that occurs when an exchange is captured and resent at a later time to confuse the original recipients

Replication: The process of keeping a copy of data through either shadowing or caching.

Report: Printed or displayed output that communicates the content of files and other activities. The output is typically organized and easily read.

Request for Comments (RFC): The document series, begun in 1969, that describes the Internet suite of protocols and related experiments. Not all (in fact, very few) RFCs describe Internet standards, but all Internet standards are written up as RFCs.

Residue: Data left in storage after processing operations and before degaussing or rewriting has occurred.

Resource: In a computer system, any function, device, or data collection that can be allocated to users or programs.

Risk: The probability that a particular security threat will exploit a particular vulnerability.

Risk Analysis: An analysis that examines an organization's information resources, its existing controls, and its remaining organization and computer system vulnerabilities. It combines the loss potential for each resource or combination of resources with an estimated rate of occurrence to establish a potential level of damage in dollars or other assets.

Risk Assessment: Synonymous with risk analysis.

Role: A job type defined in terms of a set of responsibilities.

Rollback: (1) Restoration of a system to its former condition after it has switched to a fallback mode of operation when the cause of the fallback has been removed. (2) The restoration of the database to an original position or condition often after major damage to the physical medium. (3) The restoration of the information processing facility or other related assets following physical destruction or damage.

Router: A system responsible for making decisions about which of several paths network (or Internet) traffic will follow. To do this, it uses a routing protocol to gain information about the network, and algorithms to choose the best route based on several criteria known as "routing metrics."

RSA: A public-key cryptographic system that may be used for encryption and authentication. It was invented in 1977 and named for its inventors: Ron Rivest, Adi Shamir, and Leonard Adleman.

Safeguard: Synonymous with control.

Sanitizing: The degaussing or overwriting of sensitive information in magnetic or other storage media.

Scalability: The likelihood that an artifact can be extended to provide additional functionality with little or no additional effort.

Scavenging: The searching of residue for the purpose of unauthorized data acquisition.

Scripts: Executable programs used to perform specified tasks for servers and clients.

Search Engine: A program written to allow users to search the Web for documents that match user-specified parameters.

Secrecy: A security principle that keeps information from being disclosed to anyone not authorized to access it.

Secure Electronic Transaction (SET): The SET specification has been developed to allow for secure credit card and offline debit card (check card) transactions over the World Wide Web.

Secure Operating System: An operating system that effectively controls hardware, software, and firmware functions to provide the level of protection appropriate to the value of the data resources managed by this operating system.

Secure Socket Layer (SSL): An encryption technology for the Web used to secure transactions such as the transmission of credit card numbers for e-commerce.

Security Audit: An examination of data security procedures and measures to evaluate their adequacy and compliance with established policy.

Security Controls: Techniques and methods to ensure that only authorized users can access the computer information system and its resources.

Security Filter: A set of software or firmware routines and techniques employed in a computer system to prevent automatic forwarding of specified data over unprotected links or to unauthorized persons.

Security Kernel: The central part of a computer system (hardware, software, or firmware) that implements the fundamental security procedures for controlling access to system resources.

Security Program: A systems program that controls access to data in files and permits only authorized use of terminals and other related equipment. Control is usually exercised through various levels of safeguards assigned on the basis of the user's need-to-know.

Seepage: The accidental flow, to unauthorized individuals, of data or information that is presumed to be protected by computer security safeguards.

Sensitive Data: Data that is considered confidential or proprietary. The kind of data that, if disclosed to a competitor, might give away an advantage.

Sensitive Information: Any information that requires protection and that should not be made generally available.

Serial Line Internet Protocol (SLIP): An Internet protocol used to run IP over serial lines such as telephone circuits or RS-232 cables interconnecting two systems. SLIP is now being replaced by Point-to-Point Protocol. *See* Point-to-Point Protocol.

Server: A computer that provides a service to another computer, such as a mail server, a file server, or a news server.

Session: A completed connection to an Internet service, and the ensuing connect time.

Session Layer: The OSI layer that provides means for dialogue control between end systems.

Shareware: Software available on the Internet that may be downloaded to your machine for evaluation and for which you are generally expected to pay a fee to the originator of the software if you decide to keep it.

Simple Network Management Protocol (SNMP): Provides remote administration of network device; "simple" because the agent requires minimal software.

Simulation: The use of an executable model to represent the behavior of an object. During testing, the computational hardware, the external environment, and even the coding segments may be simulated.

Simultaneous Processing: The execution of two or more computer program instructions at the same time in a multiprocessing environment.

Single Inheritance: The language mechanism that allows the definition of a class to include the attributes and methods defined for, at most, one superclass.

Social Engineering: An attack based on deceiving users or administrators at the target site.

Socket: A paring of an IP address and a port number. *See* port.

Softlifting: Illegal copying of licensed software for personal use.

Software: Computer programs, procedures, rules, and possibly documentation and data pertaining to the operation of the computer system.

Software Life Cycle: The period of time beginning when a software product is conceived and ending when the product is no longer available for use. The software life cycle is typically broken into phases (e.g., requirements, design, programming, testing, conversion, operations, and maintenance).

Software Maintenance: All changes, corrections, and enhancements that occur after an application has been placed into production.

Software Piracy: To illegally copy software.

Source Document: The form that is used for the initial recording of data prior to system input.

Source Program: The computer program that is coded in an assembler or higher-level programming language.

Spam: The act of posting the same information repeatedly on inappropriate places or too many places so as to overburden the network.

Specification: A description of a problem or subject that will be implemented in a computational or other system. The specification includes both a description of the subject and aspects of the implementation that affect its representation. Also, the process and analysis and design that results in a description of a problem or subject that can be implemented in a computation or other system.

Spoofing: The deliberate inducement of a user or resource to take incorrect action.

Spooling: A technique that maximizes processing speed through the temporary use of high-speed storage devices. Input files are transferred from slower, permanent storage and queued in the high-speed devices to await processing, or output files are queued in high-speed devices to await transfer to slower storage devices.

Standard: Mandatory statement of minimum requirements that support some part of a policy.

Standard Generalized Markup Language (SGML): An international standard for encoding textual information that specifies particular ways to annotate text documents separating the structure of the document from the information content. HTML is a generalized form of SGML.

State Transition: A change of state for an object; something that can be signaled by an event.

State Variable: A property or type that is part of an identified state of a given type.

Static Data: Data that, once established, remains constant.

Stream Cipher: An encryption method in which a cryptographic key and an algorithm are applied to each bit in a datastream, one bit at a time.

Structured Design: A methodology for designing systems and programs through a top-down, hierarchical segmentation.

Structured Programming: The process of writing computer programs using logical, hierarchical control structures to carry out processing.

Structured Query Language (SQL): The international standard language for defining and accessing a relational database.

Subnet: A portion of a network, which may be a physically independent network segment, that shares a network address with other portions of the network and is distinguished by a subnet number. A subnet is to a network what a network is to the Internet.

Subnet Address: The subnet portion of an IP address. In a subnetted network, the host portion of an IP address is split into a subnet and a host portion using an address (subnet) mask.

Subroutine: A segment of code that can be called up by a program and executed at any time from any point.

Superclass: A class from which another class inherits attributes and methods.

Swapping: A method of computer processing in which programs not actively being processed are held on special storage devices and alternated in and out of memory with other programs according to priority.

Synchronous: A protocol of transmitting data over a network where the sending and receiving terminals are kept in synchronization with each other by a clock signal embedded in the data.

Synchronous Optical NETwork (SONET): SONET is an international standard for high-speed data communications over fiber-optic media. The transmission rates range from 51.84 Mbps to 2.5 Gbps.

System: A series of related procedures designed to perform a specific task.

System Analysis: The process of studying information requirements and preparing a set of functional specifications that identify what a new or replacement system should accomplish.

System Design: The development of a plan for implementing a set of functional requirements as an operational system.

System Integrity Procedures: Procedures established to ensure that hardware, software, firmware, and data in a computer system maintain their state of original integrity and are not tampered with by unauthorized personnel.

System Log: An audit trail of relevant system happenings (e.g., transaction entries, database changes).

Systems Analysis: The process of studying information requirements and preparing a set of functional specifications that identify what a new or replacement system should accomplish.

Systems Design: The development of a plan for implementing a set of functional requirements as an operational system.

Systems Development Life Cycle (SDLC): (1) The classical operational development methodology that typically includes the phases of requirements gathering, analysis, design, programming, testing, integration, and implementation. (2) The systematic systems building process consisting of specific phases; for example, preliminary investigation, requirements determination, systems analysis, systems design, systems development, and systems implementation.

TACACS (Terminal Access Controller Access Control System): Authentication protocol, developed by the DDN community, that provides remote access authentication and related services, such as event logging. User passwords are administered in a central database rather than in individual routers, providing an easily scalable network security solution.

Technological Attack: An attack that can be perpetrated by circumventing or nullifying hardware, software, and firmware access control mechanisms rather than by subverting system personnel or other users.

Telecommunications: Any transmission, emission, or reception of signs, signals, writing, images, sounds, or other information by wire, radio, visual, satellite, or electromagnetic systems.

Teleprocessing: Information processing and transmission performed by an integrated system of telecommunications, computers, and person-to-machine interface equipment.

Teleprocessing Security: The protection that results from all measures designed to prevent deliberate, inadvertent, or unauthorized disclosure or acquisition of information stored in or transmitted by a teleprocessing system.

TEMPEST: The study and control of spurious electronic signals emitted from electronic equipment. TEMPEST is a classification of technology designed to minimize the electromagnetic emanations generated by computing devices. TEMPEST technology makes it difficult, if not impossible, to compromise confidentiality by capturing emanated information.

Test Data: Data that simulates actual data to form and content and is used to evaluate a system or program before it is put into operation.

Threat Monitoring: The analysis assessment and review of audit trails and other data collected to search out system events that may constitute violations or precipitate incidents involving data privacy.

Three-Way Handshake: The process whereby two protocol entities synchronize during connection establishment.

Throughput: The process of measuring the amount of work a computer system can handle within a specified timeframe.

Timestamping: The practice of tagging each record with some moment in time, usually when the record was created or when the record was passed from one environment to another.

Time-Dependent Password: A password that is valid only at a certain time of day or during a specified timeframe.

Token Passing: A network access method that uses a distinctive character sequence as a symbol (token), which is passed from node to node, indicating when to begin transmission. Any node can remove the token, begin transmission, and replace the token when it is finished.

Token Ring: A type of area network in which the devices are arranged in a virtual ring in which the devices use a particular type of message called a token to communicate with one another.

Traceroute: A program available on many systems that traces the path a packet takes to a destination. It is mostly used to debug routing problems between hosts. There is also a traceroute protocol defined in RFC 1393.

Trademark: A registered word, letter, or device granting the owner exclusive rights to sell/distribute the goods to which it is applied.

Traffic Analysis: A type of security threat that occurs when an outside entity is able to monitor and analyze traffic patterns on a network.

Traffic Flow Security: The protection that results from those features in some cryptography equipment that conceal the presence of valid messages on a communications circuit, usually by causing the circuit to appear busy at all times or by encrypting the source and destination addresses of valid messages.

Transaction: A transaction is an activity or request to a computer. Purchase orders, changes, additions, and deletions are examples of transactions that are recorded in a business information environment.

Transmission Control Protocol (TCP): The major transport protocol in the Internet suite of protocols providing reliable, connection-oriented, full-duplex streams.

Transport Layer: The OSI layer that is responsible for reliable end-to-end data transfer between end systems.

Trojan Horse: A computer program that is apparently or actually useful and contains a trapdoor or unexpected code.

Trust: Reliance on the ability of a system or process to meet its specifications.

Trusted Computer Security Evaluation Criteria (TCSEC): A security development standard for system manufacturers and a basis for comparing and evaluating different computer systems. Also known as the *Orange Book*.

Tunneling: Tunneling refers to encapsulation of protocol A with protocol B, such that A treats B as though it were a data-link layer. Tunneling is used to get data between administrative domains, which use a protocol that is not supported by the internet connecting those domains.

Twisted Pair: A type of network physical medium made of copper wires twisted around each other. Example: Ordinary telephone cable.

UDP: User Datagram Protocol. Connectionless transport layer protocol in the TCP/IP stack. UDP is a simple protocol that exchanges datagrams without acknowledgments or guaranteed delivery, requiring that error processing and retransmission be handled by other protocols. UDP is defined in RFC 768.

Uniform Resource Locator (URL): The primary means of navigating the web; consists of the means of access, the Web site, the path, and the document name of a Web resource, such as http://www.auerbach-publications.com.

Unshielded Twisted Pair (UTP): A generic term for "telephone" wire used to carry data such as 10Base-T and 100Base-T. Various categories (qualities) of cable exist that are certified for different kinds of networking technologies.

Update: The file processing activity in which master records are altered to reflect the current business activity contained in transactional files.

USENET: A facility of the Internet, also called "the news," that allows users to read and post messages to thousands of discussion groups on various topics.

User Datagram Protocol (UDP): A transport protocol in the Internet suite of protocols. UDP, like TCP, uses IP for delivery; however, unlike TCP, UDP provides for exchange of datagrams without acknowledgments or guaranteed delivery.

Validation: The determination of the correctness, with respect to the user needs and requirements, of the final program or software produced from a development project.

Validation, Verification, and Testing: Used as an entity to define a procedure of review, analysis, and testing throughout the software life cycle to discover errors; the process of validation, verification, and testing determines that functions operate as specified and ensures the production of quality software.

Value-Added Network (VAN): A communications network using existing common carrier networks and providing such additional features as message switching and protocol handling.

Verification: (1) The authentication process by which the biometric system matches a captured biometric against the person's stored template. (2) The demonstration of consistency, completeness, and correctness of the software at and between each stage of the development life cycle.

Virtual Circuit: A network service that provides connection-oriented service, regardless of the underlying network structure.

Virtual Memory: A method of extending computer memory using secondary storage devices to store program pages that are not being executed at the time.

Virtual Private Network (VPN): A VPN allows IP traffic to travel securely over public TCP/IP network by encrypting all traffic from one network to another. A VPN uses "tunneling" to encrypt all information at the IP level.

Virus: A type of malicious software that can destroy the computer's hard drive, files, and programs in memory, and that replicates itself to other disks.

WAN (Wide Area Network): Data communications network that serves users across a broad geographic area and often uses transmission devices provided by common carriers. Frame Relay, SMDS, and X.25 are examples of WANs. *Compare with* LAN and MAN.

Waterfall Life Cycle: A software development process that structures the analysis, design, programming, and testing. Each step is completed before the next step begins.

Web Crawler: A software program that searches the Web for specified purposes such as to find a list of all URLs within a particular site.

Whois: An Internet resource that permits users to initiate queries to a database containing information on users, hosts, networks, and domains.

Wiring Closet: Specially designed room used for wiring a data or voice network. Wiring closets serve as a central junction point for the wiring and wiring equipment that is used for interconnecting devices.

Work Factor: The effort and time required to break a protective measure.

X.400: ITU-T recommendation specifying a standard for email transfer.

X.500: The CITT and ISO standard for electronic directory services.

XDSL: A group term used to refer to ADSL (Asymmetrical Digital Subscriber Line), HDSL (High data rate Digital Subscriber Line), and SDSL (Symmetrical Digital Subscriber Line). All are digital technologies using the existing copper infrastructure provided by the telephone companies. XDSL is a high-speed alternative to ISDN.
